All contributions to the 2017 PLEA Conference included herein were independently peer reviewed as a full paper, prior to publication.

# Introduction to the Proceedings of PLEA 2017

---

The question we all too often forget to ask is Why? Why, for instance did we in Edinburgh set out on the PLEA 2017 journey to give ourselves all the very hard work of creating a huge conference in which people from all over the world were invited to discuss and develop ideas of Passive and Low Energy Buildings (PLEA)? Well the answer is that we believe the issue of good building design, embraced for thirty five years by the PLEA movement is simply one of the most important there is in the evolution of a safer world in which people will be able to live comfortable and affordable lives in a rapidly changing world.

The PLEA organisation started in 1982 as a small group of international friends dedicated to the ideal of sharing knowledge on how to design and operate minimal and renewable energy buildings. The development of solar buildings lay at the core of its ethos in those early days and still does. PLEA now has a membership of several thousand professionals, academics and students from over forty countries ([www.plea-arch.org](http://www.plea-arch.org)). Having expected three to five hundred abstracts for the 2017 PLEA conference we were overwhelmed by more than fourteen hundred.

*It is obvious that the time for PLEA thinking has come.*

Where better to share these important ideas than in Edinburgh, the 18th Century capital of the European 'Age of Enlightenment'? It is here we set about creating our Team Scotland to organise the conference, held on the 2nd – 5th July 2017 and including 665 papers published in these Proceedings. The impressive list of people who helped us included: the Scottish schools of architecture and engineering, the City of Edinburgh, the Scottish Government, Historic Environment Scotland, the Royal Incorporation of Architects in Scotland, the Chartered Institution of Building Services Engineers and a host of related professional companies and organisations.

Reflecting the diverse interests of the team involved, the subject matter of the conference is separated in the following proceedings into papers sorted according to the thirty-one Forums in which they were presented at the conference. Readers should first review the contents lists to see which subject areas are of particular interest to them and then browse through the varied papers by selected Forums. Separation of the papers into these various fields enabled authors to present their ideas at the conference to smaller groups with whom they could expertly explore and discuss their own results while learning from other related studies that might lend light to their own thinking.

# Introduction to the Proceedings of PLEA 2017

---

In discussions at one of our Forum Leader meetings we decided that in reality many of the larger challenges we face could be distilled down into five different themes:

- Building Better, Safer Places for All (inclusion and resilience)
  - Designing to Thrive in a Changing world (affordability and well-being in good buildings)
  - Learning from, and building on, the Lessons of the Past (evidence based design evolution)
  - Powering our Lives with Sustainable Energy (clear, durable and affordable futures)
  - Empowering Current Generations (Education for change)
- 

These themes run through in the pages of these proceedings, and were accompanied at the conference itself by a fascinating exchange of ideas, interpretations and assumptions and their attendant design solutions.

The conference was also accompanied by a simple Enlightenment message, presented in four flanking banners in the Ballroom of the Assembly Rooms where generations have deliberated since it was first opened at the height of the original Age of Enlightenment two hundred and thirty ago:

Sun – Light – Wind – Natural Energy Buildings

# Volume Contents

---

*PLEA 2017 Conference*

## **Volume I includes the following forums:**

- Adapting to Climate Change
- Aesthetics and Design
- Bridging the Performance Gap
- Building Performance Evaluation
- Carbon Accounting
- Comfort and Delight
- Community Energy
- Construction

## **Volume II includes the following forums:**

- Cool Cities and Urban Heat Islands
- Culture and Society
- Digital Design
- Education and Training
- Energy Efficiency
- Future City Visions
- Green Infrastructure
- Health and Air Quality
- Historic Buildings and Refurbishment
- Light

## **Volume III includes the following forums:**

- Low Carbon Design
- Materials
- Overheating
- Passive Climatic Design
- Place Making and Well-being
- Renewables Solar and Hydrogen Buildings
- Resilience Aging and Adapting to Change
- Sound
- Transition Communities
- Transport
- Ventilation
- Water and Waste
- Windcatchers and Windows

## Volume 1

<b>Adapting to Climate Change</b>	<b>1</b>
Building Resilience for Future Climate: An Investigation of Fabric Optimisation to Improve Thermal Comfort in Residential Buildings in Lagos, Nigeria	2
Abdulquadri Ademakinwa, Lucelia Rodrigues	
Effectiveness of passive climate adaptation measures in residential buildings in Germany	10
Farzan Banihashemi, Johannes Maderspacher, Julia Brasche, Werner Lang	
Adapting cities to climate change: incorporating the knowledge and practices of urban professionals in a design-aid tool	18
Marion Bonhomme, Maja Karoline Rynning, Serge Farault, Luc Adolphe, Catherine Dubois and Geneviève Cloutier	
Spatial Analysis on Intra-Urban Temperature Variation under Extreme Hot Weather by Incorporating Urban Planning and Environmental Parameters: A pilot study from Hong Kong	26
Meng Cai, Chao Ren, Kevin Ka-Lun Lau and Yong Xu	
Green Roofs in Cuban Housing. Types, Evaluation and Proposals	33
Dania González Couret and Luis Guillermo Pérez González	
The 'Second Skin' and Thermal Adaptation In Changing Climate	41
Meshack Efeoma	
Resilient Urban Edges: Adaptive and Mitigative Design in Chennai	49
Vaishali Marlene Enos and Rosa Schiano-Phan	
Method for definition of climatic classification based on human comfort	57
Carlos J. Esparza López, Carlos Escobar del Pozo, Jorge A. Ojeda Sánchez, Adolfo Gomez Amador and Miguel F. Elizondo Mata	
The impact of shading levels on users' thermal comfort in public leisure spaces	65
Fabiana Benevenuto Faustini, Marina Lisboa Maia, Thysse Ortolani Rioli, João Roberto Gomes de Faria and Maria Solange Gurgel de Castro Fontes	
The Integrated Urban Regeneration and Climate Change in the Spanish Peninsular Mediterranean: The Case of the Coast of Malaga	73
Cristina Gallardo Ramírez, M <sup>a</sup> Teresa Pérez Cano and Domingo Sánchez Fuentes	
Productive Landscaping in Urban Built Environment	81
Jagadeesh Gorle and Hema Rallapalli	
Correlation between air-conditioning usage and peak demand of electricity from Libyan homes	89
Abdusalam Himdan, David Jenkins, Edward Owens and Ali El Bakkush	
Uncertainty and sensitivity analysis of residential cooling energy against future climate in hot-humid Taiwan	96
I-Ting Lai, Kuo-Tsang Huang and Ruey-Lung Hwang	

Energy and thermal performance assessment of existing residential buildings: the first step to introducing successful retrofitting strategies in Albania Jonida Murataj, Rajat Gupta, and Fergus Nicol	104
Impact of building envelope construction on thermal comfort: a parametric analysis of modern, low income housing in south-west Nigeria for current and future climates Stephanie Ogunrin and Steve Sharples	112
The Impact of Different Watering Strategies on the Cooling Effects of Pavement-Watering during Heat-Waves Sophie Parison, Martin Hendel, Kristine Jurski and Laurent Royon	120
Formulating a methodology to study adaptability in buildings to climate-change: climate-responsive adaptability in Indian conditions Aysha Saifudeen, Monto Mani	128
Quantifying the Behaviour of Modern and Traditional Construction Systems on the Basis of Thermal Comfort Seyed Masoud Sajadian, Steve Sharples	136
Adapting to a Warmer Climate – Affordable Low-carbon Retrofits and Occupant Options for Typical Australian Houses John James Shiel, Behdad Moghtaderi, Richard Aynsley, Adrian Page, John M Clarke	144
Simulation of microclimatic effects for green infrastructure in the city of São Paulo, Brazil Paula Shinzato, Helge Simon, Michael Bruse, Denise Helena Silva Duarte	152
Resilience in Latin America: exploring flooding mitigation in Bogotá (Colombia) Linda Toledo, Francisco Javier Novegil-González-Anleo and Rolando-Arturo Cubillos-González	160
Vertical Farms: Historic Development, Current State and Future Directions Diana Waldron	168
Urban micro-climate change evaluation and mitigation solutions—a case from Xi'an, China Yupeng Wang, Dian Zhou and Rui Dong	176
Progressive building energy criteria modification in response to future climate change Yu-Teng Weng, Kuo-Tsang Huang, Ruey-Lung Hwang	184
<b>Aesthetics and Design</b>	<b>191</b>
Towards Advanced Active Façades: Analysis of façade requirements and development of an innovative construction system Angela Clua Longas, Sophie Lufkin and Emmanuel Rey	192
Architecture and Landscape, Frank Lloyd Wright's circular house designs Michael Desmond	200
An Evolution of Sustainable Aesthetics Elizabeth Donovan	208
Architectural design and aesthetics of Zero Emission Buildings: An analysis of perceived architectural qualities in the ZEB Living Lab in Trondheim Luca Finocchiaro, and Solvår Irene Wågø	216
Contributions to Sustainable Construction Socialisation Project and Construction of Secondary School in Mendoza, Argentina Daniel Gelardi and Alfredo Esteves	224
RED on RED: A Framework for the Interaction of Color in the Build Environment Esther Hagenlocher and Landry Smith	232
Theory and Precedent in the Design of Sustainable Environments: A Case Study of Two Schools of Art – Manchester and Glasgow Prof Dean Hawkes and Dr Ranald Lawrence	240
Towards a Tropical Architecture: Modernism in Northeast of Brazil Daniele Abreu e Lima	248
Fifty Shades of Green: an empirical analysis of sustainable design approaches in fifty case studies of contemporary architecture Marianna Nigra	256

Formal Representations of Seasonal Adaptation - On a Search for Sustainable Architectural Forms Agnes Nyilas, Yoshihito Kurazumi	264
Design of Low-energy Homes using Thermal and Daylight Simulations in Interactive Generative Parametric Modelling Steffen Petersen, Lonnie Rou, Pil Brix Purup and Poul Henning Kirkegaard	272
Frames and Finishes: The Evolution of a Performance Based Aesthetic Craig Robertson, Nic Crawley, Julia Yao	280
Presence of energy concerns in the conceptual approach of Fernand Pouillon in the 50s: The Case Study of Pouillon's Housing Estate in Algiers Mohamed Tehami and Karima Anouche	288
From lightweight pioneering steel houses to zero energy buildings Francesca Thiebat, Andrea Veglia and Luca Raimondo	296
Outsider ethics and marginalized aesthetics: The value of contemporary environmental philosophies for designing sustainable architecture Andrea Wheeler	304
Biomimetics in architecture Barbara Widera	312
Renovating Abandoned Houses for Sustaining a Declining Community in Japan Kentaro Yagi	320
Passivhaus: The Architectural Typology of Low Energy Housing Jill Zhao and Kate Carter	328
<b>Bridging the Performance Gap</b>	<b>336</b>
Bridging the Theory of Regenerative Design and the Current Building Practice: Evaluation of Regenerative Design Support Tools Aysegul Akturk	337
Are occupants more satisfied with indoor environmental quality in greencertified buildings? Sergio Altomonte, Stefano Schiavon, Michael Kent and Gail Brager	345
Mind the Gap; Methodology Discussion of the Extraction and Analysis of Pilot Phase Data to Generate Multi-Configuration Household Behavioural Profiles AbdelRahman A.I.M. Aly, Amira ElNokaly, Glen Mills	353
Discrepancies between theoretical and actual heating demand in Scottish modern dwellings Julio Bros-Williamson, Jon Stinson, Celine Garnier and John Currie	361
Sustainable building design in practice – survey among Danish DGNB Consultants Camilla Brunsgaard, Anne Kirkegaard Bejder	369
Green School Design – Key Strategies in Tropical Developing Regions Chunya Cai	377
The near Zero Energy Building standard and the Passivhaus standard – a case Study Shane Colclough, Tomas O'Leary, Neil Hewitt, Philip Griffiths	385
Limitations of Environmental Assessment Methods for Bioclimatic Building Design Dani Craig and Rosa Schiano-Phan	393
[Re] Measuring [LEED] Sustainability: From a Global Rating System to Tropical Specificity Eileen Diaz-Lamboy	401
Zero-Energy Me - The Struggle for Individual Energy Neutrality Andy van den Dobbelsteen, Craig Lee Martin and Greg Keeffe	409
Cognitive mapping as a link between the urban designer and space user Dr. Marwa Adel Elsayed, Dr. Walaa S.E. Ismaeel	417
Indoor Environmental Quality Design for Advanced Occupant's Comfort – A Pre-post Occupancy Evaluation of a Green-Certified Office Building Ihab Elzeyadi and Stanley Gatland II	425
Active House Label – tool to empower house owners and developers to design sustainable buildings Kurt Emil Eriksen, Rory Bergin, Amdi Worm	433

Soft Landings Driven Design Management process: Achieving sustainability in a school building in the UK Victoria Gana and Giridharan Renganathan	441
Temporal Indoor Overheating risk management challenges for free-running spaces: Highlighting the demand functions for decision-support Linda Gichuya	449
Sustainability performance tracking of social housing: the tale of two projects in Brazil Vanessa Gomes and Mariana Adão	457
Meta-study of building fabric performance gap in low energy housing in UK Rajat Gupta and Alkis Kotopouleas	465
Buiksloterham Integrated Energy Systems S.C. Jansen, R.M.J. Bokel, M.J. Elswijk, Saskia Müller	473
Modern Buildings and Environmental Comfort – Reuse of Existing and Vacant Buildings Nathália Mara Lorenzetti Lima and Roberta Consentino Kronka Mülfarth	481
Development of Generic Energy Efficiency Category: An Accreditation Comparison of Different Green Rating Systems for a Case Study in Canada Sherif Mahmoud, Tarek Zayed and Mohammad Fahmy	489
An online decision-making guide for the sustainable refurbishment of Belgian Walloon schools Catherine Massart, Coralie Cauwerts	497
'Ventilate Right' – Methods of Effective Communication to New Residents Rosalie Menon, Janice Foster	503
How Can the Combination of BREEAM and Soft Landings Successfully Deliver a Low Energy, Comfortable Building? Sahar Mirzaie and Gillian Menzies	511
Bridging the gap: A framework for a robust sustainable design process Sarah O'Dwyer and Vivienne Brophy	519
Norway's electric vehicle deployment success and PLEA Harald N. Røstvik	527
Application of LCA results in the early design phase of environmental-friendly Buildings Toktam Bashirzadeh Tabizi, Glen Hill1, Mathew Aitchison	534
REALISING INTENTIONS: An evaluation of green building rating tools for Australian buildings Leena Thomas and PC Thomas	542
'Learning from 'horror' stories: a plan of work to reduce the performance gap in deep retrofit Marina Topouzi, Gavin Killip1 and Alice Owen	550
Zero-Energy Me - The Struggle for Individual Energy Neutrality Andy van den Dobbelsteen, Craig Lee Martin1 and Greg Keeffe	558
Users in context: actions and practices in low energy buildings Gabriela Zapata-Lancaster and Chris Tweed	566
<b>Building Performance Evaluation</b>	<b>574</b>
A study on the evaluation of thermal comfort of occupants, summertime and wintertime temperatures in a single prefabricated structural timber dwelling Timothy Oluseun Adekunle and Marialena Nikolopoulou	575
The Environmental Performance of the Engineering Science and Learning Centre UK: An investigation of thermal and light benefits from an atrium covered by ETFE cushions Abdulquadri Ademakinwa, Benson Lau and Lucelia Rodrigues	583
Evaluating indoor environmental performance of laboratories in a Northern Nigerian university Sani Muhammad Ali, David Brett Martinson and Sura Almaiayah	591
Measuring and presenting real time environmental indicators for optimised building performance John Allison, Joseph Clarke, Jeremy Cockroft, Anastasios Markopoulos, Aizaz Samuel	599
A New Parametric Framework: Developing Design Options in Real Time Mohamed Aly Etman, Naomi Keena and Anna Dyson	607

Experimental evaluation of the impact of window improvement in Social Housing and in real weather conditions REVen Laboratory in Madrid Beatriz Arranz, Ignacio Oteiza	615
Usability Tool – accounting for understanding and usability in BPE Magdalena Baborska-Narożny, Fionn Stevenson, Jack Baker, Arturo Valeriano, Fanny Cocom	623
The performance under the ergonomic approach of building icons of Brazilian modernist architecture in São Paulo, built between 1930 and 1964: buildings for commercial and service use Barbara Iamauchi Barroso and Roberta Kronka Consentino Mülfarth	631
How user practice and habits impact the energy consumption in nearly zero energy youth housing in Denmark Anne Kirkegaard Bejder, Mary-Ann Knudstrup and Camilla Brunsgaard	639
Towards benchmarking of HVAC energy in commercial buildings in warm Climates Edward H. Borgstein, Roberto Lamberts, Jan L.M. Hensen	647
Can Activity-Based Working spaces increase worker's physical activity, perceived productivity and satisfaction? Christhina Candido, Sihui Wang, Tamara Croft, Fan Zhang, Martin Mackey	655
Indoor Environmental Quality conditions in Activity-Based offices in green Buildings Christhina Candido, Sihui Wang, Leena Thomas, Fan Zhang, Shamila Haddad and Wei Ye	662
Enhance: The Assembly Rooms Energy Living Lab Kate Carter, Evan Morgan, Lynda Webb, Nigel Goddard and Jan Webb	669
Seven key lessons from Active House demonstration buildings Kurt Emil Eriksen, Peter Foldbjerg, Thorkjørn Færøn Asmussen, Jens Christoffersen	677
Form Follows Performance Blanca Dasi Espuig and Joyce Chan	685
The impact of imposed façade design on the occupants' visual and thermal satisfaction in educational buildings in Jordan: The case study of the German Jordanian University in evaluating the performance of Architecture Karma Gammoh, Rawan Qubrosi	693
Thermal and Energy Audits in Existing Wineries. A Case Study Carolina Ganem and Helena Coch	701
Monitoring occupant behaviour in multifamily residential buildings Enedir Ghisi, Bruna F. Balvedi	709
Performance analysis and practice in container building based on BIM Juanli Guo, Hongxin Feng, Gang Liu and Jiehui Wang	716
Reducing Agitation in Dementia Patients: A role for environmental design Neveen Hamza	724
Towards a Holistic approach to Low Energy-Building Design: Introducing Metrics for Evaluation of Spatial Quality Stina Rask Jensen, Pil Brix Purup, Poul Henning Kirkegaard, Steffen Petersen and Anders Strange	732
Investigation the impact of students background on their thermal perception at higher education building Mina Jowkar, Azadeh Montazami and Christopher Lunn	740
Sustainable Renovation Framework: Introducing three levels of Integrated Design Process Implementation and Evaluation Aliakbar Kamari, Rossella Corrao, Steffen Petersen and Poul Henning Kirkegaard	748
Campus Audit Squads for Energy (CASE): understanding behavioural patterns and energy use of plug loads Alison G. Kwok, Sara Nita Tjahjana and María Isabel Rivera	756
Assessment of thermal comfort an passive design strategies in Millennium Schools in Ecuador Gabriela Ledesma, Neveen Hamza	764

Performance-based Green Residential Building Evaluation and Design Tools and Method in Cold Climatic Zones of Northern China Nianxiong Liu, Muzhou Wang and Jingyu Zhang	772
A long term parameter dataset for calibration of low energy building retrofit models for education and research Adam O' Donovan, Michael D. Murphy, Paul D. O' Sullivan	780
Analysis of comfort in multi-family housing in Madrid, Spain (1940- 1980). Four case studies monitored for energy rehabilitation Ignacio Oteiza, Carmen Alonso, Fernando Martín-Consuegra, Borja Frutos and Sara Martín	788
Retrofit Strategies for the Existing Residential Tower Blocks in Northern Cyprus Bertug Ozarisoy and Heba Elsharkawy	796
Observation and analysis of passive solar home control strategies for active Users Ulrike Passe, Kaylinn Taggart, Shan He	804
Exploring the influence of contemporary facade design on occupant satisfaction: a preliminary study in office buildings Luisa Pastore, Marilynne Andersen	812
The Impact Of Constructivism Density Of The Urban Tissue In Improving The Urban Ambience-Thermal, Visual - Of The Street. For Saharian Cities: Case Study Of The City Of Biskra Dr-Rami Qaoud and Pr-Alkama Djamel	820
What do the traditional pol houses teach us for contemporary dwellings in India? Rajan Rawal, Devarsh Kumar and Sanyogita Manu	827
Climate change scenarios analysed with the transient energy ratio Aidan Reilly and Oliver Kinnane	835
Cluster analysis for thermal behaviour assessment of low-income housing Aline Schaefer, Enedir Ghisi and Fernando Pacheco	843
The Thermal Preference, Comfort and Satisfaction: Norwegian and British Workplaces Sally Shahzad, John Brennan, Dimitris Theodosopoulos, John Kaiser Calautit, Ben Hughes	851
An Investigation into Energy Consumption Behaviour and Lifestyles in UK Homes: Developing A Smart Application as A Tool for Reducing Home Energy Use Wei Shi, Heba Elsharkawy and Hassan Abdalla	859
Embedding building performance evaluation in UK practice Fionn Stevenson	867
Vulnerability and resilience in energy efficient homes: thermal response to Heatwaves Linda Toledo, Paul C Cropper and Andrew J Wright	875
How do you live? Evaluation of environmental quality of housing in Uberlândia (Brazil) Simone Barbosa Villa and Rita de Cássia Pereira Saramago	883
Building façade design for indoor air temperature and cooling load reduction Nyuk Hien Wong, Shanshan Tong, Erna Tan, Jianxiu Wen, Alice Goh, Sui Fung Lee and Ruixin Li	891
Retrofit for Optimizing Building Thermal Performance in Warm-Humid Climate Roshni Udyavar Yehuda and Dr. Archana Bhatnagar	899
Building Performance Evaluation for the Retrofit of Council Housing in the UK: A case study of a tower block in London Sahar Zahiri and Heba Elsharkawy	907
<b>Carbon Accounting</b>	<b>915</b>
Assessing and Mapping the Carbon Foot-Print of A Campus Environment Using BIM and Geo-Spatial Techniques Vineeth AC, Dinakar Raj N. S, Rajasekar Elangovan	916
Development of a Framework for Carbon Footprint Assessment of Building construction systems Sweta Haldar, Rajasekar Elangovan, Govindaraj V., Amit Barde	924
Calculation of greenhouse gases in the construction sector in the Aburrá Valley, Colombia Nicolas Pardo, Guillermo Penagos, Alexander González and Alejandro Botero	932

Addressing Embodied Carbon in High Performance Design Lindsay Rasmussen, Alison G. Kwok	940
<b>Comfort &amp; Delight</b> <span style="float: right;"><b>948</b></span>	
Indoor Thermal Comfort for Residential Buildings in the Hot-Humid Climate of Nigeria during the dry season Michael U. Adaji, Richard Watkins and Gerald Adler	949
The Impact of the Microclimatic Conditions on Pedestrians' Thermal Comfort in Dubai Nihal Al Sabbagh	957
Model View Definition (MVD) for Thermal Comfort Simulation in Conventional BEPS tools Fawaz Alshehri, Paul Kenny, Sergio Pinheiro and James O'Donnell	965
Envelope Design and Thermal Comfort Performance in a High-Rise Office Building in Saudi Arabia Fahad Alyami, Steve Sharples	973
The Residential Balcony in the Mediterranean Climates Angeliki Antoniou, Simos Yannas	981
The Improvement Potential on Building Performance Using Seasonal Adaptable Facades – The Context of Residential Buildings with High Thermal Load in Humid Subtropical Climates Beatriz Arantes, Daniel Cóstola, Lucila Chebel Labaki	989
Outdoor thermal comfort in a hot urban climate: analysing the impact of creating wind passageways in Al-Moski, Egypt using ENVI-met Yara Ayyad and Steve Sharples	997
A field study in southwest area of Spain: Thinking of thermal comfort and energy efficiency in existing buildings Elena Barbadilla-Martín, José Guadix Martín, José Manuel Salmerón Lissén, Pablo Aparicio-Ruiz and Luisa Brotons	1005
Exploring alternative solutions for the alleviation of energy poverty: the thermal refuge study case in Pamplona (North of Spain) Jorge San Miguel Bellod, Ana Sánchez Ostiz	1013
Assessing the impact of zoning on the thermal comfort analysis of a naturally ventilated house during early design considering closed internal doors María Pilar Casatejada, Karin Maria Soares Chvatal and Ranji Ranjithan	1021
Field Study of Thermal Comfort in University Buildings in Malaysia Siti Aisyah Damiati, Sheikh Ahmad Zaki, Hom Bahadur Rijal, Azli Abd Razak	1029
Influences of Building and Urban Typologies on the Study of Thermal Comfort in 'Shophouse' Dwellings in Ho Chi Minh City, Vietnam Hung Thanh Dang, Adrian Pitts	1037
Sustainability and Energy Efficiency of the health facilities in a city in southern Brazil: an exploratory study Chiara Mariele Gurgacz Destro, Layane Santos de Souza, Ana Mirthes Hackenberg and Elisa Henning	1045
Can thermal perception in a building be predicted by the perceived spatial openness of a building in a hot and humid climate? Xiaoyu Du, Regina Bokel and Andy van den Dobbelsteen	1053
Airflow pattern and thermal comfort in winter by different combinations of air distribution strategies and window types in an office unit Qiuhua Duan, Jiali Wang and Hua Zhao	1061
Impact of Technology and innovation on adaptation of architectonic tradition for a sustainable future in the Middle East Isra'a Fardous and Dr. Amar Bennadji	1069
Field Investigation on Unacceptable Sensation of Thermal Environment in Taiwan Office Yuta Fukawa, Masayuki Ichinose and Eriko Tokuda	1076
Are heavyweight buildings more comfortable? The potential of thermal mass in increasing thermal comfort Stephanie Gauthier, Despoina Teli, Patrick James, Samuel Stamp	1084

None of these proceedings would have been possible without the help and support of the very large scientific committee who helped us blind reviewing more than 1400 abstracts.

Our thanks go to all of them and especially to the following Forum Leaders:

Sam Amarillo, Keith Baker, Philip Banfill, Amar Bennadji, Kate Carter, Sam Chapman, Joe Clarke, Rohinton Emmanuel, Suzanne Ewing, Jessica Fernandez, Brian Ford, Laurent Galbrun, Rajat Gupta, Bev James, David Jenkins, David Kelly, Gráinne McGill, Isaac Meir, Circe Monteiro, Tariq Munir, Andrew Peacock, Francesco Pomponi, Colin Porteous, Harald Rostvik, Ashraf Salama, Kay Saville-Smith, Tim Sharpe, Andrew Toland, Paul Touhy and Ola Uduku.

We would also like to thank Dan Carroll at Firebird Conference systems who put together the software that enabled us to handle all these abstracts and papers and to Wendy Ball and Will Finlayson at Locus-Focus for their help with the timetable and programme and Mark and Pete of Kitson Consulting for their website development, design and web support. We also want to give credits to Sally Fisher for the illustration used in this cover and throughout PLEA2017.

We would like to remember and give thanks to Jeff Cook who was such an inspiring member of the PLEA family and continued to be its great supporter in 2017 through the work of his Trust.

Lastly, we need to thank the PLEA organisation and all the sponsors, listed at the end page of this publication.  
All made this conference possible.

*Luisa Brotas*

Luisa Brotas is an architect (RIBA) with a PhD in Daylighting. She was Course Leader of the MSc Architecture, Energy and Sustainability and co-director of the Low energy architecture Research unit at London Metropolitan University until 2016. Luisa also taught at other Universities and worked in National Research Institutes in both UK and Portugal. She is Vice-Chair of the Daylight Group of CIBSE and Secretary of the Network for Comfort and Energy Use in Buildings. Luisa is currently Director of Submissions for the PLEA 2017 and organiser the International Windsor Conference 2018. Luisa has also been the initiator of six People and Buildings, a conference for Masters Students in sustainable buildings. Research and consultancy include projects related to daylight and thermal analysis, visual and adaptive thermal comfort, energy efficiency in new and retrofit buildings, eco materials and sustainability, natural ventilation and Passivhaus standard. Recent interests also address climate change and overheating in Europe and resilient buildings and cities

*Sue Roaf*

Sue Roaf (B.A.Hons, A.A. Dipl., PhD, ARB, FRIAS) is Emeritus Professor of Architectural Engineering at Heriot Watt University and an award winning author, architect and solar energy pioneer. She was an Oxford City Councillor for seven years and in 2016 was elected to sit on the UK Architects Registration Board. Her research covers windcatchers and nomadic architecture in Iran, Mesopotamian archaeology, photovoltaics, low carbon, resilient and sustainable design, material considerations in design and thermal comfort. She is known for her pioneering work on ecohouses. Building her own Oxford Ecohome resulted in the internationally best-selling book *Ecohouse: A Design Guide* on the subject. Her other books include *Adapting Buildings* and *Cites for Climate Change and Benchmarks for Sustainable Buildings*. She is currently working on *How to design a Comfortable Building*. She is the Chair of the PLEA 2017 conference on the 2nd to 5th July 2017([www.plea2017.net](http://www.plea2017.net)). Her recent awards include 2013 Top 6 - UK 'First Women' Awards as a 'Visionary' in the Built Environment'; 2013 Top 10 'Women in Architecture' Awards, Architect's Journal, and in 2010 'the AJ's most influential UK architectural academic' in the field of Sustainable Design

*Fergus Nicol*

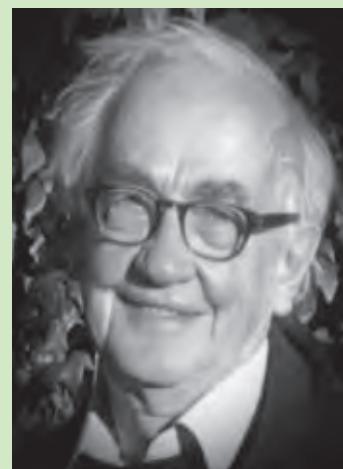

Fergus Nicol is best known for his work in human thermal comfort, principally the 'adaptive' approach and with Professors Michael Humphreys and Susan Roaf is author of the leading book on the subject *Adaptive thermal comfort: principles and practice*, (2012 Routledge). The second volume of this intended trilogy is *Adaptive thermal comfort: foundation and analysis* (2016) is recently published with Humphreys as lead author. He led the EU project Smart Controls and Thermal Comfort (SCATS) which is the basis of European comfort standard EN15251 which he helped draft. Fergus helped develop Masters courses on sustainability at Oxford Brookes and London Metropolitan Universities and supervises a number of PhD students. He has co-authored numerous journal articles and other publications including the comfort chapter in CIBSE Guide A. He was a member of the CIBSE task force on overheating in buildings and is the principal author of CIBSE TM52 *The limits of thermal comfort, avoiding overheating in European buildings* (2013). Fergus convenes the Network for Comfort and Energy use in Buildings and is presently organising their 9th international conference 'Making Comfort relevant' in Windsor, UK in April 2016. He is part-retired but divides his working time between London Metropolitan, Oxford Brookes and Heriot Watt Universities and University College London.

## **Building Resilience for Future Climate: An Investigation of Fabric Optimisation to Improve Thermal Comfort in Residential Buildings in Lagos, Nigeria**

**Abdulquadri Ademakinwa<sup>1</sup>, Lucelia Rodrigues<sup>2</sup>**

<sup>1</sup> Department of Architecture and Built Environment, University of Nottingham, Nottingham, NG7 2RD, United Kingdom, abdulquadriademakinwa@gmail.com

<sup>2</sup> Department of Architecture and Built Environment, University of Nottingham, Nottingham, NG7 2RD, United Kingdom, Lucelia.Rodrigues@nottingham.ac.uk

**Abstract:** Nigeria is not left out of the consequences of climate change. In recent time, Lagos experienced one of the most intense heat wave in its history which was a prolonged period of abnormally hot weather with temperature exceeding 32.2°C accompanied by high humidity levels that resulted in the increase in the level of thermal discomfort of occupants within the residential environment. The Lagos future climate is projected to cause more increase in temperature and frequent occurrence of a heat wave. The author investigated the current and the future performance of the residential buildings in respects to the time within and above comfort temperature. This study was developed using Lagos HOMS residential building typology, a low-cost mass housing project by the Lagos state government to reduce the housing deficit. It was selected as it is a repeated mass housing with an expected lifespan of 20 -100 years. This study hopes to improve the thermal performance of the buildings and life of the occupants in changing climate. The current performance of the building presented a high degree of overheating period while the future performance indicated a more severe overheating period. The improvement study showed that the optimisations of the building fabric resulted in slight improvement to the present and 2050 time in comfort period, but in 2080 it presented a significant improvement in the comfort period.

**Keywords:** Climate Change, Thermal Performance, Thermal Comfort, Residential Buildings, Lagos, Nigeria

### **Introduction**

Africa has been identified as one of the most vulnerable continents due to its high exposure and low adaptive ability as reported by fifth assessment report of the Intergovernmental Panel on Climate Change (IPCC, 2014). One of the expected consequences of climate change is the increase in occurrences of heat waves and hot weathers in many urban environments (Huth et al., 2000, Beniston et al., 2007). The study by New et al. (2006) shows that the number of cold days and cold nights have decreased and the number of warm days and warm nights have increased between 1961 and 2000 in West Africa and Sahel. It was projected that the Temperatures in Africa are to rise faster than the global average increase during the 21st century (Christensen et al., 2007; Joshi et al., 2011).

Lagos is a coastal city located in the southwestern geopolitical zone of Nigeria. Lagos has been more vulnerable to consequences of climate change in Nigeria, in last few years, the city has experienced several heat waves. The most recent and intense heatwave that hit Lagos was in March 2016 with the temperature reading as high as 36°C with high humidity as recorded by the Nigerian Meteorological Agency (NIMET) (Kazeem, 2016). At all times of

the day during the heat wave period, the room temperature exceeded the normal threshold in many houses making people feel ill at ease (Atuma, 2016). It also made smooth night's rest almost impossible leaving millions of households in restlessness and several heat-related illnesses like heat rash, heat cramp and fatigue. (Dumo & Olajide, 2016).

The use of active cooling system can reduce thermal discomfort during the heat waves, but the erratic power supply in Nigeria coupled with high energy consumption and the cost of maintaining gasoline and diesel power generators make it unaffordable especially for low-income households. Aside from that studies revealed that the use of active cooling system in building is not the ultimate solution and environmentally friendly method as it emitted waste heat to the surrounding environment of the building, which in turn intensify the urban heat island effect (Levermore, et al., 2004, Sailor, 2011, Li & Zhao, 2012).

This paper presents a study of thermal performance of typical Lagos Home Ownership Mortgage Scheme, a low-income mass housing typology, to current and future climates and the application of fabric optimisations to improve indoor thermal comfort in changing climate scenarios.

### **Lagos Home Ownership Mortgage Scheme (Lagos Homs)**

The Lagos HOMS was the selected residential building case study because of its significant representation of residential mass housing that is repeated in different locations in Lagos and is not designed to use the active cooling system as the build costs would be too high to be considered for a low-income earner's scheme. It is expected that newly built housing typical lifespan is 20 – 100 years which makes Lagos HOMS an important case study to investigate the influence of future climate scenario on thermal comfort in residential housing in Lagos.

#### ***Case Study Description***

The selected prototype design comprises of 12 residential apartments of one to three bedroom on four floors. Each floor of the prototype comprises of three apartments as shown in Figure 1. It has a courtyard opened to the stair halls. The bedrooms have two windows which are mainly in the east, west and north façade, while the kitchen windows are opened to the courtyard. It has a butterfly roof covered by long span aluminium roofing sheet which slopes inwards with central concrete roof slab. The roof has 1m eaves at all its sides. Figure 2 shows one of the completed Lagos HOMS. The windows used are casement with 90% effective opening.

Figure 1. Floor plans and completed blocks of Lagos HOMS at Ilupeju Lagos

The building structural frames are made of reinforced concrete. The external and internal walls are made of rendered and painted sandcrete hollow blocks. The roof covering is long-span aluminium roofing sheet while the ceiling and the floor are finished with PVC tiles and Vitrified ceramic tiles respectively.

### **Thermal Simulation and Base Case Study**

The scope of the simulations is based on the indoor air temperature in relation to thermal comfort temperature of the selected simulation spaces. The dynamic model approach was used for this study to understand building performance in different climate scenarios. IES-VE was selected as the simulation software because of its sufficient validity for calculating thermal analysis and humidity in spaces and it could perform accurately in nearly all the analysed hour of thermal simulation.

The third-floor level was chosen as the study floor because it represents the worst case scenario of the building as it is closest to the roof that is fully exposed to solar radiation. The results of the dynamic building simulations were analysed in terms of percentage of hours in thermal comfort. The adopted limits of comfort temperature for Lagos is (23.5°C to 28.5°C) using Szokolay (2008)  $T_n$  equation, thus, any temperature below 23.5°C is considered to be under heated and if it is above 28.5°C is considered as overheating.

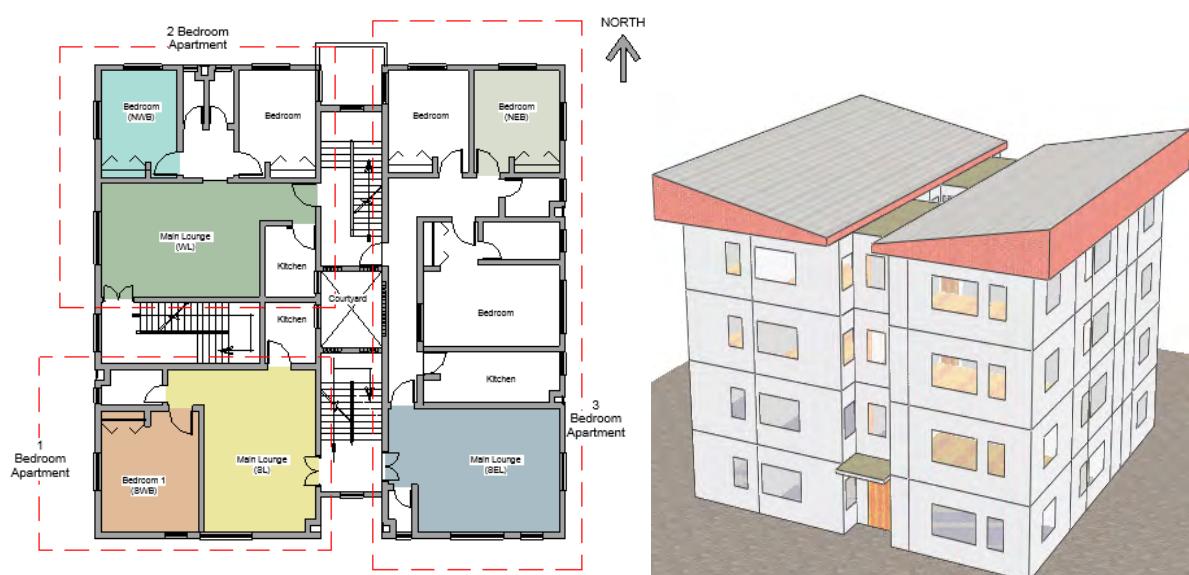

Figure 2. Selected analysed spaces and 3D view of Lagos HOMS thermal simulation model in IES-VE

### **Base Case Study**

The base case study investigated the current thermal performance of building to the present climate and its effects on thermal comfort. The dynamic building simulations consisted of 4 different cases and simulated under the existing building envelope. The assumptions made for the base case study simulation are presented in Table 1.

Table 1. Base case study general assumptions

Weather file	EnergyPlus weather data of Lagos (Lat. 6.45°N Long. 2.4°E Altitude 3m).
Calendar	The simulations were conducted for 8760 hours of a typical year
ventilation and Infiltration rates	Natural Ventilation = 5ACH Infiltration rate = 1ACH
Occupants	1 people were assumed for all the bedrooms. One bedroom apartment Living room = 1 occupant. Two bedroom apartment Living room = 2 occupants. Two bedroom apartment Living room = 3 occupants
Occupants heat gains	the heat gain assumed for each person in the living room was 75 W and the latent heat gain of 55 W while for bedrooms, sensible heat gain of 65 W and the latent heat gain of 30 W.
Construction U-Values(W/m <sup>2</sup> K)	Wall= 3.12, Floor= 2.33, Roof (covering, air space and ceiling) = 3.0 Single glazed Window = 5.59
Lighting	5w/m <sup>2</sup> for the bedrooms and living room respectively
Equipment	Living rooms and bedrooms were 10w/m <sup>2</sup> and 5w/m <sup>2</sup> respectively regardless of the apartment.
Comfort temp. range	23.5°C - 28.5°C
Cooling set point	No cooling and auxiliary cooling system

### Results and discussions

The base case study LHA0 presented a high degree of overheating under the current building fabrics. All the rooms were out of comfort temperature for an average of 67% of a typical year. This base case shows that the existing building fabric performed woefully without internal gains and the current climate scenario. To understand the impact of the occupancy, case LHA01 showed the rooms were out of comfort temperature for an average of 76.4% which is 4.5% higher than LHA0. Further analysis to assess the influences of lighting and equipment's gains, case LHA02 presented much worse overheating and period out of comfort temperature reached an average of 76.4% of a typical year. This showed that internal gain can increase the base case LHA0 by 14.03%.

The case with ventilation, LHA03 presented a significant improvement in the period within the comfort zone and it is noted that all the room reached an average of 55% in comfort zone. This indicated 84.03% improvement of LHA0 period within comfort temperature and 41.04% reduction in time outside comfort zone in a year. Figure 3 shows the summary of the base cases on the period in comfort temperature.

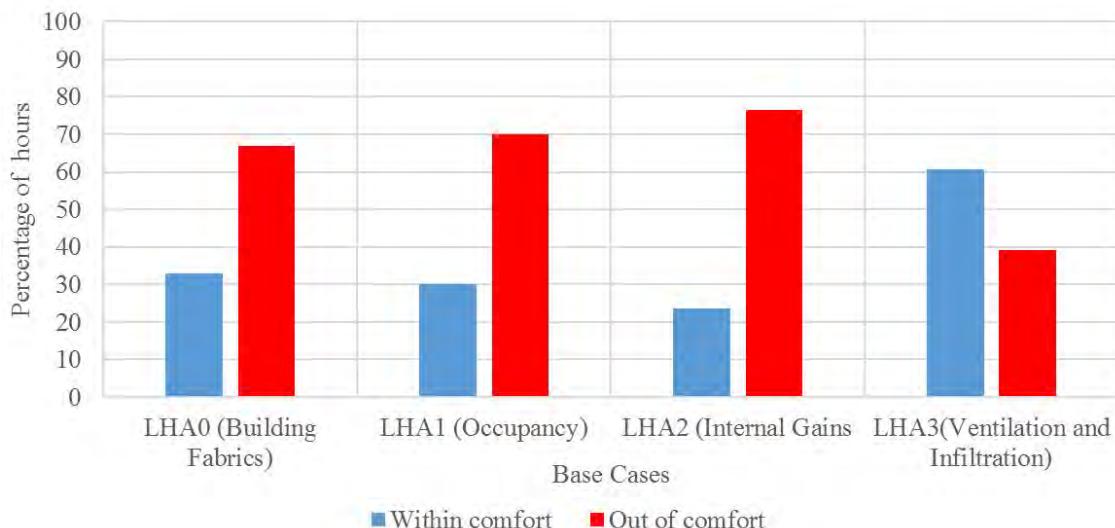

Figure 3. Percentage of time within and above comfort zone for all base cases

## Lagos Homs in Future Weather Scenarios 2050 And 2080

This examines the impact of projected future climate change scenarios of 2050 and 2080 respectively on thermal comfort using the existing building fabric, occupancy, lighting and equipment loads, and ventilation on the internal temperature. The methodology of sensitive analysis was employed to have a critical understanding of the building performance to the future weather condition using dynamic simulation.

### **Simulation Future Weather Data and Assumptions**

The future weather data of Lagos was generated by transforming present EnergyPlus weather (EPW) data into future data of 2050 and 2080 respectively using the morphing methodology in the climate change world weather file generator. It uses IPCC TAR model summary data of the HadCM3 A2 experiment for use in building performance simulation programs (Jentsch, et al., 2013). The morphing methodology used by this tool is based on the methods developed by Belcher, et al. (2005). All assumptions made in Table 1 remain the same except the weather file that was obtained from EnergyPlus weather data of Lagos morphed into weather data for 2050 and 2080.

### *Results and discussions*

The sensitive study of the future performance of Lagos HOMS in 2050 and 2080 respectively, presented a severe degree of overheating under projected future climate change scenarios. The future performance of the building envelope in 2050 showed an average of 90% of the year out of comfort temperature. With the internal gains, it showed a significantly more adverse impact on the indoor temperature with an average of 92% above comfort temperature. The 2050 future case showed no distinctive improvement with the addition of ventilation and infiltration rates. During the warmest period, the internal temperature of the rooms reached an average of 35.84°C.

Further sensitive analysis of 2080 future climate presented more severe overheating period. The envelope performed woefully in the absences of internal gains with an average 99.6% of the year out of comfort temperature. The introduction of internal gains resulted in a more degree of overheating in all the rooms with an average of 100% out of comfortable indoor temperature. With the addition of ventilation and infiltration rates, the rooms were still affected by severe overheating with an average of 99.95% out of comfort temperature. On the warmest period, the average temperature of rooms reached 39.79°C.

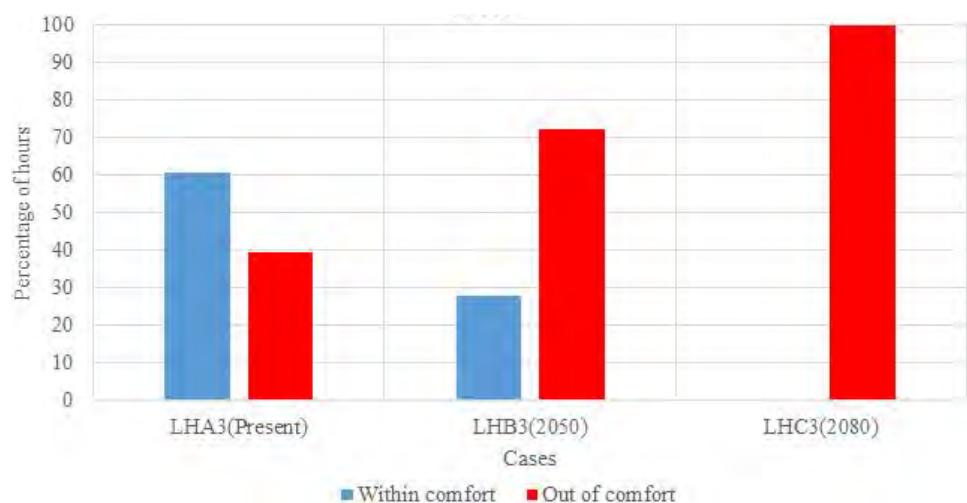

Figure 4. Percentage of time within and out of comfort temperature in present and future climate scenarios

## Optimisation Study of Lagos Homes Building Fabrics

This study investigated the most sensitive building fabrics in terms of the corresponding percentage of time in comfort temperature to establish a resilient building envelope to the changing climates as the existing building envelope presented a bad performance to the current and future weather scenarios.

The methodology of sensitive analysis of different building envelope of the wall; roof, floor and window thermal properties were carried out. The simulation is divided into 4 sections consisted of 24 different simulation studies of the current and the future years (2050 and 2080) as illustrated in Table 2. The assumptions were retained from the current and future studies except for the construction material details and thermal properties presented in Table 2.

Table 2. Simulation matrix of building fabrics optimisation and construction U-value of improved fabrics

Building Fabrics Optimisation	Construction U-Values W/m <sup>2</sup> K	Present	2050	2080
		A	B	C
Wall	W1- 500mm thick 2 layers hollow block (1.62)	AW1	BW1	CW1
	W2- 355mm thick hollow block with 100mm EPS insulation (0.39)	AW2	BW2	CW2
	W3- 450mm thick insulated block wall with 250mm EPS (0.15)	AW3	BW3	CW3
Roof	R1- Aluminium foil roof insulation (0.48)	AR1	BR1	CR1
	R2- Insulated roof ceiling with 25mm EPS (0.45)	AR2	BR2	CR2
	R3- Insulated roof and ceiling (0.35)	AR3	BR3	CR3
Glazing	24mm thick double glazing with 12mm cavity (1.6)	AG	BG	CG
Combination of best (wall + roof+ glazing)		AC	BC	CC

## Results and discussions

The optimisation of wall a slight improvement in the percentage of time in comfort temperature for the present-day and 2050 but presented a significant improvement in 2080. There was a significant reduction of 12.2% in 2080 percentage of time above.

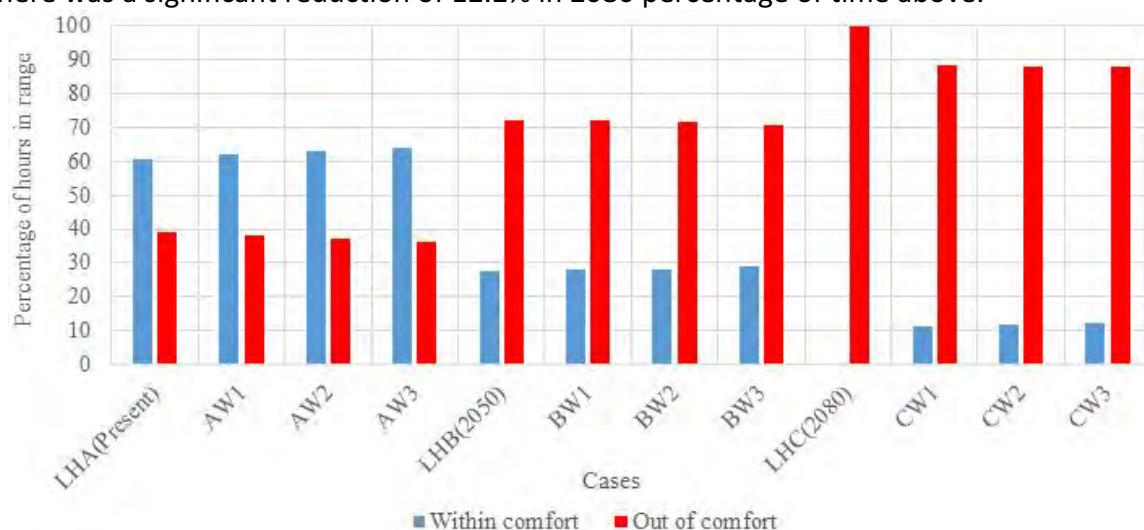

Figure 5. Wall optimisations percentage of time in and out of comfort for the present and future cases

The optimisation of the roof especially the increase in insulation level of the ceiling showed less improvement to the present condition but gave a significant reduction in the time above comfort temperature for the future cases. Potential increase in the roof insulation to the Passive House standard might increase the percentage of time in comfort.

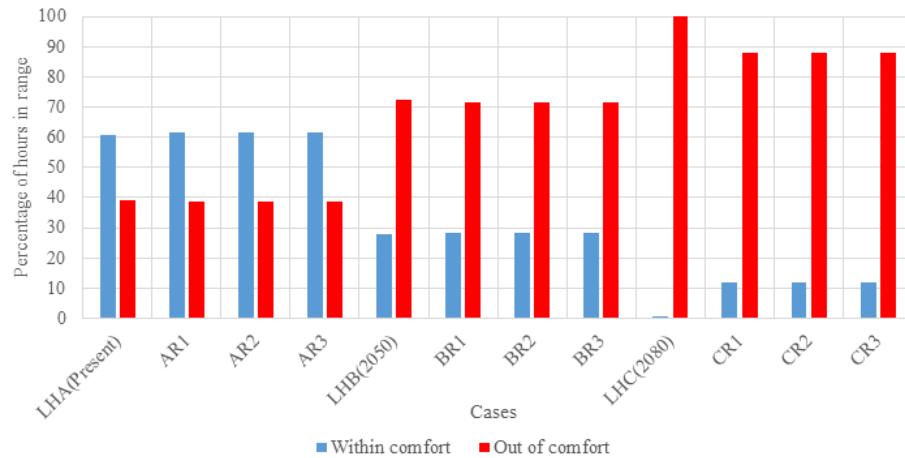

Figure 6. Roof optimisations percentage of time in and out of comfort for the present and future cases

The improvement to double glazing showed a negligible improvement to present-day and future percentage of time in comfort temperature. Despite the slight improvement, the most sensitive building fabrics are the wall and the ceiling.

The combination of all the building fabric optimisation showed a minimal improvement in the time within comfort temperature for the present and 2050 future scenarios but presented a noticeable improvement in time within comfort zone for 2080 future scenario.

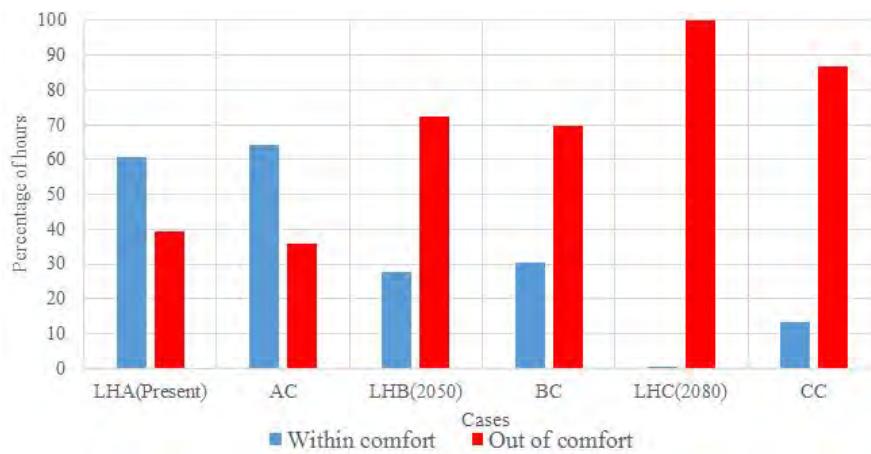

Figure 7. Combined optimisations percentage of time in and out of comfort for the present and future cases

## Conclusion

This study outcome is derived from the dynamic simulation results of Lagos HOMS in different climate scenarios. The current performance of the building presented a high degree of overheating period under the current building envelope. The addition of internal gains resulted into more severe overheating period, it is important to put off appliances and lighting fixtures to improve the period in comfort temperature. It was noted that the weekends are most overheating days during the warm period because the internal gains are higher as a result of full occupancy schedule. The introduction of ventilation reduced the time out of comfort significantly.

The study of projected future climate scenarios indicated a very low performance of the current building envelope with more severe overheating for all times of the year. Also, the addition of the ventilation and infiltration have lesser effects on both 2050 and 2080 percentage of time in comfort temperature as contrary to the positive impact of ventilation rate under current weather situation.

Furthermore, the study of optimisation of the building envelope using fabric first approach presented a slight improvement in the percentage of time in comfort temperature under Lagos present-day and future case 2050 but gave a significant improvement in 2080. Despite the slight improvement of building envelope optimisation, the most sensitive building envelopes are the wall and the roof.

Conclusively, the optimisation of the building envelope is an important passive strategy to improve the comfort period, occupants' health and reduce the energy consumption and the cost of maintaining gasoline and diesel power generators in changing climate. Further study should be carried out on other passive strategies to improve the period in changing climate scenarios.

## Acknowledgment

I would like to thank the Meteotest Company for providing me the weather data of Lagos and Dr Lucelia Rodrigues for her insightful supervision and guidance during this study.

## Effectiveness of passive climate adaptation measures in residential buildings in Germany

Farzan Banihashemi<sup>1, 2</sup>, Johannes Maderspacher<sup>1, 2</sup>, Julia Brasche<sup>1, 2</sup>, Werner Lang<sup>1, 2</sup>

<sup>1</sup> Centre for Urban Ecology and Climate Adaptation, Munich, Germany, correspondence email: Farzan.banihashemi@tum.de;

<sup>2</sup> Technical University of Munich, Institute of Energy Efficient and Sustainable Design and Building, Munich, Germany

**Abstract:** Current climate scenarios indicate that, summer and winter periods in Germany will get warmer and milder, respectively by 2090. This will affect the energy demand and the thermal comfort of the buildings' inhabitants. Whereas milder winters will reduce the heating demand, warmer summers will increase the overheating potential of the buildings. The resulting discomfort during summer could lead to an increased potential for active cooling and therefore to additional CO<sub>2</sub> emissions. This topic is investigated in a detached single family house which represents a large part of the German building stock. In order to reduce the potential cooling demand of the single family house, three passive climate adaptation measures: solar protection glazing, shading, and natural ventilation were combined and assessed. These measures were quantified with a dynamical thermal building simulation tool for the periods 2030-2060 and 2060-2090, by assessing the performance indicators: overheating degree hours, heating and cooling demand, and CO<sub>2</sub> emissions. The results demonstrate that a combination of automated blinds and ventilations can significantly reduce the overheating degree hours and the potential cooling demand. Furthermore, they illustrate the necessity to consider passive measures in a state of art refurbishment of existing buildings.

**Keywords:** Passive climate adaptation measures, climate change, building energy simulation, energy consumption, overheating

### Introduction

The Fifth Intergovernmental Panel on Climate Change report shows that even if anthropogenic CO<sub>2</sub> emissions are reduced, climate change still takes place (IPCC, 2013). In Germany, climate change scenarios based on the IPCC report indicate that an increase of temperature between 2 and 5°C is to be expected in the year 2090 compared to 2000 (Jacob *et al.*, 2012). This rising temperature will result in milder winters and hotter summers. While milder winters potentially reduce the energy demand for heating, hotter summers might increase the overheating potential of buildings and thus lead to a higher need for active cooling. However, since the majority of the residential buildings in Germany is not equipped with active cooling systems (machine cooling), the likelihood of retrofitting and thus increase in energy demand is high.

The building sector accounts for about 30% of anthropogenic greenhouse gas emissions in Germany (Bürger *et al.*, 2016). The building sector not only impacts climate change, it will be also affected by it in the future. It is therefore important to analyze the future climatic conditions and to assess buildings' energy performance with respect to climate change mitigation and adaptation. The refurbishment cycle of buildings averages between 30 and 60

years (Nemeth, 2011), which means that buildings that are refurbished today will be impacted by climate change in the future. Therefore, both existing and new buildings should adapt to the changing climatic conditions to ensure the thermal comfort of their occupants.

The focus of this paper is on non-active cooling systems, since equipping buildings with active systems will lead to an increased energy demand which results in more CO<sub>2</sub> emissions and thus accelerating the climate change. A sustainable approach to avoid this increased energy demand is through passive climate adaptation measures.

In this study, the effectiveness of three passive climate adaptation measures will be evaluated in a detached single-family house, which is representative of a large share of the German building stock. Only passive measures are investigated, as they do not directly contribute to an increased energy consumption and higher CO<sub>2</sub> emissions. It is assumed that the case study will be retrofitted according to the German law. Therefore, the goal of this study is to optimize the refurbishment with passive measures, which can be implemented in any conventional refurbishment in order to adapt it to the changing climate. Several publications investigated the effectiveness of passive climate adaptation measures on both residential and commercial buildings in North-Western European countries (Hamdy and Hensen, 2015; Porritt *et al.*, 2013; van Hooff *et al.*, 2014). They studied a range of possible climate change adaptation measures, and showed that not all of them were equally effective. This study, therefore, will focus on three of the most effective adaptation measures based on the mentioned studies. The investigated measures are: solar protection glazing, shading, and natural ventilation.

To include climate change in the analysis, weather data from the regional climate model REMO (Jacob *et al.*, 2012) are used as boundary conditions for simulation until the year 2090.

In the next section, the methodology of this study will be addressed, after which the results of the investigation will be analyzed and discussed and in the end, a conclusion will be drawn.

## **Methodology**

In this study, the evaluation of the passive adaptation measures is carried out with a dynamical thermal building simulation tool. For this purpose, the software tool IDA ICE was used (EQUA, 2013). Although numerous simulations are required for this work we can simplify the process by linking the IDA ICE program to the statistical program R (Venables and Smith, 2016) to parallelize the simulations, which leads to lower computation times.

### ***Investigated building type***

Detached single-family houses are the most common residential buildings in Germany. Therefore, a detached single-family house in Neuauing-Westkreuz, Munich, was selected for this study. Fig. 1 shows the floorplans and the building facades. This building has a floor area of 147 m<sup>2</sup> and a heated building volume of about 389 m<sup>3</sup>.

For the case study, it is assumed that the building built in the 1950's will be refurbished according to the German law EnEV (EnEV, 2014). State of the art rules and regulations in Germany (for example the EnEV) do not consider the long-term impact of climate change, because they are just used as a proof of concept for different types of buildings. This study, however, focuses on the need to assess passive measures to adapt refurbishments to the changing climate. The construction details according to the German law are summarized in Table 1. This refurbishment represents the base case, which is then optimized with the passive measures.

Figure 1. Facades, floor plans of the detached single-family house in Neuauing-Westkreuz, Munich.

Table 1. Base case construction details based on EnEV 2014

U-value External Walls [W/m <sup>2</sup> K]	U-value roof [W/m <sup>2</sup> K]	U-value internal floor [W/m <sup>2</sup> K]	U-value Window [W/m <sup>2</sup> K]	g-value Window [-]	T <sub>vis</sub> -value window [-]	Shading system
0.24	0.24	0.3	1.3	0.6	0.8	-

### Combined passive climate adaptation measures

In order to increase the effectiveness of the above mentioned passive measures, these methods are combined. Another reason for the creation of these combinations is the requirement of the standard DIN 4108-2:2013-02, which regulates thermal building simulations to protect buildings from overheating in Germany. This standard requires high rates of natural or mechanical ventilations before using sun protection systems like sun protection glazing or shading systems. Therefore, three combinations are created in which the ventilation hours are higher compared to the base case (see Table 2).

The economical combination is based on a solar protection glazing and a natural ventilation. For this purpose, only a sun protection glazing with a low g-value of 0.2 [-] is used in the refurbishment (hence the name economical). The building is ventilated by a maximum natural ventilation driven by the user. Due to the low g-value of the sun protection glazing, this combination increases the heating demand, which is a negative side effect. The moderate combination is created for the reduction of this negative side effect. In this combination, a sun protection glazing with a higher g-value of 0.35 [-] is used. Like the economical combination, this combination is also ventilated by a maximum natural ventilation. Additionally, an automated shading blind is installed to optimize the solar gains in summer without affecting the heating demand in winter. The intelligent combination avoids the negative effect of the increasing heating demand of the two other combinations, by not replacing the glazing during the refurbishment. For reducing the solar gains in summer, a

shading system is installed on the windows. In addition, an automated window ventilation is used, which runs all day. When the outside temperature rises above 26°C, this device is turned off. The intelligent combination is therefore completely automated by the use of the shading system and the automated window ventilation.

Table 2. Combined passive adaptation measures investigated

Combination	g-value [-]	F <sub>c</sub> -value [-] <sup>(1)</sup>	g <sub>tot</sub> -value [-] <sup>(2)</sup>	T <sub>vis</sub> -value [-] <sup>(3)</sup>	Window Ventilation
Base case	0.6	1	0.6	0.8	Minimum by user (7:00 - 7:30 & 21:00 - 23:00 h)
Economical	0.2	1	0.2	0.35	Maximum by user (23:00 - 7:30 & 12:00 - 15:00 h)
Moderate	0.35	0.3	0.1	0.6 <sup>(4)</sup>	Maximum by user (23:00 - 7:30 & 12:00 - 15:00 h)
Intelligent	0.6	0.25	0.15	0.8 <sup>(4)</sup>	Automated (all day, only when θ <sub>op</sub> ≥ θ <sub>amb</sub> and θ <sub>amb</sub> ≤ 26°C) <sup>(5)</sup>

(1) F<sub>c</sub>-value is the multiplier for the drawn shading

(2) The g<sub>tot</sub>-value represents the reduced solar energy entering the building through the window, when the shade is drawn, and is calculated by the following formula: 
$$g_{tot} = g \times F_c$$
 Formula (1)

(3) T<sub>vis</sub>: visible light transmittance degree values according to (Keller *et al.*, 2011)

(4) The T<sub>vis</sub>-values are only valid when the shading system is lifted

(5) θ<sub>op</sub> = Operative temperature, θ<sub>amb</sub> = Ambient temperature

### Building simulation parameters

The parameters used in the building simulation are summarized in Table 3.

Table 3. Building simulation parameters

Parameter	Values		
Maximum ventilation rate during days (when θ <sub>op</sub> * ≥ 23°C)	- 3 [h <sup>-1</sup> ] (from 6 a.m. to 23 p.m.)		
Maximum ventilation rate during nights (when θ <sub>op</sub> ≥ 23°C)	- 2 [h <sup>-1</sup> ] (from 23 p.m. to 6 a.m.)		
Shading is activated when solar radiation on the window is higher than the value:	- 200 [W/m <sup>2</sup> ] (North, northeast, northwest direction) - 300 [W/m <sup>2</sup> ] (All other directions)		
Infiltration	0.1 [h <sup>-1</sup> ]	Heating set point	21 [°C]
Internal heat gains	4 [W/m <sup>2</sup> ]	Cooling set point	26 [°C]
short wave reflectivity of the facade	0.5 [-]	Presence time	24 [h/d]

### Climate Data

For the investigation, weather data are generated from the regional climate model REMO (Jacob *et al.*, 2012), which has a temporal resolution of one hour. The climatic scenario A1B was chosen because it represents a moderate development of the climate change scenario (IPCC, 2013).

The climate data is subdivided into the three periods: 2000-2030, 2030-2060, and 2060-2090. Since we are now in the first period (2000-2030) and assume that the dwelling is being refurbished in the present with a refurbishment cycle of 30-60 years (Nemeth, 2011), we study the impact of climate change on the building over the remaining periods (period 2030-2060 and 2060-2090). The data include the following parameters: outside air temperature, relative humidity, solar radiation wind direction and the wind speed.

## Results and discussions

### Overheating Degree hours

In the first step, the overheating degree hours for the base case and combinations were calculated in the investigated periods. The overheating degree hour ( $Gh_{26}$ ) is calculated from the operative temperature ( $\theta_{op}$ ) by the following formula, according to DIN 4108-2:2013-022:

$$Gh_{26} = \sum (\theta_{op} - 26^\circ\text{C}) \quad \text{when } \theta_{op} \geq 26^\circ\text{C} \quad \text{Formula (2)}$$

For the calculation according to DIN 4108-2:2013-02, standard test reference years should be used. However, in this study the REMO climate model is used for the investigation, which does not follow the prescriptions of the regulation. Therefore, this regulation is just used for estimating the risk of overheating and comparing the risk in the investigated periods.

Figure 2 shows the reduction of the overheating degree hours through the use of the combinations in the periods 2030-2060 and 2060-2090 compared to the base case. Each boxplot shows the results of the 30 years simulated in the period. For each floor plan the zone with the highest overheating degree hours is presented (Living 2 in ground floor and bedroom 1 in first floor, see Figure 1). The standard DIN 4108-2 prescribes overheating degree hours under 1200 Kh/a, as shown by the red lines. In the period 2030-2060, the required value is complied to by all the combinations. In the period 2060-2090, the overheating degree hours are also significantly reduced in comparison to the base case but the requirement value cannot be kept by the combinations in this period.

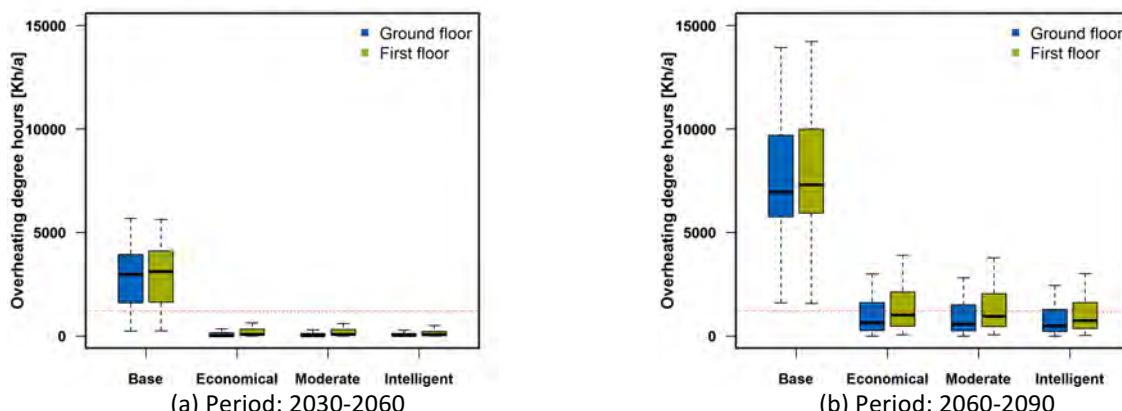

Figure 2. Number of degree hours for the detached single house in the base case and combinations

### Heating and cooling demand

Figure 3 shows the yearly heating and cooling demand in the investigated periods for the combinations in comparison with the base case. Figure 3 (a) shows that the economical combination leads to an approximately 20% increase in the heating demand in both periods. The moderate combination results in only a 10% increase in the heating demand. Only the intelligent combination solves this problem with an unchanged heating demand compared to the base case, as the glazing is not changed in this combination.

The potential for active cooling could be significantly reduced in both periods with using the combinations (see Figure 3 (b)). The potential cooling attains very low results in the period 2030-2060 (under 1 kWh/m<sup>2</sup>a), so that in reality, machine cooling can be avoided if the combinations are used. However, the potential for active cooling increases in the last period, which leads to necessitated machine cooling systems during this period. The results show that the moderate and economical combination are equally effective in reducing the cooling

demand. The effectiveness of the intelligent combination increases in comparison with the two other combinations in the last period. In order to justify this effectiveness, the climate data of both periods have been analyzed more precisely. The analysis shows that in the last period the annual average ambient temperature will increase by almost 20% in comparison to the period 2030-2060. The solar radiation will increase by just 3% in the later period. This means that the increased outside temperature is the reason behind the higher cooling demands. As the intelligent combination is based on an automated ventilation which ventilates all day only when  $\theta_{op} \geq \theta_{amb}$ , and  $\theta_{amb} \leq 26^\circ\text{C}$ , it operates more efficiently in the last period compared to the other two combinations, which are based on a user-activated ventilation. It must be considered that the investigated climate model is just a prognosis for the future climate. Therefore, other climate scenarios from the REMO model can differ in the results regarding the rising outside temperature and solar radiation.

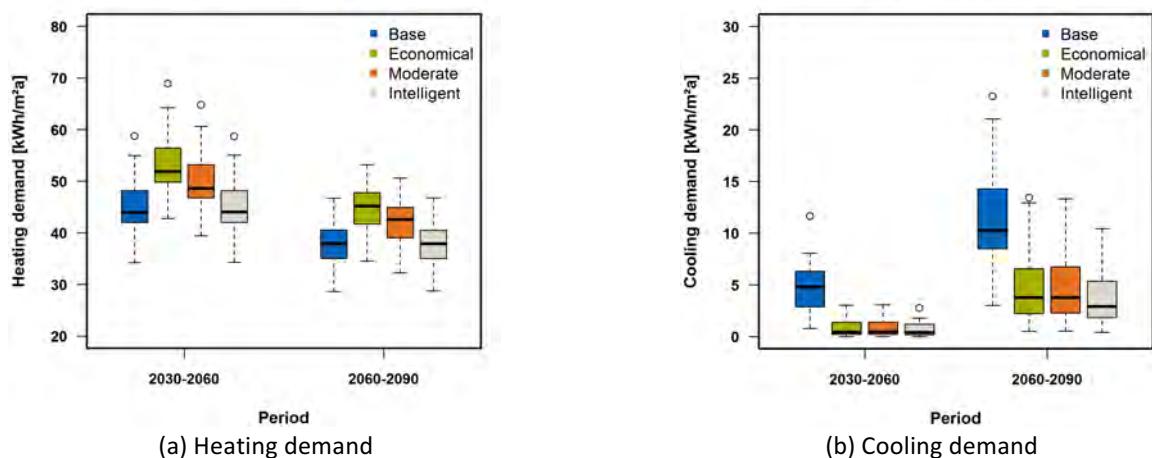

Figure 3. Yearly heating and cooling demand for the detached single house in the base case and combinations

#### **Greenhouse gas emissions ( $\text{CO}_2$ equivalent emissions)**

Despite the significant reduction of the potential cooling demand, this demand could not be avoided in the later period. Therefore it is important to find out to what extent greenhouse gas emissions can be saved by the use of the combinations if a machine cooling system would also be used in the building. For this reason, two different machine cooling systems and their  $\text{CO}_2$  equivalent emissions were analyzed (see Table 4).

Table 4  $\text{CO}_2$  equivalent scenarios

	Scenario 1	Scenario 2
Specification	Efficient heating + inefficient cooling $\eta = 0.9$ ; 0.02 [KgCO <sub>2</sub> eq/kWh]	Efficient heating + efficient cooling $\eta = 0.9$ ; 0.02 [KgCO <sub>2</sub> eq /kWh]
Heating		
Cooling	COP = 2.5 ; 0.535 [KgCO <sub>2</sub> eq /kWh]	COP = 4.5 ; 0.535 [KgCO <sub>2</sub> eq /kWh]

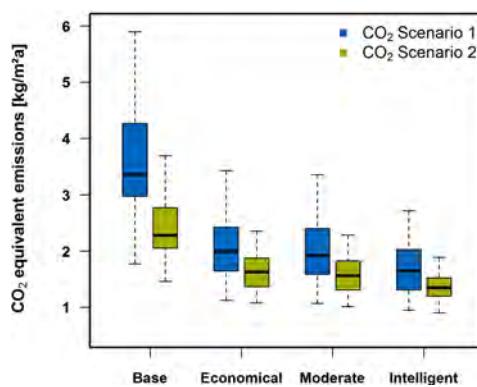

Figure 4.  $\text{CO}_2$  equivalent scenarios for the detached house in the period: 2060-2090 (see Table 4)

The results show a reduction of greenhouse gas emissions above 40% through the use of the combinations (Figure 4). The graphic illustrates that the use of passive measures in combination with an inefficient cooling system is more effective than using an efficient cooling system without using passive measures.

## Conclusions

This study analyzed the performance of three combinations of passive adaptation measures using dynamical thermal building simulations to adapt refurbishments to the changing climate. The following conclusions can be made out of this study:

(1) Today's refurbishments can be optimized by passive measures with little increased effort so that the buildings can be adapted to the changing climate. The use of passive measures makes it possible to significantly increase the thermal comfort of the inhabitants.

(2) The results showed that the additional demand for active cooling can be eliminated through the use of passive measures in the period 2030-2060. However, this demand cannot be completely prevented in the period 2060-2090. Still, for the examined residential building, the results showed a reduction of the cooling demand for this period by more than 50% in comparison to a refurbishment according to the current German law.

(3) As potential cooling demand could not be avoided in the period 2060-2090, two scenarios with machine cooling systems were investigated to evaluate the effectiveness of the passive measures. The application of passive measures in combination with an inefficient cooling system proved to be more effective than the application of an efficient cooling system without using passive measures. Therefore, a positive impact on both climate mitigation and climate adaptation could be achieved through the use of passive adaptation measures.

Today, as the refurbishment cycles of buildings average between 30 and 60 years (Nemeth, 2011), it is already necessary to implement passive adaptation measures in refurbishments. It was shown that the use of a sun protection system in combination with natural ventilation is sufficient to prevent the overheating problem in the period 2030-2060. In the period 2060-2090, the need for an automated window ventilation increases. This indicates that in today's refurbishments, the use of a shading system or a sun protection glazing for overheating protection is a priority. Other measures like the automated ventilation can be used for additional refurbishments in the future, to make the buildings more effective against the overheating problem due to climate change.

## Limitations and future work

This investigation is based on the prognosis of the climate scenario A1B from the REMO model. Since the probability of occurrence of alternative climatic scenarios is the same (IPCC, 2013), further examination of the alternative climatic scenarios would be necessary. This allows a more detailed and accurate assessment of the results in the light of uncertainties in the future climate.

Secondly, the present study only examined the German law (EnEV 2014) as the refurbishment standard investigated. A higher insulation standard such as the passive house should be assessed in future works as a proof of concept.

Thirdly, the investigations carried out are based on refurbishments of existing buildings. However, it must be borne in mind that the results of this study should also be investigated on new buildings because the requirements for the standard according to EnEV and DIN 4108-2:2013-02 are mandatory for new buildings in Germany. Therefore, the necessity of using

passive measures must also be taken into account in the planning process for new buildings. Additionally, other building types should be investigated in future works.

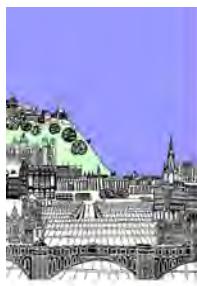

The use of green infrastructure (for example trees, green roofs, and green facades) provides shading of the open space and building walls (Zölch *et al.*, 2016). Accordingly, a simultaneous assessment of the building and the greening situation outdoors can be taken into account for further optimizations.

<sup>3</sup> École supérieure d'aménagement et de développement régional (ESAD), Laval University, Université Laval, Québec City, Canada;

**Abstract:** Urban practitioners can be key actors for climate change action through city development. However, adaptation and mitigation are insufficiently integrated in current design practices. The CapaCity research project hypothesize that this is partially due to lacks of knowledge-transfer. Its goal is therefore to develop a prototype design-aid tool for enhancing a project's adaptive character, with particular focus on practitioners-usability. The first phase included a series of consultations with professionals working in Toulouse (France) through a survey and two design workshops. The aim was to assess how they address climate change in a development project, and their use of tools in a design process. The results are presented here. Evaluation-tools were very little used. Moreover, the findings indicated that a solution-based design approach is common among practitioners, and that main sources of knowledge are initial education and professional experience. A design-aid tool should reflect design practices, and be an educational-tool to support practitioners' 'learning by doing'. The second part of the paper describes the structure of the suggested approach: a web application to guide practitioners following three common stages of an urban project (diagnostic, program, and design) recommending methods, adaptation solutions, and concrete examples relevant to users' specific projects.

**Keywords:** climate adaptation, practitioners, design, education, design-aid tool.

### Introduction

City life and its resulting greenhouse gas emissions (GHG) contribute greatly to climate change, but urbanization also holds solutions. One strategy is to introduce mitigation and adaptation measures through urban and building development (Gunawansa and Kua, 2014; Kleerekoper et al., 2012; Shaw et al., 2007; Smith et al., 2013; de Wilde and Coley, 2012). Urban designers and architects can be key actors to achieve this. However, studies indicate that climate change is insufficiently integrated in design practices. (Dubois, 2014). In part, because tools developed by research tends to fail to respond to designers' actual needs, and so remain little incorporated in design projects (Bierbaum et al., 2013; Dilling and Lemos, 2011; Harries and Penning-Rowsell, 2011; Horvat et al., 2011; McAndrews et al., 2013). According to Lemos and colleagues (2012: 789), what scientists see as useful information does not necessarily correspond with what professionals see as useful. Designers have a

particular way of knowing and problem-solving (Cross, 2006; Lawson, 2006a, 2007; Schön, 1983), which must to be addressed more adequately by the scientific community.

The research project CapaCity: from Concepts to Action for a Proactive Adaptation of Cities, seeks to address these and other disparities research-practice in order to fill the gap between the two. Its objective is to develop a prototype design-aid tool to support practitioners towards adaptive urban projects. For this tool to be understandable and usable for practitioners, gaining insights from design practices was important. In order to do so, a two-fold study was conducted in 2015. The objectives were to: i) assess current the knowledge among city and building professionals with regards to climate change adaptation, ii) examine how they consider, seek, and apply knowledge from different sources, and iii) observe a climate adaptive design process. The results from these enquiries guided the development of the prototype tool, which is currently being finalized. This paper presents main findings, and their implication for the suggested prototype tool.

### **Theoretical framework**

There are important gap between research and practice (Kirkeby, 2012; Lawson, 2013; Skogheim, 2008). As a result, studies have reported that research-based knowledge is little integrated in urban design processes, despite its proven necessity with regards to climate adaptation and mitigation (Tennøy, 2012). Research produces so-called context-independent knowledge, while design is strongly context-dependent (Kirkeby, 2012; Lawson, 2013; Skogheim, 2008). This can render research-based knowledge seemingly unapplicable in design projects. Practitioners tend to apply a solution-based approach to tackle design problems. The exploration of potential solutions produces a deeper understanding of the project at hand (Darde, 1979; Kirkeby, 2012; Lawson, 2006a), contributing to detect interdependencies between different aspects of a problem. This allows professionals to go beyond the client's brief, and to identify potential issues and challenges not addressed by the latter, in order to establish what the problem 'really is'. This is consistent with the notion of "setting and framing the problem" (Rittel and Webber, 1973; Schön, 1983). The designers' knowledge of solutions builds over time, through various academic, professional, and personal experiences. Own experience, and that of their colleagues, remain the prime source for information, however (Kirkeby, 2012; Skogheim, 2008; Tennøy, 2012), for instance precedents, references, and types of form (Cross, 2006; Schön, 1988). Whole or partial solutions, they are a straightforward and pragmatic way to link problems to solutions, and to accelerate thinking (Augustin and Coleman, 2012). The designers' reliance on rules of thumb to rapidly evaluate the performance of an idea is another manifestation of this solution-based knowledge (Lawson, 2006b).

In a longer perspective, a better understanding by the scientific community of designers' particular way of knowing (solution-focused, experience-based and context-dependent) could help bridge the gap between research and practice, and strengthen climate adaptation actions.

### **Method**

The first phase of the CapaCity-project focused on gaining an understanding of design practices, and the use of various tools, as well as information kinds and sources in a process. Therefore, a series of consultations with urban practitioners working in the Toulouse Region (France) were undertaken: an online survey and two design workshops.

### ***Online Questionnaire***

2660 email-invitations were sent to practitioners via three professional networks. The survey was composed of eleven questions, available through an online open source platform. 115 respondents anonymously completed the questionnaire, and the results were statistically processed. The first half provided an overall portrait of the respondents (age, sex, education, employment categories, professional experience, and typically project). The second half focused on: i) environmental issues considered in design projects, ii) data and tools employed in the design process, iii) qualities and shortcomings of existing design-aid tools.

### ***Design Workshops***

Design workshops were chosen as a method in order to observe how practitioners proceed when asked to design a neighbourhood adapted to the future climate of Toulouse. What do they actually know? What kind of information is sought? How and when are design-aid tools employed? Two workshops were held in May and in June 2015 at the Toulouse School of Architecture with eighteen urban practitioners from various educational and professional backgrounds, primarily architecture, planning, landscape architecture, and geography.

The workshops had two main parts: a one-hour session on adaptation in an urban context, followed by a two-hour design game where participants worked in multidisciplinary teams. A facilitator guided the game. The objective was to establish a proposal for an urban renewal project located in Toulouse, which had to be exemplary regarding climate change adaptation. The design brief specified 400 dwellings, 200 parking spaces, and one public place. The teams started with basic information about the project, and tools such as tracing paper and an aerial photo. Throughout the game they could access complementary data and resources using six playing cards. Three cards allowed consulting either “technical” or “technological” resources (e.g. simulation software). Three others offered a consultation with an expert (e.g. mobility or energy), or the client (a person from Toulouse Métropole). Unpredictable events could occur throughout as the facilitator had seven joker cards that would compel a team to integrate further climate adaptive objectives. Each team was filmed throughout the entire game. This was transcribed, and a content-analysis conducted focusing on: i) kinds of, and sources for, applied knowledge, ii) elements that influenced the process and/or shaped the design proposal, and iii) the nature of applied design solutions.

Design workshops come with methodological limits such as the relatively low number of participants (18), the short duration of the design game, and the challenge for participants to work on a project with new people from various disciplinary backgrounds and experiences. However, seen in light of the theoretical framework, the results provide satisfactory insights into design practices, and indications of practitioners’ actual needs, in order to nourish the development of a climate adaptive design-aid tool. Furthermore, during and after the workshop, participants underlined the parallels between the design game and an actual design process, thus confirming its relevance as an opportunity to observe them in action.

### **Consultation results**

The questionnaires and workshops provided a number of insights regarding architectural and urban design practices and processes, consistent with the literature review.

### ***First finding: sources of knowledge***

In the questionnaire, respondents were asked to range a list of tool-categories based on the occurrence of their use. Technical guidelines and standards for environmental quality (e.g. books, technical papers, websites) are ‘frequently’ consulted (60%). The majority of the respondents (92%) ‘not frequently’ or ‘never’ use numerical simulation tools (e.g. Pleïade-Combie, ArchiWIZARD, Ecotect, Dialux, IES). However, more than 50% stated to ‘frequently’ use *simplified* computation tools (e.g. Excel, rules of thumb, abacuses) in order to evaluate the performance of potential solutions. These results support previous studies on the topic (Dubois et al., 2015; Horvat et al., 2011).

During the workshops, the participants appeared to rely primarily on their own experience and education, or that of their fellow team-members, as source of knowledge. They were also more prone to choose direct, face-to-face access to knowledge (i.e. consulting experts), consistent with a study conducted by Kirkeby (2012). Indeed, despite the technical and technological resources available, all teams prioritized 10-minute discussions with the client and various experts. Computer tools on the other hand, were very little used, and if so, mainly to obtain information the experts could not provide. Interestingly, knowledge rooted in experience was primarily shared among the designers by referring to urban and architectural precedents and rules of thumb. This specific kind of knowledge aided several teams in imagining solutions for the future of Toulouse. One participant, for example, suggested the following idea based on a trip to Morocco: “They know in the Maghreb, how to deal with extreme heats: streets are deep and narrow, and canvas are sometimes stretched over public spaces to provide extra shade on the hottest days.” The most experienced participants were the main users of rules of thumb; a means to address operational issues, often allowing for a rapid estimation of the size of building blocks, streets, buildings, and parking.

### ***Second finding: a solution based approach***

During the workshops, all teams adopted a solution-based approach in order to address the complexity of designing a neighbourhood adapted to the future climate of Toulouse. As an example, when a team debated the possibility of comb-shaped buildings, the initial intention was to avoid long facades that would act as barriers with the surrounding neighbourhoods. By doing so, gables would be facing West and the main facade South. A second advantage was then identified with regards to integrating passive-design strategies. Consequently, some adjustments were made to the combs’ thickness in order to assure that each dwelling could be day-lit, cross-ventilated, and partly heated by the sun in the winter. This example illustrates the win-win, holistic nature of design solutions, and the practitioners’ overall holistic approach to the design problem. The latter seems rooted in a ‘global objective’ the designers appeared to have: improving the living context and the quality of the neighbourhood for its future inhabitants. On a more general level, often an underlying and often decisive argument for design choices (Gehl, 2010).

### **Discussion: A climate adaptation tool built on design practices**

The findings from the questionnaire and the workshops provide an outline of essential characteristics of the planned design-aid tool. First of all, the tool is modelled on the different phases of a typical design process: (1) Diagnostic, (2) Programming, and (3) Design. Its intended purpose is to support practitioners in designing climate adaptive projects, contributing to practitioners’ continued education by adapting to their ‘learning by doing’-

approach (i.e. through projects). Its use could enhance their understanding of how climate change will manifest in an urban context, and how their design can contribute to adaptation. Education also influences the practitioners' 'guiding principles' (Lawson, 1993). Composed of a practitioner's design principles, values, and beliefs, it is constructed throughout a professional career, and heavily influences design decisions. Therefore the proposed tool is will be a pedagogical tool, and could furthermore support e-learning and future training workshops. It will display different types of information to popularize scientific concepts. Moreover, Identifying urban and architectural precedents as well as relevant rules of thumb, is a promising way to facilitate integration of adaptive solutions into a design process. In this regard, the tool will also function as a adaptation-database, containing exemplary projects (e.g. eco-neighbourhoods), and concrete levers of action (e.g. "green roof", "albedo", "ecological corridor"). In a longer perspective, we imagine that the database could evolve with contributions from architects and urban planners to aid 'translating' the scientific knowledge to design practices.

Based on these main strategies, the prototype-tool is envisioned as an online application offering different levels of information regarding climate change adaptation. Over time it will offer an extensive database comprising exemplary urban and architectural precedents. This simple and solution-oriented information could be presented as: (A) Fact-sheets providing knowledge on environmental issues, and a questionnaire to guide an environmentally oriented site analysis; (B) "Solution sheets" providing in-depth information, including strengths and weaknesses of suggested solutions, and (C) "Project sheets" exhibiting detailed case studies. The following details the suggested approach for using the CapaCity-tool in a concrete design situation. Users can create an account to save their projects; an aid in constructing adaptation knowledge.

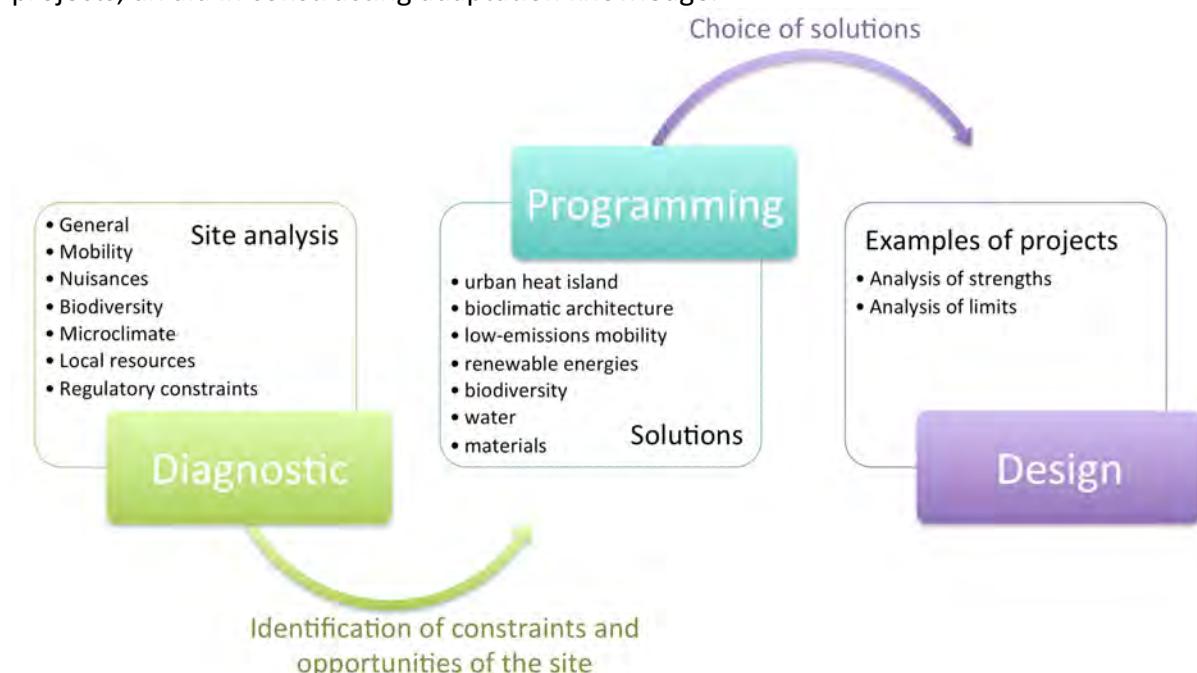

Figure 1. General structure of the CapaCity-tool

### **Component 1: Diagnostic**

In "Diagnostic" a first interface will allow the user to complete a questionnaire to conduct an environmentally-oriented site analysis in order to define an environmental

profile of a project. For each segment of the analysis, the user will be asked to answer a series of questions structured according to seven environmental themes. For the prototype these correspond to main adaptation challenges for the Toulouse-region. Each answer to the multiple-choice questions is associated with a coefficient. The sum of these provides an overall score for each of the seven environmental themes, thus defining a "proposed environmental profile". This profile will allow to identify adaptation constraints and opportunities of the site, and to select the main environmental themes to be treated in priority in the programming phase (see Table 1). Text, external links, and pictures accompany the questions, a means to enable the user to better understand an environmental theme, which data to be collected, and possible tools to deepen the environmental site analysis.

Environmental themes in the prototype tool						
Constraints due to the urban heat island	Opportunities to implement bioclimatic architecture	Opportunities to implement low-emissions mobility	Constraints to preserve biodiversity	Opportunities to implement renewable energies	Constraints due to water management on site	Opportunities to implement local materials

Table 1. The environmental themes the most important for climate adaptation in the Toulouse-region

At the end of the Diagnostic, the environmental profile of the project is displayed. The environmental themes will be ranked according to their scores into three categories: High Priority, Medium Priority, and Low Priority. The users will be able to modify this ranking, for instance according to particular client requirements, in order to define a final "environmental profile of the user" to be used in the "Programming".

### ***Programming***

For "Programming" the tool offers a series of "High Priority" environmental issues based on the profile. However, users can consult the totality of the database topics. Here the environmental issues of the tool will be presented as "Solution sheets", enabling the user to understand potential physical processes involved in the issues, and mechanisms that can be used to adapt a neighbourhood to climate change (e.g. "green roof", "albedo", "ecological corridor"). The user will be able to select "Solution sheets" in relation to the environmental profile of the project. When doing so, the tool will alert the user to possible interactions and interdependencies among the solutions that should be taken in to consideration.

### ***Design***

In "Design" exemplary projects where solutions selected in the previous steps are implemented are displayed. These will be exemplary urban projects, analysed as much with regards to their short-comings as to their strengths. In addition to the analysis (texts and pictures), these "Project sheets" will contain tags with a score between 0 and 3 to identify the implementation of different solutions. This allows assigning each project with a note corresponding to the suitability of the example project with the user's project and potential solutions selected in section 2. Projects with the highest scores will appear first in the list.

## **Conclusion**

The results of the first phase of the CapaCity-project drew attention to the need for research to gain a deeper understanding of designers' particular way of knowing and acting when tackling complex problems such as climate adaptation. Establishing a constructive dialogue between research and practice is necessary to better integrate expert knowledge in the design process. It could also provide researchers with a better vocabulary to translate climate change to the urban context. Due to the relatively small number of survey respondents and design workshops participants, the use of the reported results should be done with caution. However, they provide good indications of designers' needs and tendencies. The findings suggest that practitioners are concerned with climate-related issues. Their knowledge of solutions is rooted in their experience and education. Workshop participants extensively referred to urban and architectural precedents, as well as rules of thumbs, in order to develop their design schemes. At the opposite, they barely consulted any of the technical and technological resources available during the design game. Survey respondents reported to disregard tools they perceive as complex, time-consuming, costly, or that pose problems of incompatibility and interoperability. A determining influence of design constraints and guiding principles on a projects' resolution was also observed.

These results allowed identifying strategies to be implemented in the climate adaptation design-aid tool prototype, in order to meet the specific needs of urban designers and architects. The suggested tool reflects the solution-based design process, but also strive to be an educational tool. The application will guide the users following three stages of an urban project (diagnostic, programming and design), suggesting methods, solutions, and examples relevant to their specific projects. The tool is primarily intended for urban design and architecture professionals, but also for students in these fields. The tool is currently being finalized. The first component, "Diagnostic", was recently tested with a group of seven professionals and students within architecture, applying it for an environmental site analysis of a specific neighbourhood in Toulouse. All participants expressed an interest for this segment of the tool. They appreciated the design time saved with the "Diagnostic"-part, and the provided information about environmental site analyses.

The long-term goal of CapaCity is to develop a tool that is truly usable for urban practitioners, and supporting them in engaging further in climate adaptation. Thus strengthening a city's contribution to meeting the consequences of climate change.

## **Spatial Analysis on Intra-Urban Temperature Variation under Extreme Hot Weather by Incorporating Urban Planning and Environmental Parameters: A pilot study from Hong Kong**

**Meng Cai<sup>1</sup>, Chao Ren<sup>1, 2, 3</sup>, Kevin Ka-Lun Lau<sup>1, 3, 4</sup> and Yong Xu<sup>1</sup>**

<sup>1</sup>Institute of Future Cities, The Chinese University of Hong Kong, Hong Kong

<sup>2</sup>School of Architecture, The Chinese University of Hong Kong, Hong Kong

<sup>3</sup>Institute of Energy, Environment and Sustainability, The Chinese University of Hong Kong, Hong Kong

<sup>4</sup>Institute of Aging, The Chinese University of Hong Kong, Hong Kong

**Abstract:** The number of extreme hot weather events have raised significantly in Hong Kong. Due to urban heat island effect, urban thermal environment of Hong Kong has been deteriorated. However, there is limited spatial understanding of intra-urban temperature variation under extreme hot weather conditions and climate-sensitive design for reducing heat load in severe heat events. Thus, there is a need to analyse the spatial distribution of intra-urban temperature variation of extreme hot weather and the impact of urban environment parameters on intra-urban temperature differences. In this paper, firstly, hourly air temperature records from 40 Hong Kong Observatory stations from 2011 to 2015 were collected to analysis hot night and very hot day. Secondly, for spatially mapping the very hot days and hot nights, kriging, a geostatistical interpolation algorithm, was adopted. Thirdly, urban environmental parameters (digital elevation model information, sky view factor and the NDVI) were incorporated in co-kriging interpolation for a more comprehensive understanding of the correlation of extreme hot weather and their spatial patterns. The generated maps of very hot day and hot night can provide better understanding of intra-urban temperature differences under extreme hot weather events and help to create climate-sensitive design strategies to cope with climate change locally.

**Keywords:** extreme hot weather, intra-urban temperature variation, climate-sensitive design, high density city, climate change

### **Introduction**

There is a growing number of heat waves since the end of the twentieth century and this growing trend will continue throughout the 21th century(IPCC, 2014). Hong Kong has more frequent extreme weather events such as very hot days and hot nights since its urbanization started in the 1960s(HKO, 2015). Urban thermal environment of Hong Kong has been deteriorated due to urban heat island effect. It's reported that Increase in 1 °C in hot days was associated with 6.82% increase in deaths in Hong Kong(Fung, 2004). As the number and duration of extreme heat events are likely to increase with climate change, it is important to obtain a more comprehensive understanding of extreme hot weather in urban environment. The conditions of extreme hot weather are generally based on the meteorological data acquired at ground-level meteorological stations(WMO& WHO, 2010). However, there is insufficient information on the spatial distribution of intra-urban temperature difference variations due to the limited coverage of the stations(WHO/Europe, 2004; WMO& WHO,

2010). Moreover, the problem is aggravated with the limited knowledge of the effect of urban environment on extreme hot weather and appropriate urban planning and design in the context of adapting and mitigating the extreme heat events. Therefore, there is an urgent need for better understanding of the spatial variation of extreme hot weather for more climate-responsive urban planning and design and hence more sustainable urban living.

This study aims to obtain a comprehensive understanding of spatial variation of intra-urban differences in temperature under extreme hot weather using spatial interpolation techniques. The understanding of the intra-urban temperature variation under extreme hot weather can help policy makers and urban planners to have a better understanding on the spatial distribution of the extreme hot weather, thus taking effective and targeted action for the most vulnerable areas. Also, the urban environment characteristics can contribute to the urban planning and building design for the resilience and adaption strategies of Hong Kong, therefore reducing the adverse impact of heatwaves at present and under climate change.

## **Materials and Methodology**

### ***Study Area***

Hong Kong ( $22^{\circ} 16' 50''$  N,  $114^{\circ} 10' 20''$  E), located on the southeast coast of China, has total area of about 1104 square kilometres covering Hong Kong Island, Kowloon and the New Territories and Islands. The terrain of Hong Kong is mountainous with steep slopes, where the elevation ranges from sea level to over 900m above sea level(Morton, 1995).

Hong Kong has monsoon-influenced subtropical climate, experiencing very hot weather in summer. Air temperatures typically reach  $33^{\circ}\text{C}$  on the hottest summer days, cooling to  $26^{\circ}\text{C}$  in urban and  $24^{\circ}\text{C}$  in rural areas at night(Nichol et al., 2012). On one hand, the temperature is continuously growing. The annual mean temperature increased  $0.12^{\circ}\text{C}$  per decade from 1885 to 2015 in average. The rate of increase in average temperature reached  $0.17^{\circ}\text{C}$  per decade during 1986-2015(HKO, 2015). On the other hand, there are more frequent occurrence of the extreme hot weather in Hong Kong. The annual count of hot nights and very hot days has increased significantly, by 19 and 10 respectively from 1885 to 2015(HKO, 2015). Moreover, extreme temperature in Hong Kong further suggests that the number of extreme hot weather is expected to increase significantly in the 21th century (HKO, 2015).

### ***Data***

Hourly air temperature data from 40 air temperature stations of the Hong Kong Observatory in June, July, and August (the months defined as summer in Hong Kong) were used for mapping out the intra-urban temperature variation under extreme hot weather. The 40 stations can represent both city and rural environments of Hong Kong (Figure 1). The years 2011-2015 were selected for this study because the past five years have more extreme hot records and most complete database of temperature recordings available for Hong Kong. And also this is a pilot study. Later the findings will be applied to a case study with a longer study period.

Based on the findings of Hong Kong Urban Climatic Map project, urban morphology parameters include digital elevation model (DEM) information, sky view factor (SVF) and the normalized difference vegetation index (NDVI) were selected to capture and describe urban geographical and morphological characteristic(Ng et al., 2015; Ng et al., 2012; Ren et al., 2011). The intra-urban distribution of the temperature excess is largely dependent on local surface characteristics and previous studies have identified a link between these parameters and air temperature(Unger, 2008). Air temperature generally decreases with elevation and air

temperature is often lower with higher altitude(HKO, 2017). SVF is important for the spatial variation of air temperature within the urban environment(Maru et al., 2015). Temperature studies in Hong Kong showed that places with higher greenery coverage often have lower maximum temperature than that with lower greenery coverage, in particular in summer(HKO, 2017).

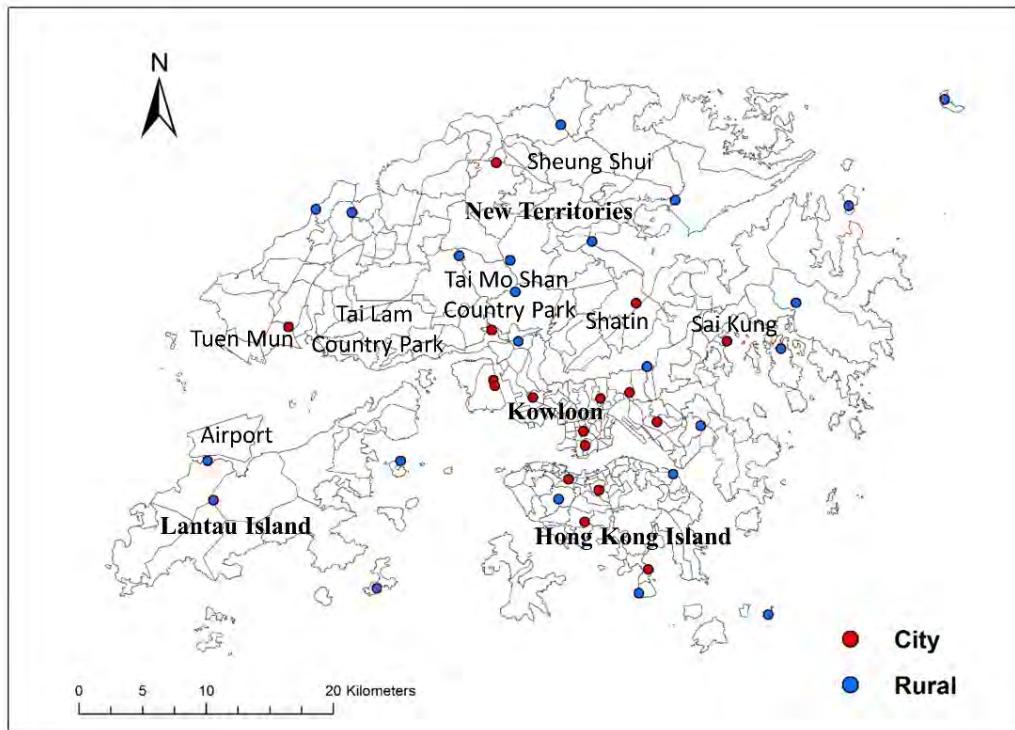

Figure 1. Distribution of the HKO stations.

Table 1. Urban Morphology Parameters.

parameter	resolution	year
SVF	1km	2009
DEM	1km	2009
NDVI	1km	2016

### Kriging Analysis

In order to represent different levels of extreme hot weather, temperature classes defined by HKO were used (HKO, 2015). The classes are defined as hot nights (days with a minimum temperature of 28°C or above) and very hot days (days with a maximum temperature of 33°C or above). However, the existing definition of extreme hot weather in Hong Kong is inadequate in days with many hot hours but the minimum temperature less than 28° C. It cannot be classified as a hot night according to the HKO definition but it may still have high potential of heat hazard. In order to represent the heat hazard in a more objective and comprehensive way, the cumulative hours above 28° C and 33°C thresholds are chosen as measure for hot nights and very hot day.

First, the annual mean hot night hours and very hot day hours of each station over the ten years were counted based on the observatory data. The selected hazard measures at each site were plotted as point values in GIS. Second, a geostatistical interpolation algorithm, called kriging, was applied to map the very hot days and hot nights. The kriging interpolation

expresses the spatial variation of the property in terms of the variogram, and minimizes the prediction errors which are themselves estimated(Oliver, 1990).

In addition, urban morphology parameters such as the SVF, NDVI and DEM also have influence on the spatial pattern of extreme hot weather. These factors were also involved in the interpolation process by co-kriging to gain a more comprehensive understanding of the correlation of hot weather and spatial patterns.

## **Result and Analysis**

### ***Very Hot Day and Hot Night between City and Rural Stations***

According to the statistical results of the extreme hot weather under city and rural stations, it can be observed that city stations have higher mean, median very hot day hours and hot night hours than rural stations, indicating significant urban heat island (UHI) effect in Hong Kong and urban areas are more vulnerable to heat hazards(Landsberg, 1981; Oke, 1982, 2002). In addition, hot night hours have larger range and values than very hot day hours thus there are more extreme heat events during night time.

Table 2. Statistical results of the extreme hot weather between city and rural stations.

Hot weather indicator	City station	Rural station
Average very hot day hours	62.4	49.5
Median very hot day hours	48.1	37
Range of very hot day hours	11-190.6	0-149.8
Average hot night hours	527.8	223.8
Median hot night hours	533.6	202.8
Range of hot night hours	113.6-693.6	0-485

### ***Spatial distribution of very hot day***

The spatial distribution of the very hot days and hot nights was mapped and the potentially hot areas in Hong Kong identified by using kriging and co-kriging method (Figure 2&3). The most frequent very hot day hours occur in the north of the New Territories where most are rural areas according to the kriging mapping results. The number of very hot days is predominantly high in rural areas due to the more open settings without high-rise buildings or high mountains where there is better air ventilation and less sky obstruction, leading to persistently high temperature. More frequent very hot day hours are also identified in urban areas in Kowloon and the western Hong Kong Island. There are few very hot day hours in Lantau Island, Tai Mo Shan Country Park and the rest of the Hong Kong Island.

The DEM information helps differentiating very hot day hours in the mountainous areas such as Lantau Island, Hong Kong Island and Tai Mo Shan Country Park. The mapping results are similar with the kriging mapping result after incorporating NDVI and SVF. However, more very hot day hours are detected in the west of the New Territories with relatively little vegetation coverage.

The results delineate more detailed spatial distribution of the extreme heat events after incorporating all the three urban environmental factors in the interpolation process. The high frequency of very hot day hours in the northern New Territories are more scattered than that of the original kriging mapping. Also, very hot day hours are also detected in Shatin, airport in the Lantau Island, which is not represented by the previous results. In addition, very hot day hours in Tai Lam Country Park are characterized as low by taking elevation into account.

In particular, the lowest very hot day hours are located in the peak of the Tai Mo Shan Country Park which is the highest place in Hong Kong.

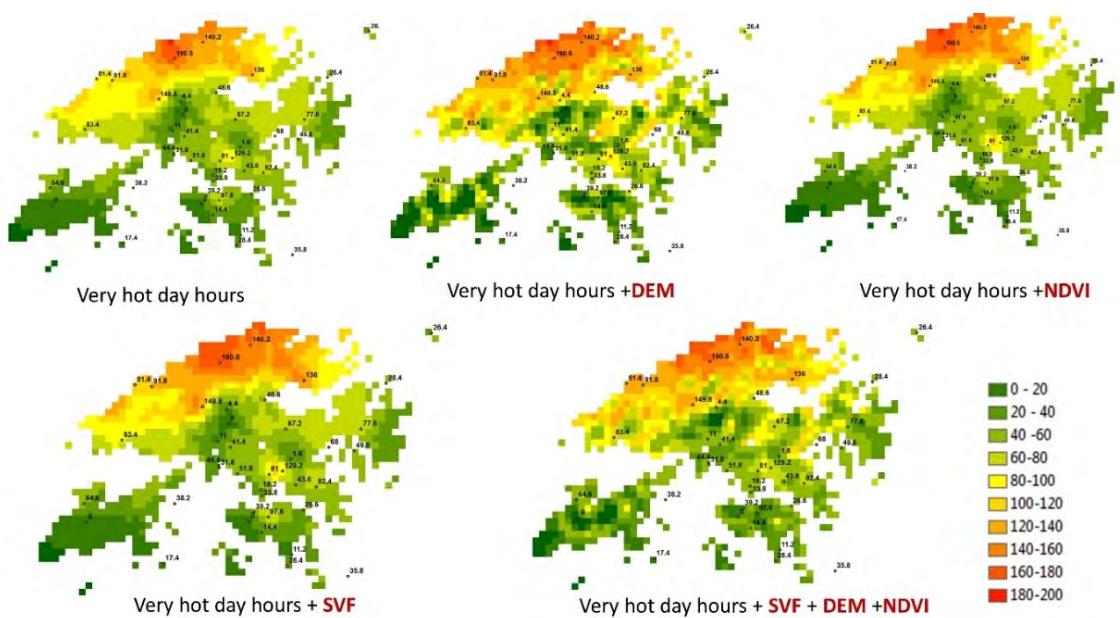

Figure 2. Mapping results of annual average very hot day hours (2011-2015).

### ***Spatial distribution of hot night hours***

High hot night hours occur most frequently in urban areas such as Kowloon and Hong Kong Island while low hot night hours are located in the rural areas in Hong Kong. Dense development with tall buildings can affect the solar radiation, reduce wind speed and slow down night time cooling rate in the urban area, leading to generally higher night time temperature in urban areas when compared with rural stations(HKO, 2010). Also, the counts of hot nights are much greater than that of very hot day which indicates that night time extreme heat events are more frequent and severe than daytime extreme heat events.

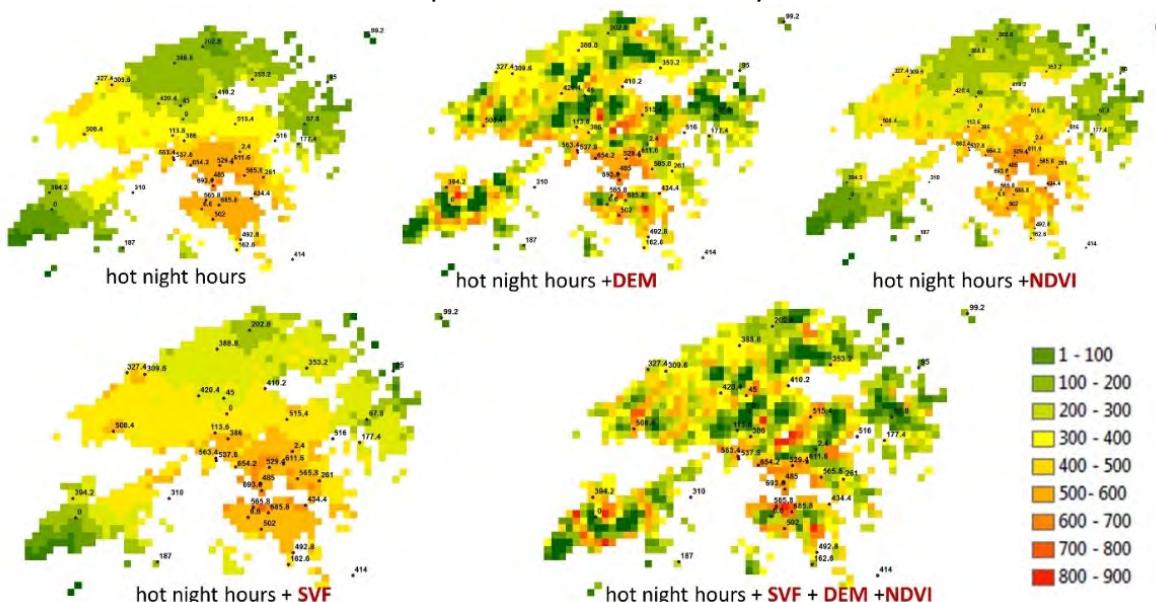

Figure 3. Mapping results of annual average hot night hours (2011-2015).

The range of hot night hours has been significantly increased after co-kriging using DEM information. Lowest values of very hot day hours have been detected in high-altitude locations such as Lantau Island and Tai Mo Shan Country Park due to their high environmental lapse rate. NDVI helps characterize hot night hour variation more detailed according to different greenery coverage. SVF increased the value of hot night hours in the whole New Territories in comparison with the original kriging mapping. Larger areas in urban areas such as Kowloon, Hong Kong Island and Shatin district are characterized as high very hot day hours by taking the three parameters into account. The co-kriging method also captured hot night hours in the west of the New Territories. The result is similar with the co-kriging mapping using DEM, demonstrating that DEM may have dominant impact on the spatial distribution of the extreme heat events in comparison of the other two parameters.

## **Conclusion**

This study mapped the intra-urban temperature variation under extreme hot weather by incorporating DEM, SVF and NDVI based on the annual average very hot day hours and hot night hours from 40 weather stations in Hong Kong. It's found that urban stations have more frequent extreme hot weather than rural areas, indicating significant UHI effect in Hong Kong. In addition, there are more extreme heat events during night time in Hong Kong. Moreover, the north of the New Territories has more daytime extreme hot weather while urban areas in Kowloon and Hong Kong Island have more extreme heat events during night time. Finally, the co-kriging mapping incorporating all the three parameters delineates the spatial distribution of the intra-urban temperature under extreme hot weather in a more detailed and reasonable way.

Findings of the present paper contribute to a better understanding of the spatial variation of extreme hot weather in high-density urban environment. It also provides local-scale information for the selection of representative meteorological stations for heat wave warning system which the World Meteorological Organization and the World Health Organization jointly call for actions by the governments.

In future, we will interpolate average, minimum and maximum air temperature to further analyse the spatial pattern of extreme hot weather and map hourly average air temperature to understand the temporal variations of extreme heat events. We also plan to determine a more appropriate heatwave threshold, to select alternative index for the kriging interpolation (Glenn et al., 2017) and as well as to link the mapping result with heat-related mortality in Hong Kong for future enhancement of local heat health risk studies, thus ensuring a healthy urban living for local citizens.

## Green Roofs in Cuban Housing. Types, Evaluation and Proposals

Dania González Couret<sup>1</sup> and Luis Guillermo Pérez González<sup>2</sup>

<sup>1</sup> Faculty of Architecture, Technological University of Havana, Cuba,  
daniagcouret@gmail.com;

<sup>2</sup> DCH, Havana, Cuba, luisguillermo@dch.ch.gob.cu

**Abstract:** Green roofs are a good alternative to mitigate and to revert climate change, reducing heat island effect and improving urban resilience. However, green roofs are traditional in vernacular cool weather architecture, but not in warm humid regions. Cubans aborigines' architecture and communities were made of natural (dry) fibers, with low heat transmittance, and very permeable to wind, and even, colonial Mediterranean architecture and urbanism were not characterized by the presence of green roofs. Green roofs arrived in Cuba with modern architecture during the second half of the 20th Century, following one of the five principles: The roof garden. Nevertheless, they proliferated from the 90's, as a result to the economic crisis, as a way to provide food in urban agriculture. Taking into account these antecedents, the paper presents the results of a research work focused on evaluating several of possible alternatives of green roofs for Cuban housing, in order to propose recommendations for their use, taking into account a cost – benefit analysis. Results show that the three studied green roof types are feasible to be used in Cuban housing, what is not only possible, but convenient, since their benefits, including the reduction of maintenance costs, compensate the slight execution extra-costs.

**Keywords:** Green Roof, Housing, Cost-benefit analysis, Warm – humid climates, Cuba.

### Introduction

Green roofs importance is increasing because of their contribution to reduce global warming and to reverse climate change, since they absorb CO<sub>2</sub> and produce O<sub>2</sub>. They also diminish the effect of the heat urban island and partially retain rainwater, decreasing the flooding risk.

However, green roofs are not traditional in Cuba, despite some existing examples in good conditions while buildings are near the end of their useful life. On the other hand, as part of the urban agriculture experience, people themselves have created ways to plant in yards, terraces and roofs by different modalities.

Because of that, it is possible to think that green roofs may constitute a viable alternative to be applied in Cuba, but other classifications should be proposed to include local Cuban experiences, and their climatic behavior in warm and humid climate have to be verified. Green roof types appropriate to housing in Cuban conditions are evaluated in the present paper.

### Materials and Methods

The research has been carried out in three steps, and diverse particular methods have been used in each of them. In the first step, information was collected, processed and discussed in order to identify variables, parameters and indicators as basis for classification and evaluation

of green roofs. Historic – logic method was also used to evaluate the evolution of the study object.

Second step is referred to green roofs in Cuba, in which theoretical research methods were also used, complemented by empirical ones, such as field work, observation, measurement, calculation and design. For that, green roof identified in Havana were visited, and experts in urban agriculture were interviewed. From the collected information, three theoretical green roof models were designed, in order to quantify their indicators to be compared to a conventional roof.

In the third step, the impact of some green roof types on the interior thermal environment was verified by an experimental research in which temperature and humidity in real cases were measured. All the collected and calculated data were integrated in a cost – benefit analysis of green roofs in Cuba, based on a qualitative – quantitative – comparative evaluation, to get to conclusions respect to the more appropriate solutions.

### **Green Roofs. Theoretical Framework**

Planting vegetation directly over the building roofs is a common practice since ancient times (Vijayaraghavan, 2016). Continue use in roofs of soil and vegetation since ancestral times, mainly in cool weather, is also recognized (Minke, 2004), in order to get thermal isolation by thermal mass (soil and vegetation) avoiding heat lost during winter.

According to Minke (2004, pp.7), in cool climates, green roofs “heat”, since they storage heat from indoor environments, and in hot climates, they “cool” since they keep indoor spaces isolated from exterior high temperatures. For him, vegetation and soil use to moderate temperature variations, and gained heat is not only storage but absorbed.

During the first half of the twenty century, with the so called “five points of the modern architecture”, the aesthetic intention of green roof is reinforced. According to Vijayaraghavan (2016), the current trend of green roofs started in Germany during the 60's. From the late twenty century, and as result of the ecological crisis, they were considered as a good way to recover the green lost as a consequence of the construction.

### ***Basis for the Cost – Benefit Analysis***

Among the more common benefit of green roofs considered in the cost – benefit analysis, is the absorption of CO<sub>2</sub> and pollution reduction by vegetation, (Borzog Chenani et al., 2015), which depends on vegetation type, roof orientation and wind behavior (Vijayaraghavan, 2016), as well as reduction of air temperature near to the roof, which may reach 1°C at night in Singapore, when the intensity of the heat urban island is higher (Li y Norford, 2016).

Another advantage reported by green roofs is noise isolation, depending on the substrate composition and thickness, as well as vegetation type and density (Connelly M y Hodgson M, 2015). However, this benefit is not significant for housing in Cuba, because of the need of permeable spaces for ventilation that make difficult to avoid noise penetration. They also have a great capacity to retain part of the rain water, diminishing flooding risk.

Food production is a benefit not related by the international literature about green roofs, probably because it is not possible in extensive solutions that are more frequent at global scale. However, productive function has been essential in contemporary Cuban green roofs, but in other different types.

Besides that, green roofs preserve impermeable layer systems from mechanical damages or chemical decomposition or biological processes, and improve their durability,

avoiding their exposition to temperature changes. On the other hand, a roof garden offers a good protection against fire (Minke, 2004).

Each green roof, despite the type, generates additional costs respect to a conventional one, due to the structural over load, needed execution materials or components, and required maintenance during the exploitation step. Costs depend on technology and roof type, but also on the location.

Maintenance of green roof doesn't need investment or specialized labor, so, it doesn't generate additional costs. Ecological solutions with permaculture techniques (Cruz, Sánchez and Cabrera, 2006) may use rainwater supplied by gravity and organic fertilizers, without additional costs. Then, it is possible to consider null maintenance costs in green roofs, with additional benefits respect to the conventional ones, increasing durability of impermeable systems (Pérez González and González Couret, 2016).

### ***Influence on Thermal Indoor Environment***

Respect to the favorable influence on indoor thermal environment under the green roof, results of a study carried out by Yang et al (2015) for a sub-tropical climate in China, evidenced an energy reduction of 4 kWh and 5 kWh per day in rooms with extensive green roof and substrate thickness of 20 cm and 10 cm respectively, related to an exposed roof. Razzaghmanesh et al (2016) said that Green roofs reduce temperature during day, but they may increase it by night, because of the thermal lag, which is not desirable in warm – humid climates as Cuban one, where temperatures are high during day and night.

On the other hand, Nichau et al., cited by Li and Norford (2016), demonstrated that the thermal isolation effect of a Green roof in winter is more significant than the cooling effect due to the water evaporation during summer. For those authors, a worrying respect to using vegetation above roofs in humid tropical zones is related to the increment of relative humidity, affecting the thermo-physiologic human comfort. In the same way, Razzaghmanesh et al. (2016), affirm that reducing temperature by vegetation is less effective when relative humidity is high.

Taking into account the exposed arguments, it is possible to conclude that green roofs are more effective to isolate interior spaces from outdoors in cool regions, while they may not be so effective to cool in warm climates, mainly, when relative humidity is high. Because of that, Vijayaraghavan (2016) recognize that thermal benefits of green roofs continue under discussion. However, it is referred to green directly related to roof, but Cuban repertory shows the existence of other modalities not considered by the international literature, where vegetation is not directly in contact to the roof, and then there is no thermal inertia but shading.

### **Green Roofs in Cuba**

Green roofs have never been a tradition in Cuba, since in the Cuban warm and humid climate thermal mass is not convenient. On the contrary, roofs should not store heat during day to be transmitted to indoors at night, when temperatures are high, for what shading or double roofs, preferably ventilated with low absorptivity external surfaces are required (González Couret, 2010).

Aborigine architecture before colonization was built by natural dry fibers, low transmittance and inertia, which envelope didn't heat and housing was permeable and ventilated. On the contrary, urban architecture later developed by the Spanish colonizers, followed the Mediterranean model: common thick walls, relative small windows and

courtyard. Differently from the original referential architecture in the dry Mediterranean climate, courtyard in the colonial Cuban architecture is full of vegetation in the warm – humid climate (González Couret, 2010). Then, in colonial cities, vegetation don't appear on the streets or roofs, but in yards.

In some over wall urbanizations as El Vedado, common walls and courtyard were lost, and vegetation appeared on gardens and streets, but normally not in roofs (González Couret, 2010). According to the research carried out, the first green roofs found in Havana correspond to the period of modern architecture of the 50's, and then, it is associated to the roof garden promoted by Le Corbusier and his five points. In a general way, these roofs could be seen from surrounding high buildings, and then, their function were more aesthetical than thermal or productive. Detected examples con intensive or extensive green roofs.

A continuity of this tradition is observed in some buildings during the early 60's. However, when these examples are referred as important exponents of modern architecture, green roofs are not mentioned (Rodriguez 2011). During the 70's, green roofs are not associate to urban buildings but to great city parks, which intention was integration to nature.

The presence of vegetation in roofs reappear in Cuba during the 90's, but because of different reasons and with other modalities. As a consequence of the necessity to produce food at the local scale generated by the economic crisis and supported by the Urban Agriculture Movement, diverse new modalities of green roofs in housing have been developed, simple and easy to execute.

Despite people also execute green roof with the substrate directly related to the roof, mainly to produce food, in a general way, there are solutions developed by self-construction (Sánchez Medina, s/f), which, on the contrary of the already mentioned, vegetation is separated from the roof, in containers or as a double roof. Those are increasing in Cuba, popularized with additional objectives, such as shading, ventilation and structural cooling to diminish indoor high temperatures during day and night during the whole year. It is due to their simplicity and economy.

### **Proposed Classification**

According to international literature, Green roofs are composed by a system of elements conforming horizontal layers installed directly over the building roofs, which could be classified as intensive and extensive (Borzog Chenani, 2015) (Connelly and Hodgson, 2015) (Li and Norford, 2016) (Minke, 2004) (Razzaghmanesh et al. 2016) (Vijayaraghavan, 2016) (Yang et al. 2015).

Independently of that, the study of Cuban repertory demands a new classification. A possible way of classification could be according to the main function. However, the most important proposal is based on the relationship between the substrate and the roof: separate or integrated (extensive or intensive). When vegetation is not directly related to the roof surface, it is in containers or planted on the ground, forming a double roof above.

### **Thermal Behaviour**

The influence of green roofs on indoor environment is an important benefit to be considered, but there have not been found precedent researches allowing to precise their impact in a warm and humid climate as Cuban one. Because of that and taking into account the possible influence of green roofs in energy and exploitation costs during the building useful life, an experimental research was carried out to measure air temperature in real case study.

For that, two green roofs types were selected: separated (double roofs) and integrated (extensive). Measurements were also taken in a common roof finished by ceramic tiles and exposed to direct solar radiation.

#### ***Case Study: Exposed Roof and Green Double Roof***

To develop the experiment, two bathrooms were taken as case study, located in housing buildings in the same block and with similar orientation, separated approximately 50 Km in New Vedado. The selected spaces have the same dimensions, windows area and function (bathroom). Roof is made of concrete 16 – 19 cm width and finished by with ceramic tiles.

Measurements were taken by data loggers HOBO locates 1m below the roof, simultaneously to other equipment located outdoors inside a wooden and ventilated cabin, protected from sun by vegetation, programmed to register values each one hour, during three days in August, 2016.

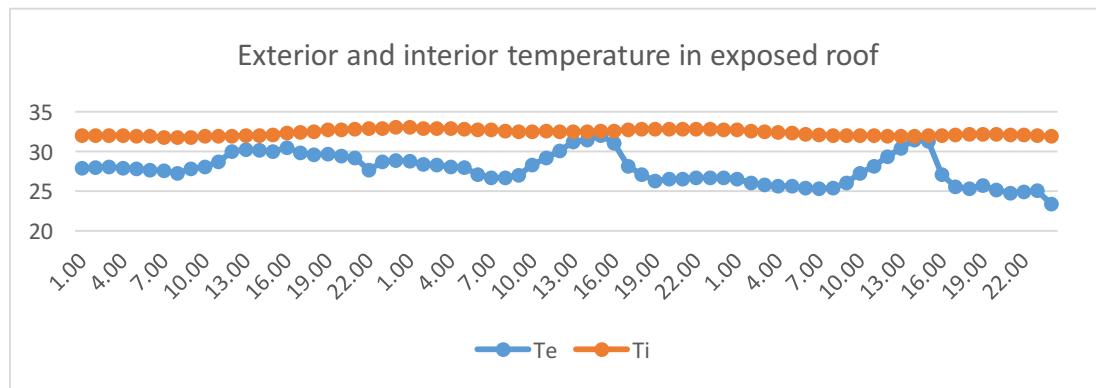

Figure 1: Indoor and outdoor temperature under the exposed roof.

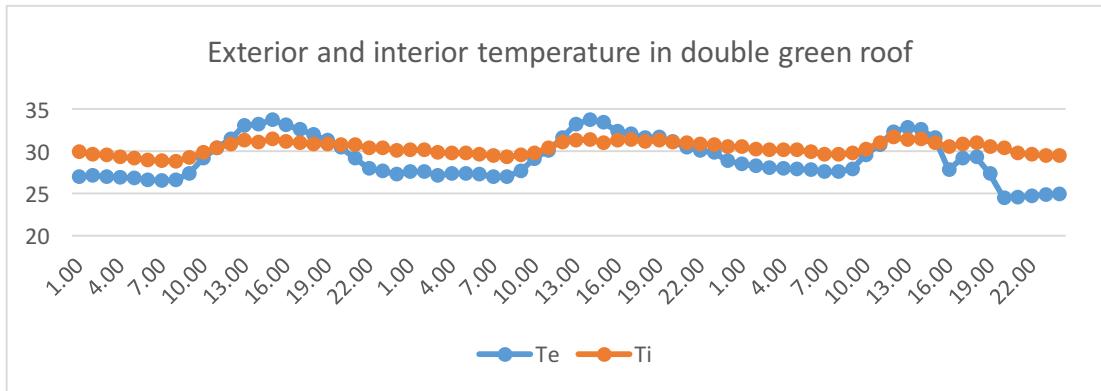

Figure 2: Indoor and outdoor temperature under the double green roof.

The interior space below green roof kept always cooler respect to outdoors (Figure 1) than the one below the exposed roof, with differences up to over 6°C (Figure 2). Major temperature differences are produced during afternoon and night, when families stay at home and people are sleeping. It demonstrate the thermal advantages of this type of green roof in the warm and humid Cuban climatic conditions.

#### ***Case Study: Extensive Green Roof***

It was very difficult to find an extensive green roof to make the experiment, because they are scarce, located far from the city, sometimes abandoned, and even some of them are being deconstructing. It was possible to coordinate to carry out measurements in a

bathroom of a Pavilion in the National Botanic Garden, half undergrounded, with an extensive green roof partially shaded by surrounded trees.

Measurements were made a similar way than the former cases, placing the data logger 1m below the roof, and taking data simultaneously to another equipment located inside a wooden and ventilated cabin under a tree, programmed to measure each 1 hour during 3 days in October 2016. However, they were rainy days with constant outdoor temperatures below 25°C and high relative humidity (between 75% and 98%). Nevertheless, high inertia in this green roof types is demonstrate, despite the additional effect of being half undergrounded (Figure 3).

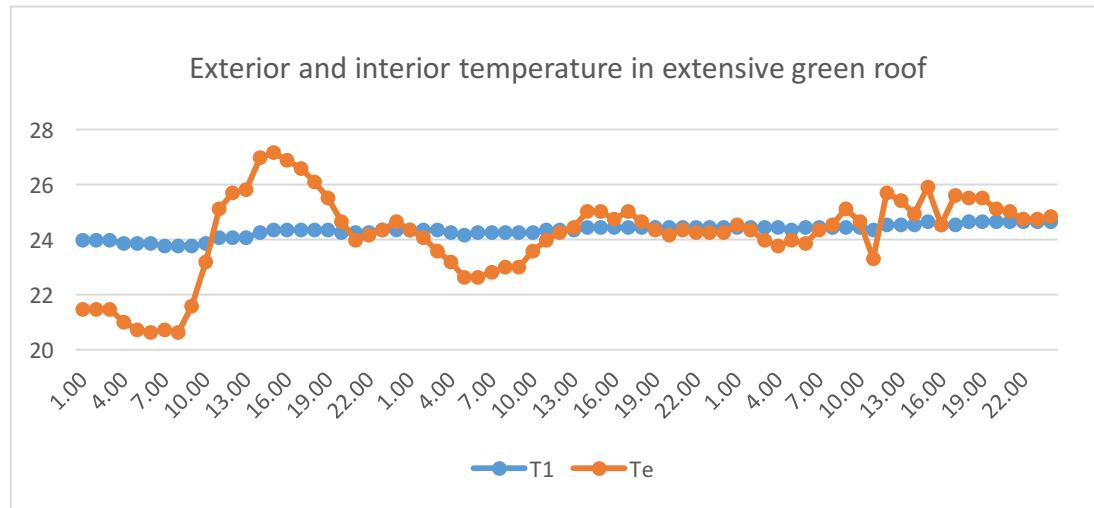

Figure 3: Indoor and outdoor temperature under the extensive green roof.

### Thermal Comfort Evaluation

Both green roofs are more favorable than the exposed roofs. However, the extensive one shows a higher thermal inertia provoking a difference of more than 2°C to outdoors at night respect to the one with double roof, but in the afternoon there is a contrary effect (Figure 4).

By plotting the combination of the extreme temperature and relative humidity conditions indoors in the Givoni's Bioclimatic Chart (Givoni, 1998), it is possible to observe that indoor environmental conditions under the exposed roof are out of the comfort zone, including the one in which is possible to improve them by ventilation. However, in the space under the green double roof (measured during the same season), thermal conditions are better, being even possible to achieve comfort by ventilation (Figure 5).

On the other hand, indoor environment under the extensive green roof in the Botanical Garden, measured during rainy days in October, shows more favorable temperatures, being possible to achieve comfort even without ventilation, despite the high relative humidity.

### Cost – Benefit Analysis

Benefits of each of the selected green roof types have been estimated based on information from international literature and national experts. They have been evaluated in a qualitative way based on quantifying the needed resources, taking into account the generic theoretical models elaborated. A double green roof costs \$3.75 extra per m<sup>2</sup> respect to a common roof, while an extensive one requires an additional investment of \$18.00 per m<sup>2</sup>, which means more than a double of the exposed roof cost. However, integral qualitative evaluation indicates that benefits compensate extra costs, despite extensive roof is the most

expensive. Then, results show that the three studied green roof types are feasible to be used in Cuban housing, what is not only possible, but convenient (Pérez González y González Courret, 2016).

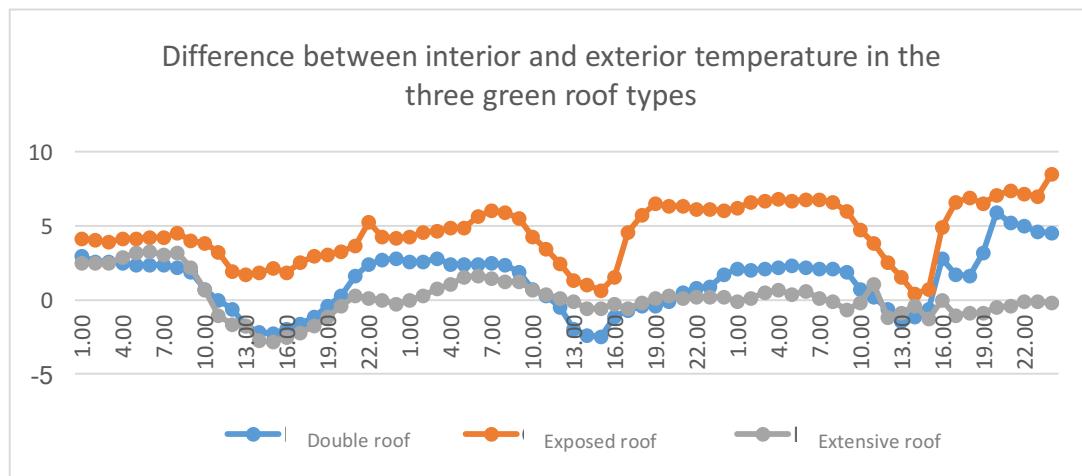

Figure 4: Difference between indoor and outdoor temperature in the three green roof type studied

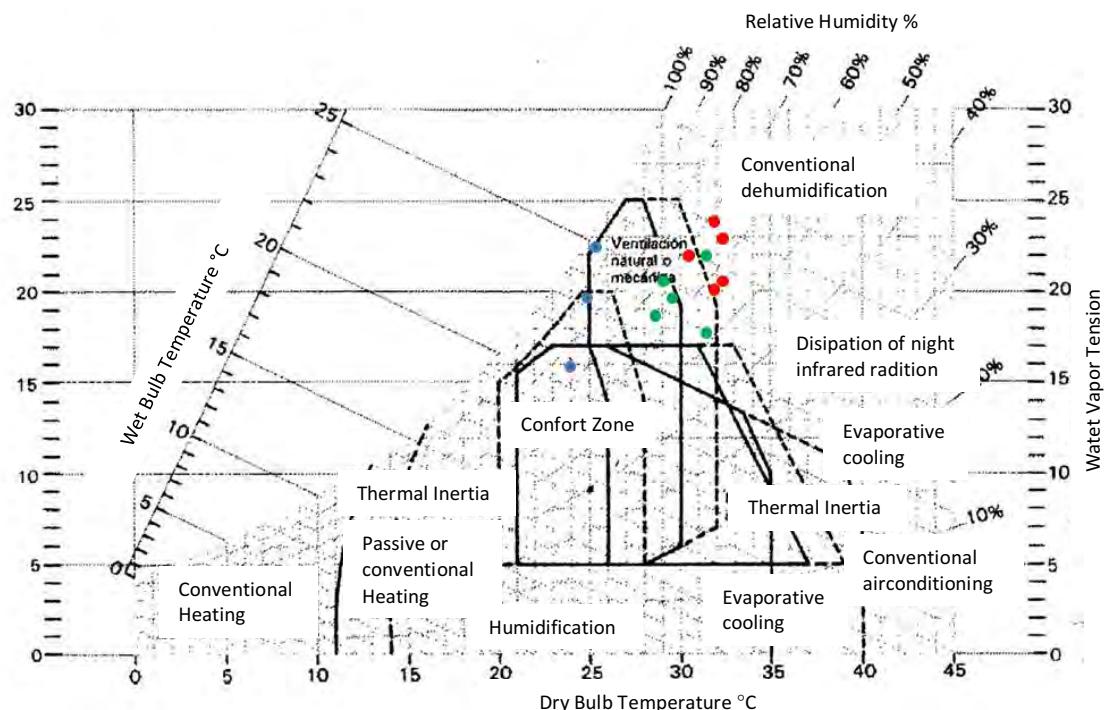

Figure 5: Combination of maximum and minimum values of temperature and relative humidity measured under the three green roof type studied, in the Givoni's Bioclimatic Chart. Exposed roof; RED; double green roof; GREEN; extensive green roof; BLUE

Some recommendations have been finally offered to use each type. Integrated green roofs (extensive) should be considered since the design step and included in the construction process. It is not recommended their further addition or being used in popular self-constructed housing. However, separated green roofs may be developed later on by people progressive actions, taking into account offered recommendations (Pérez González y González Courret, 2016).

## **Conclusions**

Green roofs are not a tradición in Cuba. They started in the 50's as part of aesthetic explorations in modern architecture, their development continues during the 60's, and they were reborn in the 90's with a productive objective, generating simple and economic popular solutions.

From the international literature and the Cuban repertory, a new classification have been proposed according to the relationship between the substrate and the roof: Integrated (intensive and extensive), and Separate (containers and double roof).

According to measurements carried out, interior spaces under double green roof present lower temperatures in up to 6°C respect to those under a roof exposed to solar radiation. Higher differences occur during night, coinciding to the mayor housing occupation. Extensive green roofs also offer favorable conditions, but with mayor thermal inertia.

The cost – benefit analysis demonstrate that any of the studied green roofs favour comfort indoors, complemented by natural ventilation.

## The 'Second Skin' and Thermal Adaptation In Changing Climate

Meshack Efeoma<sup>1</sup>

<sup>1</sup> Built Environment and Design, Faculty of Arts and Design, University of Canberra, Australia, mefeoma@gmail.com or Meshack.Efeoma@canberra.edu.au

**Abstract:** In order to determine the extent to which clothing, the 'second skin', can affects the thermal perception of building space occupants, this paper analysed the results of field studies conducted in the hot humid climate of Nigeria. Using a mixed-mode methods; climate measurements during two different climate seasons (dry and rainy seasons) were taken, also 450 subjective questionnaires were administered to participants, and a number of observational studies were also recorded. The results showed that of all the thermal variables measured and recorded during the field survey, clothing insulation had the strongest correlations to the thermal sensation of participants. The correlation coefficient of clothing insulation was 0.516; whereas indoor air temperature was 0.236, outdoor air temperature had a correction coefficient of 0.131, relative humidity, 0.115 and metabolic rate was 0.020. Thus, in hotter climate, the 'second skin' has a major role to play in enabling building occupants to better adjust to their thermal environment, with a reduced reliance on mechanical forms of ventilation, which are expensive to run and maintain. The paper concludes by recommending policy measures office managers/management can implement to ensure office workers have appropriate clothing to ensure thermal comfort in a changing climate.

**Keywords:** Adaptation, clothing, hot humid climate, 'second skin', thermal perception

### Introduction

Climate change is a global issue that affects all parts of the planet. It is a burning subject among scientist, economist, politicians, professionals in different fields including the construction and the built environment. The impact of the global warming is felt on a local scale also. In a quest to save our planet from impact of this change, the United Nations has been at the forefront of many initiatives that have been taken in this regard.

Some of the key international initiatives that have been spearheaded in response to the climate change issue, according to the United Nations Framework Convention on Climate Change (UNFCCC), have highlighted *mitigation* and *adaptation* as the main objective of the United Nations in combating climate change . **Mitigation** approach involves human intervention to reduce the sources of greenhouse gases, the major cause of global warming (IPCC, 2014a). **Adaptation** is the process of adjusting to the effects of actual or expected climatic condition. In human systems, adaptation attempts to moderate, avoid or take advantage of beneficial opportunities. In some natural systems, the intervention of humans may speed up the adjustment process (IPCC, 2014b).

As a step in the right direction, the adaptive thermal comfort has been widely recognised as an innovative approach to achieve energy efficient and sustainable building designs, in response to climate change. The adaptive principle (Nicol and Humphreys, 1973) indicates that one of the major actions usually taken by subjects in order to adapt or adjust

to any change in environmental conditions and in restoring comfort is clothing adjustment. Clothing, regarded as the ‘second skin’, allows us to adapt to the thermal conditions in our immediate surrounding. It also affects our perception of the thermal environment. However, in the emerging world; office workers are often required to wear official clothing or uniforms by their employers (Efeoma, 2016). The military and the paramilitary, wear uniforms, as do officials of state parastatals and other organisations. In private companies, employers have dress code policy for all staff, which is expected to promote the company’s corporate image. Workers, in these situations, have little or no control over their choice of clothing. Hence, such dress code or uniform policies usually restrict the ability of workers to adapt to the thermal conditions surrounding their work environment.

Hence, this paper is concerned with examining the adaptation aspect of the UNFCCC’s objective in combating climate change in relation to the built environment in the hot humid climate. The main objective is to investigate the relationship between clothing insulation and thermal perception of local office workers in the hot-humid climate of Enugu, Nigeria; in comparison with other thermal variables.

### **Practical Case Studies of Clothing Adaptation**

There are few contemporary case studies or reports on practical case studies related to clothing adaptation. The following two cases cited below are based on the campaign carried out by the Japanese Ministry of Environment. They were termed: *Cool Biz* campaign in 2005 and *Super Cool Biz* campaign in 2011.

#### **A. Japanese *Cool Biz* Campaign**

During the summer of 2005, the Japanese Ministry of the Environment began a campaign that is termed: *Cool Biz* campaign (Japanese Ministry of Environment, 2005). During the *Cool Biz* campaign, office workers in government ministries were expected to adopt a certain dress code. The *Cool Biz* dress code advises workers to wear short-sleeved shirts without ties or jackets. They were also expected to starch collars of their shirts to stand up and to wear trousers made from materials that breathe and absorb moisture. The purpose of this campaign, according to the Ministry of the Environment, is to reduce energy consumption by limiting the use of air conditioning. Hence, in all central government ministries the temperatures of air conditioners were set at 28°C until the end of the summer.

At the end of the summer, the Ministry conducted a web-based questionnaire survey on the *Cool Biz* campaign (Japanese Ministry of Environment, 2005). Of the 1,200 men and women randomly selected for the survey, 95.8% of the respondents agreed that they knew about *Cool Biz* campaign. Based on the survey conducted, the Ministry estimated that the campaign resulted in a reduction in CO<sub>2</sub> emission that is equivalent the volume of CO<sub>2</sub> emitted by about 1 million households for one month.

#### **B. Japanese *Super Cool Biz* Campaign**

Following the great east Japan earthquake of March 11, 2011, the shutdown of many nuclear power plants for safety reasons led to energy shortage, which forced the Japanese government to mandate a 15% peak power reduction to address shortage in summer (Tanabe et al., 2012). The government recommended that the temperature of air conditioners should be set at 28°C. The *Super Cool Biz* campaign was then launched to encourage workers to wear clothing appropriate for the office summer heat. Polo shirts and trainers were allowed in government office. Under certain circumstances, workers were also

allowed to wear jeans and sandals. During the summer of 2012, the *Super Cool Biz* campaign was repeated in Japan.

While the *Super Cool Biz* campaign was a good strategy for saving energy, it however affected workers productivity. According to the result of field studies conducted by Tanabe et al, the self-estimated productivity in 2011 summer was 6.6% lower than that of the previous summer (Tanabe et al., 2012).

The Japanese *Cool Biz* and *Super Cool Biz* campaigns, highlighted the extent to which clothing (the second skin) can affects both the adaptation and perception of office workers to the thermal conditions surrounding their work environment. They also showed that there is need to investigate good strategies of electricity savings that would not affect workers thermal comfort and productivity.

## Methodology

The research for this study was conducted in Enugu, a city in the hot humid climate zone of Nigeria. It is located at an altitude of approximately 223m above sea level and it lies between latitudes 5°55'15"N and 7°6'36"N, and longitudes 6°55'39"E and 7°54'26"E. It has an undulating topography with scattered hills and knolls, with approximate land area of about 7,161km<sup>2</sup> (Efeoma, 2016).

Being in tropical Nigeria, Enugu is hot all year round with a mean daily temperature of 26.7°C (Sanni et al., 2007). The climate of Enugu is humid and the peak of the humidity is experienced between March and November (Reifsnyder et al., 1989). As with the West African geographical land mass, Enugu experiences two major seasons, the rainy and dry seasons. During the dry season months of December and January, the city is also affected by the '*Harmattan*', a dust-laden trade wind from the Sahara desert, usually occurring over two to three week period, which can also affect visibility.

The data for this study were obtained from office workers and office spaces in the complexes of the Federal Radio Corporation of Nigeria (FRCN) and the Federal Road Safety Corps (FRSC), Enugu. The surveys were conducted during the dry and rainy seasons in 2014. In order to determine the wide range of environmental conditions that office workers in the climate zone can adapt to, surveys were carried out in office spaces that were both naturally ventilated and others which had mixed-mode<sup>1</sup> ventilation in place. Also, spaces included open plan (OP) offices and enclosed space (ES) offices.

Throughout the period of the survey conducted during from January to March 2014 (dry season), and in the months of May to June 2014 (rainy season), dataloggers were placed in all the office spaces surveyed to record indoor operative temperature and humidity at 15 minute intervals. The dataloggers were located within 1 meter of each participants' workstation to record the actual thermal conditions being experienced by participants during normal working hours. Dataloggers were also placed outside the buildings to simultaneously record the corresponding air temperature and humidity of the immediate outdoor environment at the same time intervals as the indoor dataloggers. A Hand-held instrument was used to measure the air speed in the different spaces surveyed at different instances during the study period.

The questionnaires used for this study were administered in two parts. Part One of the questionnaire was used for the recruitment of participants on a voluntary basis. Paper

---

<sup>1</sup> Mixed-mode ventilation in this research refers to office spaces that utilises a combination of natural ventilation from operable windows and some form of air-conditioning cooling system

copies of the first part of the questionnaires were distributed to a self-selected group of participants, who were office workers in both offices of FRCN and FRSC. For the purpose of anonymity, codes were assigned to each participants that completed the first part of the questionnaires. Part One of the questionnaire was only administered during the first stage of the field research, since the information collected from that part of the questionnaire remained unchanged throughout the course of the survey.

Part Two of the questionnaire was administered in both stages of the survey using a longitudinal approach (Efeoma and Uduku, 2016). For each day of the survey, three thermal comfort questionnaires were administered to each participant; one in the morning (before 11am), another one at mid-day (between 11am and 1pm), and the last one in the afternoon (after 1pm). This process was repeated for different days throughout the period of the two stages of the survey. Subjective thermal variables collected included: participants' subjective thermal comfort votes (COMF), thermal sensation (TSENS) and thermal preference (TPREF).

## Analysis of Results

### **A. Thermal Variables Measured and Recorded**

The thermal variables measured and recorded during the period of the survey included; indoor air temperature (TA\_In), outdoor air temperature (TA\_Out), indoor relative humidity (RH), metabolic rate (MET) and clothing insulation (CLO). The results are summarised in Table 1. As shown, there is less disparity in both indoor and outdoor air temperature measured during the period of the survey. With a coefficient of variation of 32.8%, clothing insulation has the most disparity of all the thermal variables measured and recorded.

Table 1: Summary of Thermal Variables Measured and Recorded

	TA_Out (°C)	TA_In (°C)	RH (%)	MET	CLO
<b>Maximum</b>	39.8	32.4	83.7	2.0	1.14
<b>Minimum</b>	24.4	24.4	40.2	1.0	0.51
<b>Mean</b>	33.3	28.5	59.5	1.14	0.73
<b>Std Deviation</b>	3.19	1.75	11.69	0.149	0.24
<b>Coefficient of Variation (%)</b>	9.6	6.1	19.6	13.0	32.8

In order to determine the subjective thermal sensation (TSENS) of the participants, the questionnaire adopted the ASHRAE seven-point thermal sensation scale (-3=Cold, -2=Cool, -1=Slightly cool, 0=Neutral, 1=Slightly warm, 2=Warm, 3=Hot). Participants were allowed to select all the options that apply and the resulting mean from options selected was used to determine the participants vote. The mean TSENS vote for all participants in the survey was slightly below "Neutral", between "Slightly cool" and "Neutral" with a value of -0.08. As shown in Figure 1, the breakdown of the mean TSENS votes according to office clothing policy indicates that with a median vote of 2.0 on the ASHRAE thermal sensation scale; participants in offices with strict clothing policy voted that they were much warmer compared to the group mean TSENS vote. While those of offices with flexible clothing policy are much more comparable to the group mean TSENS vote.

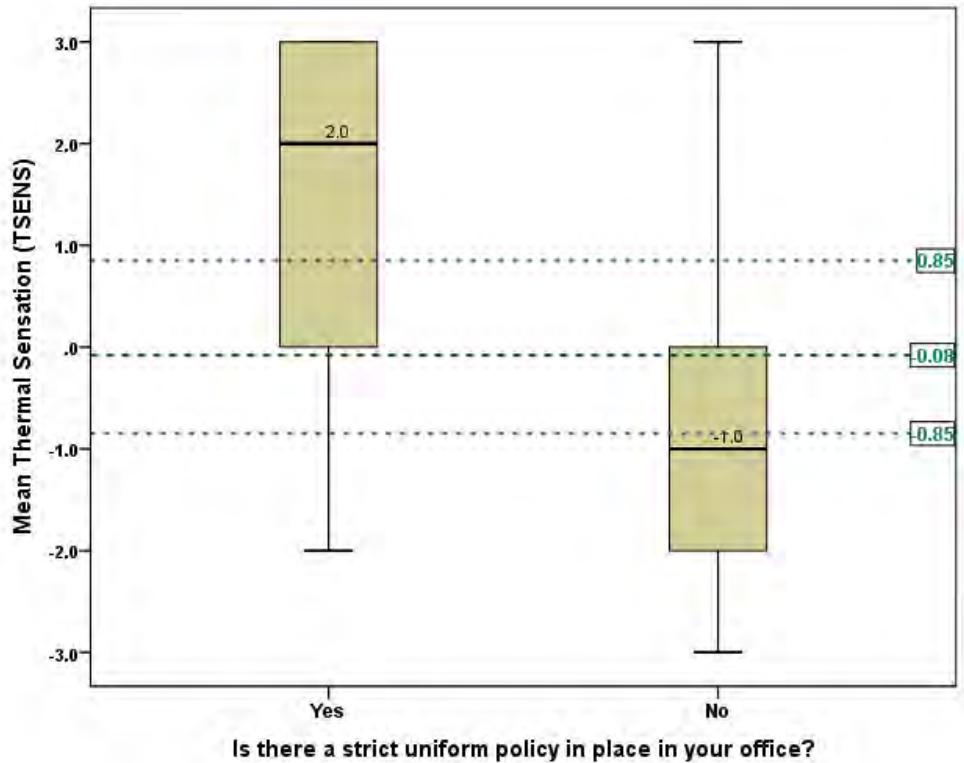

Figure 1: Distribution of mean TSENS according to office clothing policy

### **B. Correlation of Thermal Sensation to Other Variable**

Figure 2 shows the correlation matrix of the mean thermal sensation (TSENS) to the following variables: indoor air temperature, clothing insulation, outdoor air temperature, relative humidity and average metabolic rate. The bivariate scatter plots and the fitted lines are shown on both the left and right parts; Pearson's correlation values, their significance values and the corresponding R<sup>2</sup> values are shown on both the upper and lower part. The results show that thermal sensation is strongly correlated to clothing insulation ( $r=0.516$ ) and operative temperature ( $r=0.236$ ). It is also slightly correlated with outdoor air temperature ( $r=0.131$ ) and relative humidity ( $r=0.115$ ). It has a weak correlation to metabolic rate ( $r=0.020$ ).

The 2-tailed correlation is significant at the 0.01 level for clothing insulation, operative temperature and outdoor air temperature. While the correlation between the mean thermal sensation and relative humidity is significant at the 0.05 level. With a correlation significant of 0.678, there is no statistical significant correlation between mean thermal sensation and metabolic rate. This implies that, changes in the activities of participants of the survey did not affect their thermal sensation.

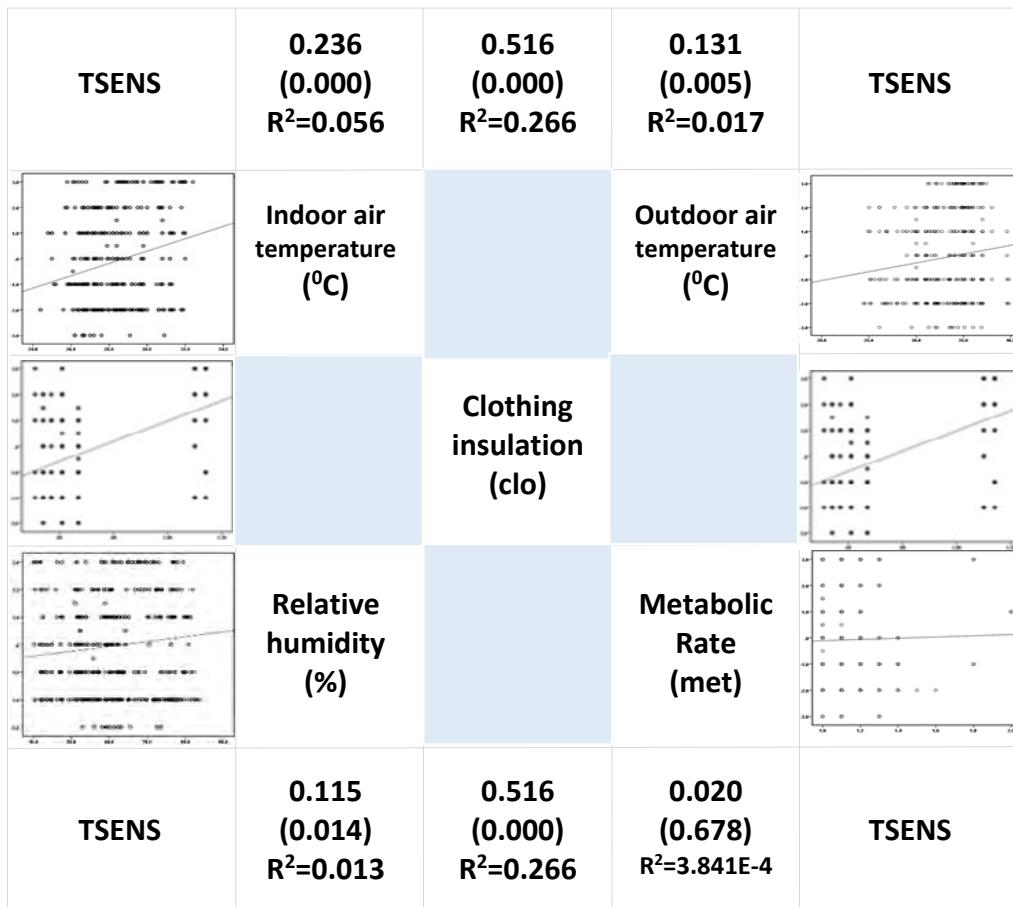

Figure 2: Correlation matrix showing the relationship between the mean thermal sensation (TSENS) and the following variables: indoor air temperature, clothing insulation, outdoor air temperature, relative humidity and metabolic rate. Bivariate scatter plots and the fitted lines are shown in both the left and right parts; Pearson's correlation values, their significance values and the corresponding  $R^2$  values are shown in both the upper and lower parts

### C. Relationship between clothing insulation and subjective thermal sensation (TSENS)

A regression analysis was also carried out to establish the relationship between clothing insulation and the subjective thermal sensation (TSENS) of the local office workers in the hot-humid climate of Enugu. Using the SPSS software, a linear regression analysis on the TSENS was carried out with respect to clothing insulation. The result of the relationship is summarised in Table 2.

The linear regression equation for the relationship between the participants' clothing insulation and the subjective TSENS votes is  $Y = 3.960*X - 2.961$  with a correlation coefficient of 0.521 and a p-value that is statistically significant at 0.01. This yielded a subject clothing insulation comfort range (TSENS between -0.85 and +0.85) of between 0.53 clo and 0.96 clo. This is in compliance with the adaptive comfort standard of ASHRAE Standard 55-2013, which specifies a clothing insulation range of 0.5 to 1.0 clo (ASHRAE, 2013).

Table 2: Summary of thermal sensation votes responding on clothing insulation

Sample	Comfort Range	Regression Equation	Pearson	P-value
--------	---------------	---------------------	---------	---------

size (n)	-0.85≤TSENS≤+0.85 (clo)		correlations	
450	0.53 – 0.96	Y = 3.960*X-2.961	0.521	0.000

## Discussion

As shown in Figure 2, the R square value for the mean TSENS votes against clothing insulation of participants was 0.266. While this shows that the regression equation, in Table 2, could only explains 26.6% of the relationship, it is however statistically significant. Again, the low value of R square for the relationship explains how difficult it is to estimate human perception or psychology using statistical methods alone.

However, when this relationship is compared with the relationship between indoor TA\_In and TSENS, it could be seen that clothing insulation is a better predictor of the TSENS of participants than the indoor air temperature. This result is also supported by the analysis result illustrated in the correlation matrix; which shows that of all the thermal variables measured or recorded, CLO has the strongest correlation to TSENS. This strong correlation between CLO and TSENS thus shows that clothing was the major determinant of how participants perceived their thermal environment during the period of the survey.

This clearly shows that for building occupants to be comfortable within the ASHRAE adaptive comfort limits, office workers in the hot humid region should be given the opportunity to adjust their clothing within the range of 0.53 and 0.96 clo as established from this study. Strict uniform policies that specify office clothing with CLO value higher than 1, with no opportunity for workers to make adjustment, will make it difficult for the adaptive comfort of ASHRAE Standard 55-2013 to be apply in such office spaces where they occupied.

## Conclusion and Recommendation

This study has shown that there is a strong relationship between building occupants CLO and their TSENS. The relationship has also yielded a clothing insulation range of 0.53 and 0.96 clo. Hence, for adaptive comfort standard to be applicable in the hot humid climate zone of Nigeria, building occupants must be able to adjust their clothing within this CLO range. Above all, employers need to know what CLO values are and should be able to determine the CLO value of any office clothing ensemble they want to recommend to their staff.

Conceptually, the findings from this study will provide policy makers and employers with strict uniform or office clothing policy in Nigeria, and by extension the emerging world, a basis to review their current office clothing policy to a more flexible clothing policy that will encourage adaptive opportunities for workers to adjust their office clothing where necessary. This in turn will reduce reliance on mechanical cooling systems which are expensive to install and maintain.

In order to help the public and employers to understand what clothing is most appropriate to achieve thermal comfort in the local context; there is need for future research to look into the possibility of re-calibrating and publicising the clothing insulation scale as this research has shown that clothing was the most significant factor influencing thermal adaptation in the cases studied.

*Design to Thrive*

## Resilient Urban Edges: Adaptive and Mitigative Design in Chennai

Vaishali Marlene Enos<sup>1</sup> and Rosa Schiano-Phan<sup>1</sup>

<sup>1</sup> Architecture and Environmental Design MSc, Department of Architecture, University of Westminster, London, United Kingdom.

**Abstract:** This paper investigates design responses to El Nino-mediated climatic disturbances, using the December 2015 Chennai floods as a test case. The effects of such disturbances are exacerbated by human intervention: urbanisation-led impermeabilisation of soil accentuates the urban heat island, makes water percolation difficult, increasing surface run-off. Using literature, precedents and on-site interviews with residents of a tenement block in severely-flooded Chennai, downstream of the River Adyar, key issues were identified. Additionally, impact of existing morphology on comfort conditions were derived using analytical tools of Envimet, Ladybug and CFD (outdoor) and TAS (indoor). The conclusions informed testing of hypotheses which merged with informal recycling practices of the residents. The paper discusses strategies employing recycled and local materials to build permeable surfaces (water-air-ground interfaces) to be embedded into existing architectural objects (by retrofitting), or utilised to build new experimental floating structures complementing the existing. The design studies show how strategies bring extreme temperatures of 42°C within a comfortable range in indoor and outdoor spaces; whilst contributing to flood mitigation. The paper speculates upon a resilient live-work environment for 2050 employing productive self-build networks to alleviate socio-economic polarisation characterising riverfronts, contributing to urban permeability and responding adaptively to daily, seasonal and extreme events.

**Keywords:** Chennai, El Nino, adaptive, mitigative, permeable

### Introduction

The El Nino is associated with temperature differences in the east-central Equatorial Pacific caused by trade winds moving towards South America instead Asia, resulting in weak monsoons in Asia. In India, particularly in urban areas like Chennai (fig 1), El Nino-mediated climatic disturbances manifests itself as dual conditions of droughts and floods. The drought scenario is exacerbated by the Urban Heat Island (UHI) effect (Amirtham, 2016) resulting in extreme temperatures and water and food shortages, while floods are made worse due to construction on the flood plains and unplanned rapid urbanisation. The effects of unplanned concretisation of the city are found in the existence of the UHI indicating an intensity of 2.48°C and 3.35°C during summer and winter respectively (fig 3). Rapid urbanisation (fig 2) has resulted in vegetative areas declining from 70% to 48% (1991-2012) in the metropolitan area, with built areas increasing from 1.46% to 18.5% and projected to be 36% in 2026 (Ramachandra et al, 2016). Further, India's population is estimated to increase four-fold by 2050, with new populations living in urban areas, 60% of which are not yet built (McKinsey, 2015). The city is unable to satisfy the needs of its 12 million, creating a paradox of an increasingly polarised thirsty metropolis, expanding onto flood plains of rivers of the city.

Figure 1. Location

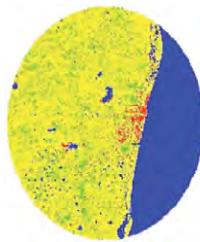

Figure 2. Growth from 2000, 2010 to 2026

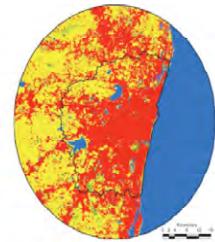

Figure 3. Heat Islands

### ***Area of focus – River and tenement settlements***

The area of focus is the river Adyar (fig 1), which burst its banks following the release of water from the Chembarakkam lake due to 539mm of rainfall on one day in December (which is the average rainfall for the month). The 12.2015 flood (fig 4,5a) turned the roads into water canals which perforated the urban fabric. The site chosen is a tenement settlement in Kotturpuram, which is on the curvilinear flood plain of the river and was inundated causing destruction to life and property - residents had to move to the terrace or be evacuated by boat. Chennai has a large number of such blanket developments built through a government housing scheme on low lying land unfavoured by real estate with informal settlements located around them. These blocks are generic in organisation with no attempt to engage with the informal lifestyle of its occupants. Therefore, the aim of this paper is to formulate design proposals that would allow for adaptation and mitigation of extreme weather events and typical conditions whilst engaging the city and local communities.

Figure 4. Before and after the flood

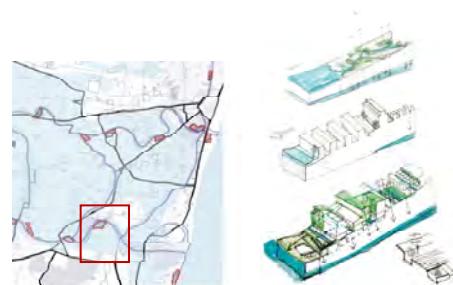

Figure 5. a) Site and b) hypotheses

### ***Hypotheses***

**Hypothesis 1 - Mitigative strategy:** What proposals can be introduced in the urban fabric to address El Nino-mediated extreme climatic events? The hypothesis is that layers of permeable surfaces, derived from the recycling economy and introduced in the fabric, will rethink landscape in cities, mitigate the heat island effect and provide ownership to the locals. This mitigative strategy explores permeability by using vegetation, water and synthetic materials in different ways in the urban and architectural fabric.

**Hypothesis 2 - Adaptive strategy:** What proposals can be introduced in the building fabric to address temperatures that are out of comfort for 95% of the year? The hypothesis is that layers of transition spaces, buffers and screens will aid in achieving outdoor and indoor temperatures within the comfort band throughout the year. This hypothesis is a design intervention where existing street typologies and unit typologies were tested, evaluated, redesigned and later applied to new typologies on the site.

Hypothesis 3 - Participative strategy: How can a riverfront be utilised to integrate the city and promote ecological awareness? The hypothesis is that a river can be more than just a connection point from A to B but also: a mobility infrastructure, a productive channel, a public realm and a climate mediator. As a participative strategy, this is an urban design place making strategy that investigates integrating the neglected rivers and its polarised edges with the rest of the city (fig 5b).

### Climate

Located at 13.0827° N 80.2707°E, Chennai has a tropical wet and dry/savanna climate (Köppen-Geiger classification: Aw) with a maximum air temperature between 41°C in the month of May and 20°C in the month of December. The climate variations from the IPCC A1B scenario for 2050 (fig 6) that were considered are an increase in temperatures (1-2°C) and out of comfort temperatures for 90% of the time, an increasing trend in rainfall in the monsoon season from October-December, increase in the global horizontal radiation annually (2716 hours of sunshine per year) and capitalisation on sea breeze from the East.

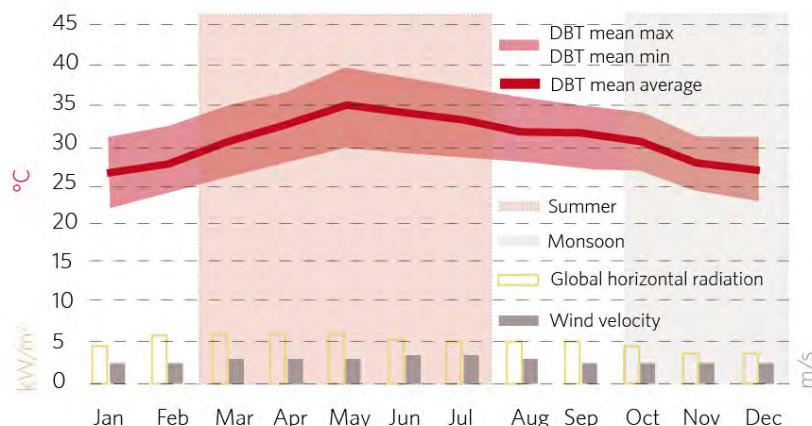

Figure 6. Monthly Average Climate Parameters - IPCC (2050) showing a rise in temperatures by 2°C

### Scope of work

The site consists of primarily 80 blocks within an area of 84,430 sqm. The orientation of the blocks (fig 7) (32x8x12m high) creates more asphalted streets in the form of East-West canyons (2.8-3.5m) than North-South canyons (8-10m). There are predominantly two types in the settlement - a ground + 3 typology (80% of blocks) where the ground and first floors were severely affected by the floods while the rest are of ground typology, which were washed away. The work is divided into two sections - Outdoor microclimate studies analyse street typologies and indoor studies compare thermal performance of units.

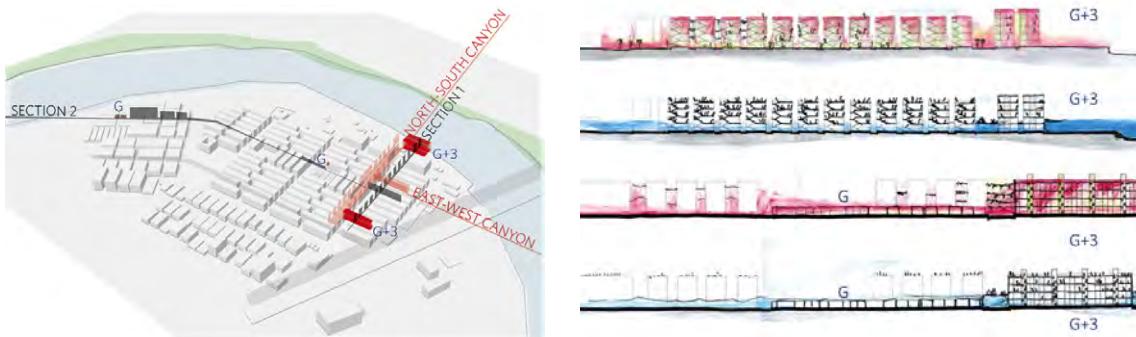

Figure 7. Sections and types (G+3/G) – orientation, behaviour during summer and monsoons

## Analytical work – existing fabric

### *Outdoor microclimate – street typologies*

The canyon geometry was analysed for solar access, wind velocity (sea breeze from the East) and existing outdoor conditions with Envimet (32°C average DBT, concrete construction and asphalt ground during Summer (May) and the following observations were made (fig 8) – The East-West canyon (30% Sky View Factor and Height-Width ratio 5:1) restricts more solar radiation than the North-South canyon (52% sky view factor and Height-width ratio 3.7:1) as a result of street geometry, morphology and sky view factor. At 14:00 hrs, the North-South canyon achieves a Dry Bulb temperature of 42°C while the East-West canyon achieved 39°C. At 2:00 hrs, the North-South canyon and East-West canyon both achieve 29°C. This indicates the North-South canyon re-radiated faster (higher sky view factor) than the East-West which behaved as a heat sink (Oke 1981). However, the wind velocity in the canyons was lower because of the lack of stacks, systematic open spaces and staggered edges which does not allow heat trapped in the lower layers to be dissipated to the upper layers. Also, the 180° orientation of blocks allows wind but 90° orientation blocks the flow. In addition, the river to the North modulates temperatures considerably.

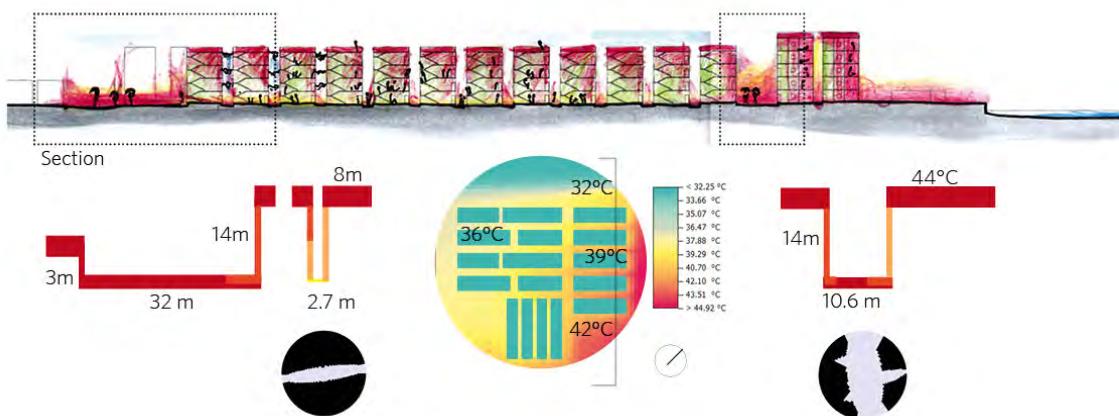

Figure 8. Typical canyon types - East-West (2.7m), North-South (10.6m) and Envimet analysis

### *Indoor – unit typologies*

The Ground+3 type typical flat (fig 9) consists of a living room, kitchen, bed and bath organised within 9.5x3.4x3m (4-6 people) of permanent concrete frame construction. The

Ground type is 6x4x3-3.5m high consisting of two multipurpose rooms with a bath (5 people) of temporary local wood and metal sheet construction.

A comparative study using dynamic thermal simulation (TAS 9.xx software) showed that indoor units (62%) have double the tendency to be out of comfort when comparing the Dry Bulb Temperatures. The G+3 type performed better (figure 11) than the G type because of obstruction from the context and materiality. However, hot air from the kitchen moved into the living room, instead of being expelled due to the lack of cross ventilation or stacks. In addition lack of night time ventilation increased hot conditions during the night. In case of semi-open areas, the stairwell had a maximum of 47% out of comfort hours, the in-between zones recorded 42% and the DBT recorded 31% indicating that urban morphology, materiality and anthropogenic heat sources caused heat retention. Therefore, strategies have been proposed to achieve indoor comfort (fig 11):

- a) Ventilation- Night time cross and stack ventilation and the use of the stairwell to expel heat from indoor and semi-open spaces during the night to cooler outdoors.
- b) Solar radiation- Shading surfaces (facades, windows, ground and roofs) exposed to solar radiation. Vegetative walls induced evaporative cooling bringing down temperatures by 3°C (Saito et al, 1990). Roof layers act as insulation and offer scoop ventilation.
- c) Daylight - The design sky illuminance of 22,000 lux requires small openings for light, reducing the perception of heat.

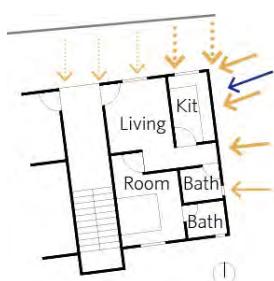

Figure 9. Typical plan

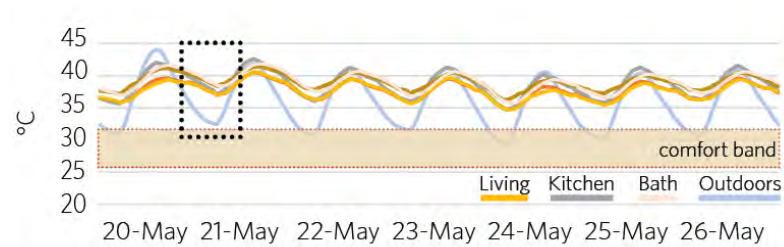

Figure 10. TAS Analysis (May 20-26) showing lack of night time ventilation

### Site strategies

The proposal involves a fluid strategy which revolves around the recycling economy using the river as its main mode of movement. It aims to turn the site from inward-looking to oriented towards the river (fig 11). This includes bringing the river into the site in the form of channels which will reduce temperatures in the interior and help in percolation. The different areas of the site are for the arrival areas for raw materials, distribution areas and workspaces. Two areas are detailed design interventions – existing street based and new floating typologies.

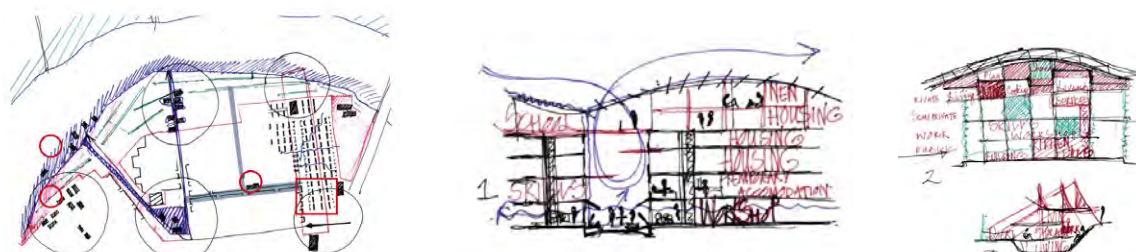

Figure 11. Site strategies – Street-based and floating types

## Propositions – existing streetscape

### Street based typologies

The intervention for the existing typologies included four stages – introduction of a new horizontal (0-6m high - fig 12.2) to mitigate floods and become informal workspaces, reorganization of existing floors (6-12m) to improve organisation and ventilation, introduction of new floors (12-18m) to increase densities and a community roof (18-21m).

The results of tested outdoor concepts were that solar access (Ladybug software – fig 12.1 and 12.2) was reduced by 50% on the East and 80% on the streets. Wind study (Autodesk CFD – fig 12.3) simulations showed that wind velocity increases from 0 to 3m/s when the block is raised by 6m and a jagged roof creates turbulence. Outdoor microclimate modelling and simulation (Envimet - fig 12 A and B) showed that when concrete construction is replaced by brick, a permeable roof, earth on the ground, vegetation and water channels are introduced, the temperatures reduce from 42 to 31°C (North-South canyon) and 39 to 30°C (East-West canyon) at 14:00 hrs on May 15 (Summer – average temperature 35.2°C). At 02:00 hrs, both measured 29°C (same as the weather station). This shows that change of material decreased sensible heat in the canyons reducing temperatures by 5-6°C, water modified edge temperatures extensively by 7-10°C, earth (instead of the asphalt) reduced temperatures by about 6°C and vegetation reduced temperatures by 2-3°C. For indoor existing units, the kitchen was reorganised and new stack windows of 24-28% window to floor area for 6m<sup>2</sup> and 45-55% for 9m<sup>2</sup> on North-South facades, and 30% for 3.5 m<sup>2</sup> on East-West facades (with shading) required. The new floors included staggered unit floor profiles to create turbulence for wind and outdoor living rooms for residents. Here, the living rooms and kitchen are combined into one cross ventilated space, built with mud, tile and stone aggregates.

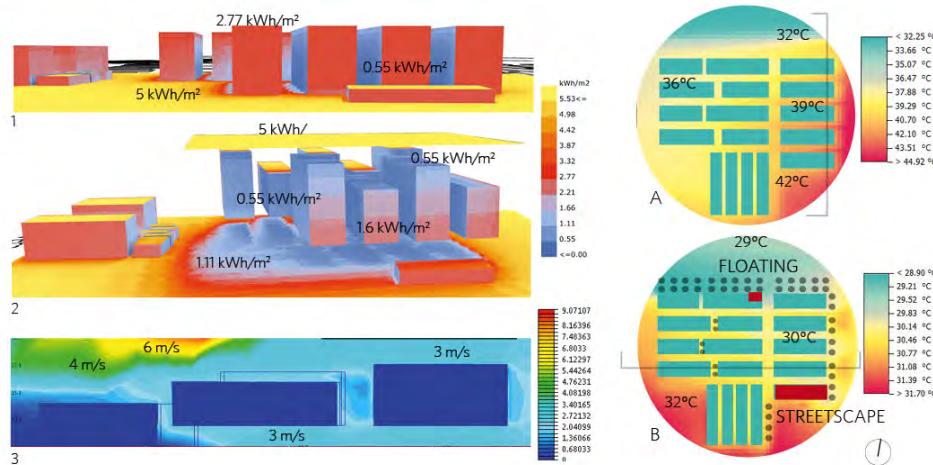

Figure 12. Monthly average daily solar radiation (1 - existing, 2 - proposed), wind studies (3 - proposed) and Envimet Comparative Analysis (A and B)

### Floating typologies

Floating typologies (fig 13) use the principles from the street typologies to house residents of the Ground typologies (largest risk to floods). The ground has workspaces, while living units (3x3x5.5m) and communal kitchens areas are lifted off the ground by 3m. Solar access was reduced by the larger insulated roof and inverted profiles beneath. The ventilation

strategies included monsoon windows, small openings at floor and large stacks near roof to increase extraction of heat. Vegetative walls on East and West induced evaporative cooling. To mitigate flooding, the type is a light weight structure of metal, wood and coconut pith boards placed on a framework of PET bottles and binding wire.

Figure 13. Configuration

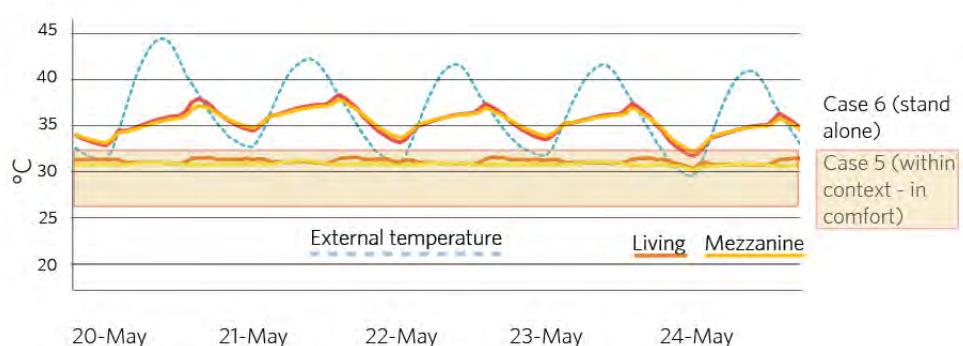

Figure 14. Case 5 + 6 TAS Comparative Analysis

### TAS Analysis – floating typologies

Cases 1-5 were tested as stand-alone units without surrounding context during May 20-24 (Summer) to examine whether they perform within the comfort range of 26-32°C. Case 1 tested a shoebox of wooden walls within a metal framework and coconut fibre boards as insulation. The units were out of comfort in comparison with diurnal DBT of 32-42°C. Case 2 included windows (2x1.2m on North-South) and stacks (1.5x.5m at 2.1 and 5m) which were enabled between 19-32°C and 90% open. Here, temperatures are in tandem with the DBT indicating the need for shading and ventilation regimes for different window sizes. Case 3 included louvered shading, stacks in floor and extensive night time ventilation instead of day time to achieve resultant temperatures of 32 to 36°C. Case 4 included internal gains of 2 people in each (9m<sup>2</sup>) unit of the living, kitchen and bath zones with different schedules. Here, the units come into range during the night.

Case 5 and 6 (fig 14) tested the principles from the outdoor analysis in Envimet. Case 5 included context (urban layout) and vegetative walls, the river and permeable ground and case 6 was tested without. Case 5 was in comfort but Case 6 required extra shading for exposed surfaces - vegetation for walls, bamboo mat shading for the roof and thicker light weight insulation.

### Conclusions

The design interventions focused on a riverside tenement block in a metropolis susceptible to urban heat islands and floods, in part aggravated by El-Nino-mediated climatic disturbances, but also caused due to anthropogenic interventions. Therefore, in addition to redevelopment of the riverside tenement block, the urban strategies also aimed at integrating the tenements by using the river and the recycling economy as a source of production. The materials derived from debris and garbage around the area is reused and re-integrated into different interfaces of the built areas to provide affordable respite to the UHI effect and mitigate the effects of flooding during the monsoons.

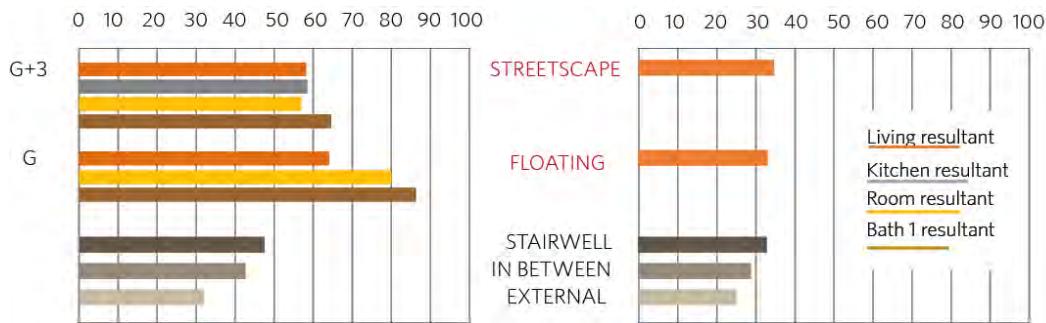

Figure 15. % of out of comfort hours : Comparison between existing (left), retrofitted and new types (right)

The streetscape type – redevelopment from existing G+3 typology into a G+5 type employs heavy weight material while the floating type (replacement for the ground type) is built from lightweight materials resting on a floating mechanism. By employing outdoor and indoor strategies, these permeable materials are tested reducing discomfort hours in the indoors by almost 50% and in the in-between areas by 12-15% (fig 15) throughout the year. This is achieved by transitional areas, shaded streets, screens and staggered buffer zones without compromising on density in order to house low income residents. The proposal aims to involve residents in a participatory process of regulating their microclimate, generating income and claiming ownership of unfavoured areas along rivers in fast developing metropolises.

## Acknowledgments

This work is the outcome of a Thesis Project for the Architecture and Environmental Design MSc, Department of Architecture, University of Westminster, London.

<sup>2</sup> Architecture and environment unit, Faculty of Electrical and Mechanical Engineering, University of Colima, Coquimatlán, México.

**Abstract:** There are some climatic classifications that are already globally recognized. In a large scale, the most used classification is the one developed by Köppen (1936). For Mexico, García (1973) adapted those postulates to the climatic characteristics of the country and produced a specific classification of the climates. Both classifications were based on different variables such as mean annual and monthly rainfall, and mean annual and monthly temperature, but the main variable was the vegetation. This kind of classification was made for the use of natural resources but not for the human environment design. In this study, the climatic classifications are based on thermal and higric comfort for humans. The proposal method was tried for eight cities of four different climates of Mexico. An effect was found named "the blanket effect" that modifies the status of every city to be in the cold. A correction step was rehearsed with good agreement with reality. Nine basic status for weather conditions were settled: comfort, hot, cold, humid, dry, hot dry, hot humid, cold humid and cold dry. Also, a correlation coefficient of  $r=-0.925$  was found between thermal swing and mean RH for 96 cities over all the country. As conclusion, the classification founded show good agreement with common knowledge of the climate, nevertheless it is necessary to extend this study to validate the method.

**Keywords:** climatic classification, blanket effect, bioclimatic chart, human comfort, human environment.

### Introduction

Weather/climate, from Greek *Klīmat*, is usually defined as the state or condition of a region averaged over a series of years, with respect of the atmospheric variables such as wind, air temperature, moisture, pressure, cloudiness, precipitation and sunshine. In architecture, these variables are the source of the inner conditions of our designs. For this, it becomes more than fundamental to knowing the climate of project settle down in order to design it with climate and not against it.

Most of the actual climate classification are based in variables that not necessarily are related to the human comfort such as vegetation, rainfall, cloudiness, distance from the sea, latitude or altitude. Dry bulb temperature and RH are two of the most important variables to define human comfort. These two variables are not the main inputs in most of the climate charts. In this study, a method for index the climate from thermal human comfort standard is presented. Also, a new concept is introduced, the blanket effect. It helps to modify the values of the control task from lower temperatures to have better agreement with common perception of the people.

## Background

In 1936, Vladimir Köppen (Köppen & Geiger 1936) published three of five books series named “handbuch der Klimatologie”. After years, Geiger finished Köppen’s work completing the other two books. In these books, Köppen section the world in five great climatic groups (Köppen & Geiger 1936, p.13):

A	Tropische Regenklimate	Tropical
B	Trockenklimate	Dry
C	Warmgemäßigte	Warm
D	Boreale Klimate	Boreal
E	Schneeklimate	Snowy or perpetual ice (Polar)

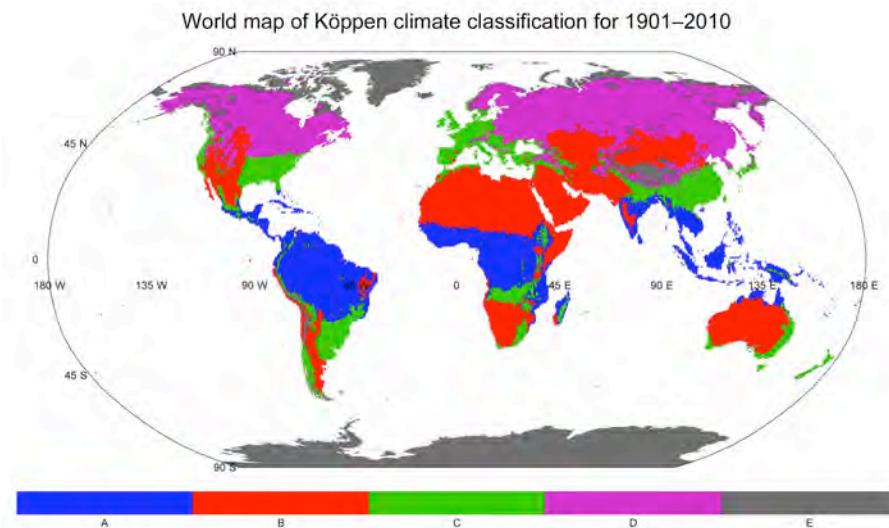

Figure 1. World map of Köppen climate classification. Source: Chen & Chen (2013, p.72)

These general groups are divided in smaller subgroups defined by the humidity, especially for rainfall:

For group A

m monsoon                          Humid with short dry season and abundant rainfall

For group A, C and D

f Equatorial                          Humid without dry season and rainfall all year

s    Dry season in summer and rainfall in winter

w savanna                            Dry season in winter and rainfall in summer

For group B

S steppe                             semi-arid

W deserted                           arid

For group E

T tundra                            dry, average temperature of hottest month between 0° and 10°C

F perpetual ice                    dry, average temperature of hottest month under 0°C

There are other descriptors that have been added due the incomplete work of the botanic Köppen. It is important to point that this kind of classifications was designed for agronomical purposes, then, its principal variables are not for human purposes. I.e., the first variable to delimitated climate is the vegetation. Köppen says that vegetation has a strong relationship with the climate conditions of a region. Subsequently, He determined a climate group studying and joining vegetal species and its requirements.

Second descriptor, rainfall or humidity, also comes from vegetation's requirements. It indicates the amount of water that can be found in a territory and the time in the year when it falls in order to designate the time of sowing or harvest. There is a third descriptor what assess the temperature. It is in the second and third descriptors when it is possible to find variables that are relative to the human comfort conditions, i.e., dry bulb temperature and RH.

Koenisberger (1977) and Evans (1980; 2007) defined in different documents climate types or zones with their meteorological variables features and presented their design recommendations for each type. Evans (2007, pp.27–30) presented three types of tropical climates: warm-humid, hot-dry and monsoon or transitional, and added three sub-climates: upland, maritime desert and tropical island.

He defined each climate zone using different variables like geographical: latitude, altitude and distance from water-land masses, and climate variables: average temperatures, thermal swing, relative humidity, cloudiness, rainfall, wind and sunshine (See table 1)

Table 1. Climate zones summary for tropical regions. Source: Evans (2007, p.30)

Climatic variable		Warm humid	Hot dry	Comfort	Cold	Very cold
Typical temperature °C		20 – 30	15 – 35	15 – 25	5 - 15	< 5
Relative humidity %		> 80 %	< 60 %	60 – 80	-	-
Temperature swing deg C		< 10° C	> 12° C	8 – 12	< 10° C	-
Climate classification	Latitude					
Warm humid	0 -15°	X				
Hot dry	20 - 35°		X	X		
Transition	10 - 30°	X	X	X		
Monsoon	5 - 30°	X	X	(X)	X	
Equatorial upland	0 - 20°			X	(X)	
Maritime desert	20 - 35	X	X			
Subtropical	30 - 40	(X)	X	X	X	
Temperate	40 - 50			X	X	
Alpine-Andean	30 - 50			X	X	X
Cool temperate	40 - 55			X	X	
Cold	> 50°			(X)	X	X
Very cold	> 60°				X	X

It is important to mention that Evans made a review and an analysis of the relation between the RH and the thermal swing. He emphasis the indirect relation of this two variables in chapter 7 of his thesis: "*with low humidity related to higher (thermal) swings...*" (Evans 2007, p.290).

Other climatic classifications were formulated from different variables along the last century, for instance, in brazil, Roriz (2012) made a proposal climatic classification using temperatures, thermal swing and RH for humidity and others variables as latitude, altitude, distance from the sea. In Mexico, García (1973) made a modification of the climatic system of Köppen to adjust the Köppen's chart to the country. Obviously, her principal variable was the vegetation. Morillón (2002; 2003) presented different bioclimatic charts for each month but the method is not clear established. Fuentes (2009; Rodríguez Viqueira et al. 2011; 2014) did a climatic classification from the bioclimatic requirements but the humidity subject was tried from the rainfall instead the RH. Finally, Gómez (2009) tried a classification for a region of Jalisco, Mexico. In his study, he found that most of the cities analysed using the adaptive comfort and degree-days for the control task indicates that are in cold. He proposed a correction value, but the justification was not clear enough. In this study, the correction step named "blanket effect" is presented.

## Method

Eight cities with different climatic conditions of Mexico were analyzed. Two for each popular knowing characteristic climatic condition: dry extreme (Mexicali and Nogales), cold (Toluca and Pachuca), hot humid (Merida and Tuxtla Gutierrez) and warm (Morelia and Cuernavaca). The climatic data used was obtained from the meteorological national service normals. These information presents the climatic conditions for each climatic station in a thirty years period. For this study, the normals used was from 1981-2010 period.

The data presented in those normals are the maximum, average and minimum temperatures, so the RH was calculated using the method developed by Tejeda (Tejeda Martínez 2007). Also, the hourly temperatures and RH for each month was calculated using the same process (See table 2)

Table 2. Example of hourly temperatures and RH of each month for Mexicali, Baja California Norte, Mexico.

A correlation between RH and thermal swing was found using data from the 96 biggest cities of the country in order to used thermal swing instead RH to determine the humidity of the region (See Fig. 2). The correlation coefficient of  $r=0.925$  of a negative correlation was found and a  $r^2=0.857$  ( $n=1152$ ,  $se=1.18$ ).

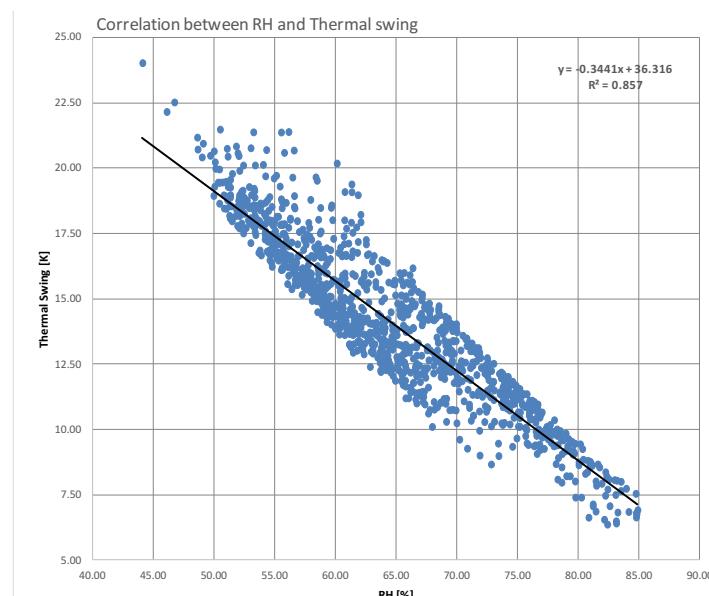

Figure 2. Correlation between RH and Thermal swing for 96 cities of Mexico.

With the equation founded, the proposal condition for dryness, higric comfort and humidity was established (See table 3).

Table 3. RH and thermal swing for each climatic condition.

RH	Thermal Swing	Condition
Less than 30%	Up to 25.9 K	Dry
Between 30% and 70%	Between 25.9-12.2 K	Comfort
Higher than 70%	Less than 12.2 K	Humid

The comfort temperature was calculated using the ANSI-ASHRAE standard (ASHRAE STANDARD 2010) for the adaptive thermal comfort for each month of every location. The amplitude was established in 2.5 K according with Auliciems and Szokolay (1997, p.59).

Then, with the hourly temperatures and RH and the comfort zone, degree-days (McGilligan et al. 2011)(Mourshed 2012) was calculated and summarised to identify the daily comfort task for each month to heat, cool, humidify and de-humidify (See Table 4).

It was noticed that in the 8 cities analysed, the annual results did not agree with the common perception of the people, and much less with the current and accepted climatic classifications. In the degree-days tables was noticed that most of the time, the temperature remains in cold below the comfort zone but in that hours, people did not notice those temperatures.

A **Blanket effect** was defined as those hours were human being is asleep and unconscious of the thermal environment in the space where he sleeps. Normally, the studies of thermal comfort made their questionnaires during daytime where people is conscious of their environmental conditions, therefore, they can express or notice comfort or discomfort. It could be said that during night time, the threshold to express discomfort is bigger than daytime, i.e., human being requires to be in higher cold or hot to wake up from sleep mode and modify the conditions of his space.

Also, there are many passive strategies to achieve comfort during night time such as increasing clo by pyjamas, bed sheet, blankets and so on, turn on/off fan or air conditioning, open/close windows.

To determine the hours where most of the people sleeps in every city, the consumptions of energy data were used from the national service (Comisión Federal de

Electricidad 2017) to identify in what hours the demand of energy increase or decrease. It was found that between 22:00 and 6:00 hours approximately, the consumption of energy decrease in the different regions of the country. Therefore, those hours were discarded from the degree-days average (the Blanket Effect Correction BEC) (See table 5).

Table 5. Deficit and surplus daily temperatures [K] for each month with blanket effect correction, Mexicali, Baja California, Mexico.

## Results and discussion

Figure 3 shows the average degree-day of every month for each location analysed. The hours in comfort zone were discarded, so it shows only the hours of control task. Most of the months and location remains in cold and requires heat to get in the comfort zone. Mexicali is the hottest location of the 8 cities. It appears from May through September in hot with almost 5 K degree day. Cities that normally are known as a hot and humid barely appears in hot, and not all the year, like Merida or Tuxtla Gutierrez (green).

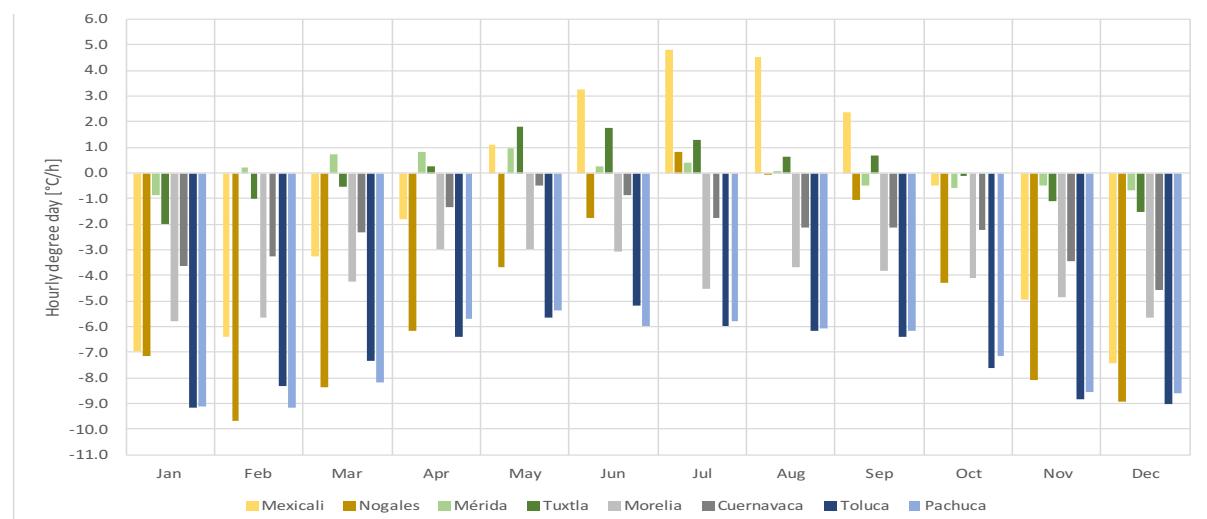

Figure 3. Average degree day of control task for each month and location.

After applying the BEC, the lag to be in cold was reduced in all the cities (See Fig. 4) Cities in green (known as hot humid) remains over the 0°C in the heat zone, this status agrees with the common perception of the people. Cities in blue (known as cold) remains below the 0°C

in the cold zone. Cities in yellow (dry extreme) remains in cold from January through April and from October through December (winter), and in hot from May through September (summer) according with the general perceptions of the people. Finally, cities in grey (warm) remains close to the 0°C of control task. They have their variations in less than 3°C/h.

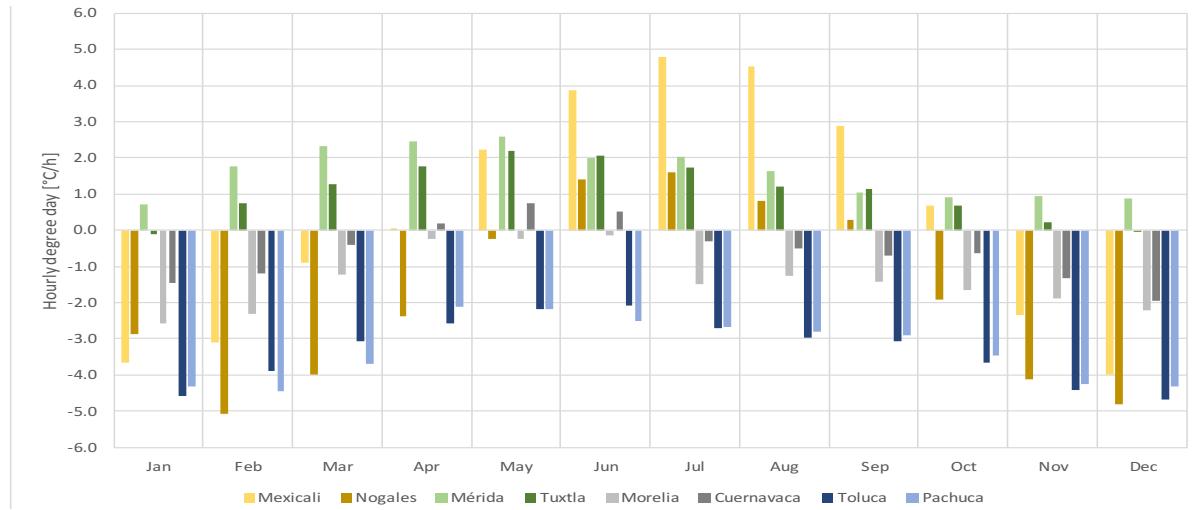

Figure 4. Average degree day of control task for each month and location after BEC.

In figure 5, control task and thermal swing are correlated to integrate the humidity to the classification. In the figure on the left, the values are presented without the correction of the blanket effect. Blue zone indicates cold, comfort thermal and higric in white, red is hot, brown is dryness and green is humidity. The corners are the combination of temperature and humidity.

In the left, most of the cities remains in cold but Mexicali, Mérida and Tuxtla Gutiérrez that appear in comfort. But if the blanket effect correction is applied, Cuernavaca gets inside the thermal comfort zone, Mérida and Tuxtla Gutiérrez almost get in the hot zone and Morelia and Nogales are in the limit between cold and comfort zones. The blue cities, continue in the cold zone, so the BEC does not affect considerably their performance as it does with the other cities that move them according to the real perception of their citizens.

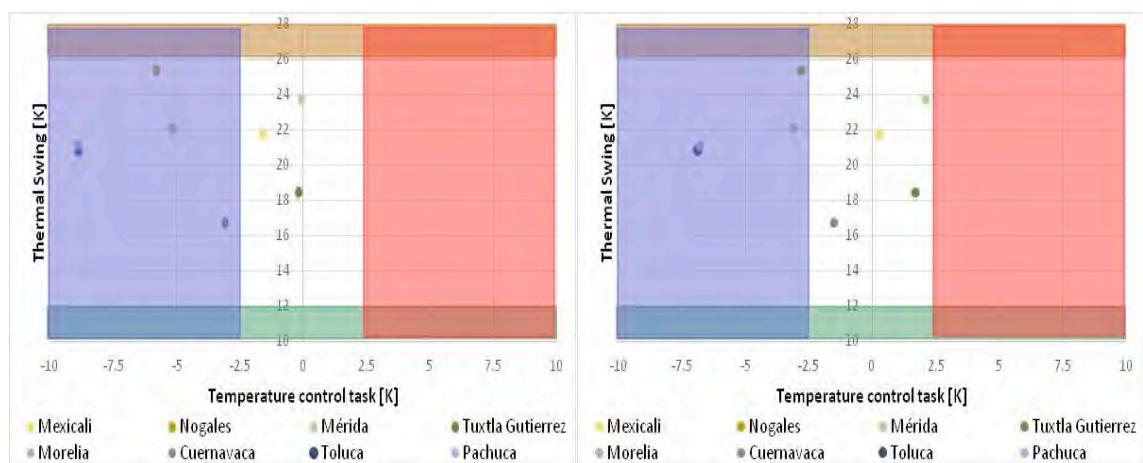

Figure 5. Control task and thermal swing correlation for the 8 cities analysed. Left without BEC, right with it.

## Conclusions

This study presented a method to sort the climate based in the human comfort guidelines. Eight cities of four different climates of Mexico were analysed. The blanket effect

correction was introduced to modified the values in cold to a better performance and agreement according with the perception of the people that lives in that cities. Also, a correlation of thermal swing and RH of the 96 biggest cities of Mexico was presented.

The values modified with the BEC show better relationship with the perception of the people and their climate than those without BEC. Nevertheless, the BEC seems to be not enough to correct the gap between reality and perception. It is possible that the BEC has some relationship with the circadian rhythm.

Further researches should aim to tune the limits of the blanket effect in terms of hours and restrictions and its possible relationship with the circadian rhythm. Also, should aims to adjust the correlation between the thermal swing and the RH to identify the confines of the climatic zones.

## Acknowledgments

**Abstract:** The knowledge about microclimate and its influence on people's thermal comfort becomes critical to the planning process of all types of environment. In leisure facility design, guaranteeing the user's thermal comfort has become increasingly essential, since it affects the activities, usage characteristics and the time people spent in these spaces. Recent researches on thermal comfort aim at creating guidelines for attractive outdoor environments that contribute to improve urban quality of life and consider environmental factors (air temperature, wind speed and relative humidity), which affect the users' thermal perception and satisfaction. In this context, this pilot project of a larger project investigated how the different levels of shading affect users' thermal comfort in outdoor leisure spaces. It was conducted in Bauru Municipal Zoo Park, São Paulo State, Brazil, through the analysis of microclimatic research, questionnaires, and field observations in cold weather conditions for three days. These surveys allowed to identify the actual sensation votes (ASV) calculated through the PET index (Physiological Equivalent Temperature), in two subspaces with the same attractiveness and different levels of shading. The analysis of the results highlighted: 1.Great number of comfortable users' in the area with greater shading during times of greater solar heating; 2. Users' short exposure in the area of high incidence of direct solar radiation; and 3. Range of thermal neutrality in the PET index varied in relation to the two subspaces. The results show the close relationship between levels of shading, thermal comfort and exposure time in the outdoor space.

**Keywords:** Outdoor thermal comfort, time exposure, levels of shading, PET index, urban parks.

## **Introduction**

Urban parks composed of large green areas are key environments for people's well-being, as they have the purpose of improving the quality of life through leisure offer, landscaping and environmental preservation.

Studies in various climatic and cultural contexts have emphasized the thermal comfort in outdoor spaces, since they affect the activities and usage characteristics of users in squares and parks (NIKOLOPOULOU; BAKER; STEEMERS, 2001; ZACHARIAS; STATHOPOULOS; WU, 2001; THORSSON; LINDQVIST; LINDQVIST, 2004; THORSSON et al., 2007; LIN, 2009 and LABAKI et al., 2012). These researches seek to provide subsidies for the creation of attractive external environments, which favor daily use by the population.

In outdoor spaces, thermal comfort state is strongly influenced by user's satisfaction, and this factor makes the definition of comfort limits very complex to define in these environments, since it involves the understanding of the interrelationship between many different parameters (NIKOLOPOULOU, STEEMERS 2003).

According to Nikolopoulou and Steemers (2003), an analysis based only on physical parameters, used in predictive models, is not enough to describe the comfort conditions in outdoor spaces. Therefore, these authors point to the importance of the adaptive conditions (physical, physiological and psychological) in the thermal comfort sensation of the users. Among them, the psychological adaptation is of extreme importance, since the behavioral and psychological factors affect the satisfaction of the users and contribute to the existing differences between the actual sensation votes (ASV) and the thermal comfort calculated through predictive indexes.

In this context, a pilot study was developed as part of a larger study investigating whether the different levels of shading affect the thermal comfort of users and their time of exposure in outdoor spaces of leisure, in different weather conditions. It is worth noting that the relationship between thermal comfort and permanence time is still a subject rarely explored in research (NIKOLOPOULOU and STEEMERS, 2003; ALJAWABRA and NIKOLOPOULOU, 2010; YANG et. al., 2013; LIN et al., 2013; LI et al., 2016; SABBAGH et al., 2016).

## **Materials and methods**

In order to investigate the relationship between levels of shading, thermal comfort and time of exposure in the outdoor space, a pilot study was developed in the Bauru Municipal Zoo Park (Lat. 22°18'54" South, Long 49°03'39" West and average altitude of 530m), medium size city of the State of São Paulo, Brazil. The local climate, according to Köepen's climatic classification, is Aw, characterized as a tropical climate with summer marked by high temperatures and rains and mild and dry winter.

The two spaces chosen to conduct the survey have the same attractiveness and are part of the feline area (Figures 1 and 2), and have been called Subspace 1 and 2. Subspace 1 is located in front of the lion cage and has a smaller Sky Vision Factor - SVF (0,473). Subspace 2, located in front of the "jaguar" cage, has a higher SVF (0,712).

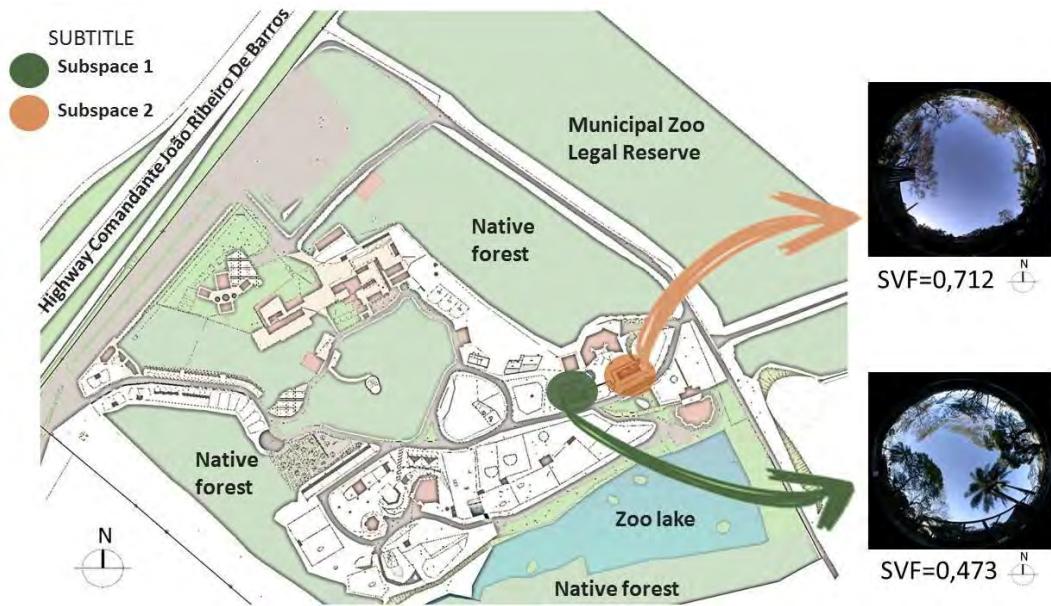

Figure 1. Internal map with highlight for the study areas and SVF. Adapted from <http://www.zoos.mono.net/upl/14646/Bauru.jpg>.

Figure 2. Areas of study.

From the choice of these subspaces, the following methodological steps were taken: image capture for SVF determination, monitoring of environmental variables, survey of activities, application of questionnaires to users, survey of climatic data and identification of comfort range. A Nikon Coolpix 4500 photo camera with fisheye converter FC-E8 was used for capturing images to calculate the Sky Vision Factor (SVF). For the monitoring of environmental variables, the HOBO H8 Pro Series was used to collect data on air temperature, globe temperature (HOBO external sensor with gray globe, built with an official ping-pong ball, painted in gray) and a direct reading thermohygrometer to collect wet bulb temperature.

Simultaneously with the microclimatic survey, questionnaires were applied, based on the RUROS Project - Rediscovering the Urban Realm and Outdoor Space (NIKOLOPOULOU; LYKOURDIS, 2006) for the identification of the Actual Sensation Vote (ASV)

of users on a 5-point scale (-2 very cold, -1 cold, 0 comfortable, +1 warm, +2 very hot), the thermal preference and thermal acceptability (comfortable, uncomfortable), and also the uses, activities developed and identification of the profile of users (gender, age group, clothing). The questionnaires were applied to a sample of 196 users (98 in each subarea), defined for a fixed user range (from 3500 to 4000 users, counting the 3 days), in which case the margin of error was approximately 10%.

The data of the meteorological variables of the field survey period were obtained at the Bauru Meteorological Center (IPMet) of the UNESP Campus of Bauru. Comfort ranges were identified through analysis of the PET index and its relationship with thermal sensation, thermal satisfaction and acceptability of users at different levels of shading (related to SVF). Users' exposure in the areas was also investigated, where photographic records were taken every 3 minutes, with a common photographic camera supported on a tripod. The field survey was performed for 3 days (02<sup>nd</sup>, 03<sup>rd</sup> and 04<sup>th</sup> of July, 2016), in the subspaces 1 and 2 (the lion and "jaguar" cages, respectively), from 10:00 a.m. to 4:00 p.m. According to IPMet, this winter period was characterized by low humidity (42.92%), and the temperature variation registered in the 3 days was of a minimum of 19.4°C (03/July at 6:30 p.m.) and the maximum of 28.2°C (on the 03<sup>rd</sup>, at 1:00 p.m.).

### **Results and discussions**

Through the analysis of the questionnaire data, it was possible to verify that 49% of the visitors are from the city of Bauru; and the majority (50.9%) says they make annual visits to the park, mainly at weekends, or during school vacations. These results reveal the importance of the zoo to the region, since the other 51% of visitors are from nearby towns. Table 1 shows the values of the users' profile, metabolic rate and level of clothing insulation.

The measurement days were characterized by the first hour with milder temperatures in the two subareas of study (Figure 3). Relative air humidity, at the beginning of the measurement, presented an average value of 71% subspace 1 and 57% subspace 2. The period from 12:00 p.m. to 01:00 p.m. on the 3 days shows higher temperatures, reaching an air temperature in subspace 1 of 29.9°C and the average relative humidity of this time of 34%. In the subspace 2, the values at this period were: average temperature of 31.5°C and average relative humidity of 27%.

Table 1- Users' profile, metabolic rate and level of clothing insulation.

GENDER	AGE	METABOLIC RATE	LEVEL OF CLOTHING INSULATION	FREQUENCY OF VISITATION
52.40% Female	31.73% 35-44 years	100% w/m <sup>2</sup>	110 60% - 0.5 clo	50.95% yearly
47.60% Male	30.29% 25-34 years		7.21% - 0.22 clo	19.71% first time
	16.83% 18-24 years		32.79% - 0.45 clo	15.87% semester

	6.25% 55-64 years			3.37% monthly
	1.44% >65 years			1.92% every two years
				0.96% every five years
				0.49% every four months

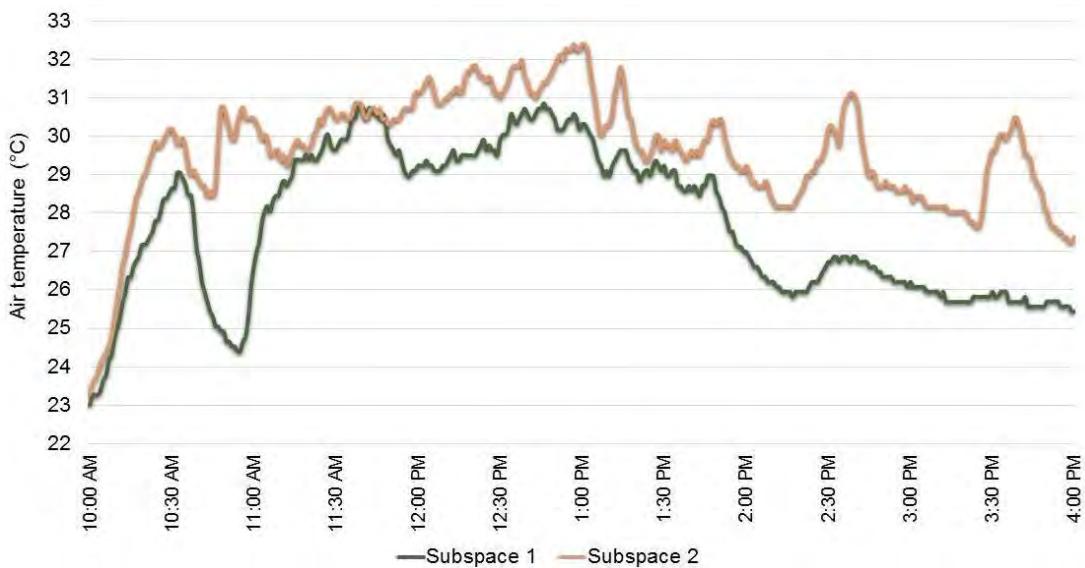

Figure 3. Average hourly temperatures of the 3 days of measurement (July 2<sup>nd</sup>, 3<sup>rd</sup> and July 4<sup>th</sup>, from 10 a.m. to 4 p.m.).

If the data collected on the subspaces were compared to those recorded by IPMet, the differences in air temperature reached 9.2°C at 12:52 a.m. of the first day of collection in the jaguar area. The air humidity in subspace 1 was higher, an average of 11% higher than the air humidity in the local Meteorological Station, whereas in subspace 2 the values were similar to those of the IPMet.

According to the questionnaire, the degree of interest of the users by these felines was similar, but the users showed little tolerance to the incidence of direct solar radiation, and therefore, the visitation period of the users to the jaguar site was shorter, due to lack of sun protection in the space.

Through the photographic records, the average length of stay in this space was less than 3 minutes, while in the lion site, the recorded time was 3 to 12 minutes. Sabbagh *et al.* (2016), in a survey conducted in Dubai, conclude that when users felt "uncomfortable", they remained no more than five minutes in the area exposed to the sun, and as a mechanism to return to the stage of "comfort" they remained a longer period in shaded areas.

An example of the records for analysis of the length of stay can be seen in Figure 4.

Figure 4. Example of records for analysis of the length of stay.

This difference cannot be attributed to the fact that one animal is more interesting than the other, because according to the questionnaires, the interest of the users by these felines was shown to be of similar degree (Figure 5), but because subspace 1 has a milder microclimate due to lower SVF.

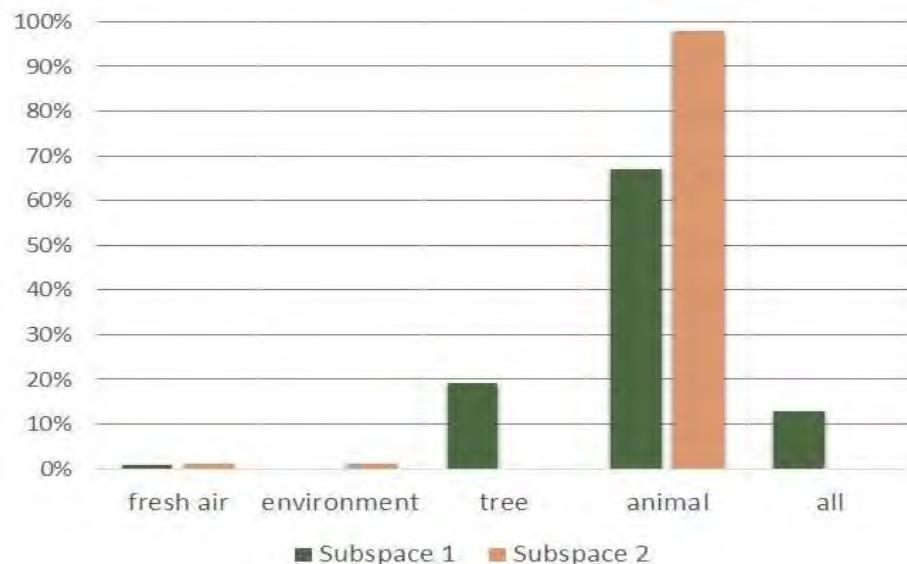

Figure 5.Location preference chart.

In subspace 1, which is shaded by vegetation and with a more pleasant microclimate, the majority of users (57.8%) showed satisfaction with the environment in general, since they felt comfortable. In the second area, the users' dissatisfaction was related to the lack of shading, where 74.8% of respondents reported as the main feature to be changed, because it directly affects the microclimate.

Figure 6 compares the thermal sensation and preference of users in the two areas of analysis.

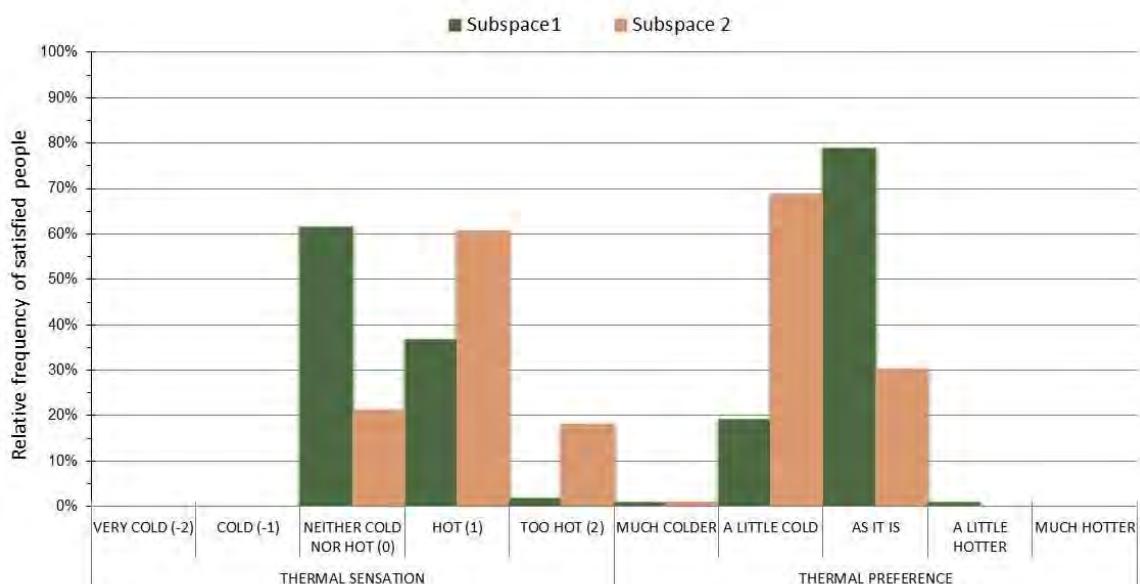

Figure 6.Comparison of thermal sensation and thermal preference of users in the study areas.

It is clear the difference reported by visitors regarding microclimate preference: in subspace 2 almost 70% of respondents throughout the day say they prefer the microclimate a little cooler, while in subspace 1 approximately 80% of users prefer the microclimate as it is. Figure 7 shows boxplot graphs for all PET temperature values grouped according to the ASV.

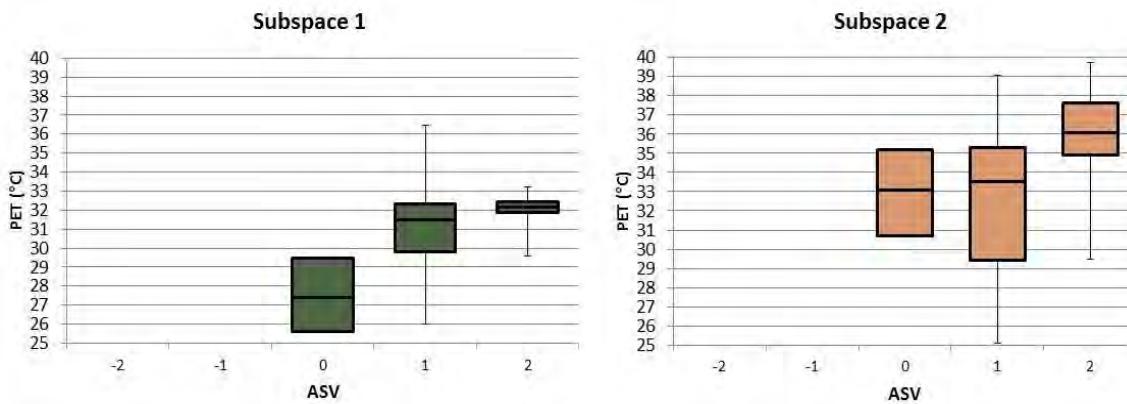

Figure 7.PET temperature range related to users' ASV ranges in subspace 1 (lion) and 2 (jaguar).

The neutrality values for the PET temperature in subspace 1 ranged from 25.6 to 29.5°C; in subspace 2 from 30.6 to 35.3°C. Referring to Figure 7, the thermal neutrality in subspace 2 is within the range of heat discomfort (+1) comprising temperatures from 24.4 to 35.4°C. Another factor observed was that although subspace 2 presented a higher percentage of uncomfortable users, the comfort limits tolerated by the respondents were greater than in subspace 1. This factor can be justified by the adaptation and tolerance of each one to comfort, which changes from person to person, and the psychological factor of satisfaction with the space where, according to Coutinho (1998), not all people have the same thermal sensation in the environment they occupy.

### **Final considerations**

The results of the research contributed to the confirmation that different levels of shading by trees, in outdoor spaces of leisure, decisively interfere in the conditions of thermal comfort and in the time of permanence of the users. Thus, the better microclimatic quality observed in subspace 1, with less SVF (Lion site), contributed to a greater percentage of comfortable people (80%) and their longer permanence time (up to 12 min) at the site. Whereas in subspace 2 (jaguar), with higher SVF, the greater thermal discomfort due to heat (75% of respondents) contributed to a reduction in exposure time (less than 3 min), due to the low tolerance of users to the direct solar incidence. It should be noted that the evaluated weather conditions were during the local winter period when air temperatures are warmer and air is drier. Therefore, the microclimatic conditions in both subspaces may be more aggravating on summer days, when temperatures are higher and relative air humidity is greater.

The research of this pilot study will continue in hot weather conditions. However, the results obtained here, in addition to highlighting the need for interventions to improve local microclimatic quality also contributed to prove the relation between thermal comfort and length of time spent in outdoor spaces, an investigation that has been little explored in the studies of the area.

## The Integrated Urban Regeneration and Climate Change in the Spanish Peninsular Mediterranean: The Case of the Coast of Málaga

Cristina Gallardo Ramírez<sup>1</sup>, Mª Teresa Pérez Cano<sup>1</sup> and Domingo Sánchez Fuentes<sup>1</sup>

<sup>1</sup> Department of Urban & Regional Planning, School of Architecture, University of Sevilla, Sevilla, Spain, crigalram@alum.us.es; tpcano@us.es; dsanchez@us.es

**Abstract:** Currently, the peninsular Mediterranean coast is the most urbanized and populated area of the country, with the Western Costa del Sol (Málaga) as a paradigmatic case, in which the anthropized surface surpasses, in some of its municipalities, 90% in its first 500m and 80% if it is advanced to 2 Km. The loss of habitats, ecosystems and their services, are the result of these urbanization processes and of their unsustainable patterns of consumption of scarce or non-renewable natural resources, with direct negative influence on the foreseeable effects of climate change on this coast, as well as on its main socio-economic activity, tourism (which also contributes to trigger this phenomenon). The objective of this research is to diagnose the initial situation and the singularities of this territory, in order to detect the main challenges and starting to outline the most appropriate strategies for their integrated regeneration, where mitigation and adaptation from the climate change would be considered. The methodology used is supported by the analysis of recent scientific production, which addresses the phenomenon of climate change in coastal areas and, from its detailed study, establishing the state of the question at hand and defining the suitable measures for the coast of Málaga.

**Keywords:** climate change, Western Costa del Sol, tourist-residential model, integrated urban regeneration.

### Introduction

As a result of the colonization process experienced by the peninsular Mediterranean coast, driven by tourism and real estate, which began in the middle of the XX century, rural territory and economy are replaced by a fragmented space, mere support of extensive tourist-residential urbanizations, accompanied by the recreational uses that these demand, generating a new economy based on service sector and construction, linked to tourism. The transition from an agricultural structure to a tourist model, led to the loss of the territory's role as a producer of food and support of resources such as water, basic for the subsistence of the population, allowing relocation and uncontrolled urban growth.

The result of the above would be the progressive filling of the first peninsular coastline in which an urban continuum is formed, where more than half of the population of this coast is concentrated in its first 2km. In this process the province of Málaga stands out in which the transformation reached 56.91% of its surface area in 2011 (Estévez et al, 2016), with the highest percentages of the coastal municipalities of the Western Costa del Sol region (henceforth WCS) (figure 1), 89% of Mijas, 86% of Benalmádena, 81% of Marbella (Villar-Lama, 2011), generating what has been defined as a linear city on a territorial scale that currently exceeds the provincial limits, entering the province of Cádiz.

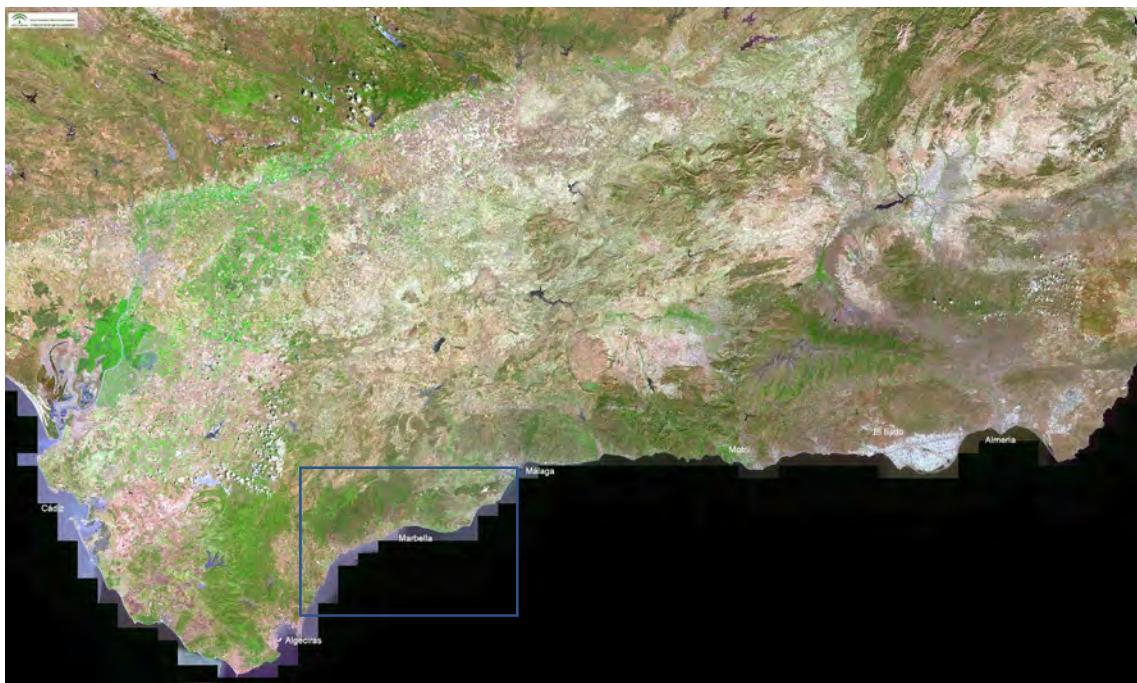

Figure 1.WCS. Andalusian Mediterranean coast. <http://laboratoriorediam.cica.es/VisorGenerico/>

Within this coastal border, the state of its first 500 m, measured from the maritime public domain on land, is particularly concerning. In which, multiple economic interests and different administrative competences converge, resulting in particular vulnerable to certain phenomena (raising the sea level, coastal regression, increased flooding due to extreme weather events, etc.) effects, all, linked to climate change.

At the tourist-real estate level, this first strip of 500 m with high scenic value generates the greatest speculative interests given its strategy value as well as for its physical proximity to the sea. Note in this regard, that the urbanisable soils included in the urban planning in force legitimise the transformation of the last vacant spaces, which paradoxically, constituting one of its main threats. On the Mediterranean coast of Andalusia, 41,60% of the area was occupied by artificial uses in 2011, while in the province of Malaga it was 74,82% (Estévez et al, 2016), however previously in 2005, the percentage surpassed in the WCS (90% of Marbella, 59% of Estepona, 91% of Mijas, 95% of Fuengirola, 90% of Torremolinos, or 85% of Benalmádena) (Prieto, 2013).

The implementation of this tourist-residential model has generated, as collateral damage, the disappearance of habitats and coastal ecosystems, wetlands, dune systems, orchards, etc., minimizing the ecosystem services of supply of water, of energy, greenhouse gases absorption, regeneration of urban waste and waste water, etc. These factors have an impact on the generation of greenhouse gases, (henceforth GHGs), responsible for the greenhouse effect that cause global warming. This phenomenon leads, in a long-term, to the changes in Earth's climate or over its weather patterns, known as global and anthropogenic climate change, whose effects on this coast are the scarcity of rainfall and with them of drinking water. The increase of the episodes of torrential rains and with them of the floods. The rise of the level of the sea, temperature increases, etc.

Lastly, this work is structured in a first section that identifies some of the main effects related to climate change in the Mediterranean coast in general, and in the Western Costa del Sol in particular. A second section analyses the urban metabolism of the WCS, which is influenced by the tourist activity, or its ecological balance, using as an indicator the ecological

footprint and the carbon footprint. Finally, the conclusions outline a set of measures, still of a general nature, to address the regeneration of this space, linked to mitigation and adaptation to climate change.

### Vulnerability to flooding and rising sea levels and their link to climate change

The Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment (AR5, 2013-2014) establishes, for the year 2100, forecasts of average sea level increases of between 26 cm and 98 cm, depending on the scenarios evaluated. At the same time, it announces for medium-latitude territories such as Andalusia, extreme precipitation events which will probably become more intense and more frequent. It will suppose on the Mediterranean coast Andalusian, an increase in the floods by overflowing river channels (usually short-haul and steep slopes), especially of the lower topographic level sections, closer to the river mouths.

The risk of flooding or coastal erosion due to sea level rise, as a result of the global warming component, has a special impact on those urban areas adjacent to the maritime public domain, where sediment inputs have been observed depleted by the presence of artificial protection elements, which have altered the coastal dynamics. These phenomena, in turn, hinder the evacuation of river waters, increasing the likelihood of overflowing their channels. This situation is exacerbated in the WCS case by the urban transformation of the coastline that has occupied and constrained the flood plains to extreme limits, might pose high socioeconomic damages in terms of the assets potentially affected by flooding, reducing the availability of spaces that allow the cushioning or adaptation to the rise of the sea level and increasing the sedimentary imbalance.

Given the environmental and socioeconomic deficits, resulting from the high level of territorial artificialization and flooding risk identified, in this analysis we will focus on the Western Costa del Sol, strip of coast of Málaga between Torremolinos and Manilva municipalities.

Recently, along the coastline of the WCS, 77,79km of coastline and 129km of river channels have been delimited, subject to potential significant flood risks of marine and fluvial origin (scenario T = 100 years), as well as 4,1km<sup>2</sup> with risk of marine flooding in which 8.655 inhabitants reside (SNCZI, 2016), mainly concentrated in Fuengirola, Marbella (figure 2 and 3), Estepona and Mijas municipalities.

Figure 2. Urban continuum in Marbella. WCS. Areas with Significant Potential Flooding Risk  
<http://sig.mapama.es/snczi/visor.html>

Figure 3. Las Chapas district, Marbella. WCS. Area with Significant Potential Flooding Risk.  
<http://sig.mapama.es/snczi/visor.html>

### The western Costa del Sol: Tourist activity and urban metabolism

Currently, the urban-tourist continuum of the WCS (figure 4) is made up of 48% of its extension by residential areas and golf courses (Villar-Lama, 2013). As a result of this expansive model and the absence of efficient public transportation, mobility in this environment depends basically on the private vehicle, as we know, a large consumer of energy and one of the first GHGs generators in this environment, to which there is no alternative than displacements by road, in the municipalities to the west of Fuengirola, where the railroad come to an end.

Figure 4. Western Costa del Sol Region. Urbanized area of the coast. 2011.  
<http://laboratoriorediam.cica.es/VisorGenerico/>

In this territory, the consumption of water, energy or the generation of urban waste is significantly higher than that of the traditional city, which is largely justified by the greater demand linked to tourism and, in a significant way, by the increasing presence of climatic immigrants (people who change their place of habitual residence, mainly for climatic motivations, at least six months a year) (Requejo-Liberal, 2007), from central and northern Europe. We point out that, on this coast, they are mainly of British origin, and given their patterns of consumption of natural resources and contamination by waste, adequate to those of their place of origin, they show higher rates than local ones.

### ***Water consumption and wastewater regeneration***

The growth of the population and the tourist activity, combined with traditional agricultural use, are the main reasons for the water demand of the Andalusian Mediterranean coast, especially intense during the summer period, when rainfall is practically zero, questioning the guarantee of supply of the area. These circumstances will be exacerbated by the average reduction in precipitation due to climate change of 7%, 16% and 25% in the periods 2011-2040, 2041-2070 and 2071-2100, which will lead to a decrease of 12%, 30% and 41% of the runoff, higher than the national forecast (CEDEX, 2012).

On the WCS, the narrow coastal strip between Estepona and the low river Guadalhorce, where a number of aquifers of interest are located, was once occupied by fertile farmland which, to a large extent, disappeared under the present continuous urban strip. Both of them uses continue to demand an enormous amount of water, the urban ones almost tripling in the summer periods. This is why it is used the resources generated by the marshes, the desalination plants, the regenerated waste water for irrigation, the direct water intakes of the river channels but, mainly, from the overexploited coastal aquifers, with a 59% of total resources (Gómez et al, 2001). Being even detected phenomena of marine intrusion, among those closest to the coast. This situation causes the deterioration of surface and groundwater, which also endangers the maintenance of ecosystems.

At the beginning of the first decade of the 21st century, the volume of demand for annual water in the WCS amounted to 187,44hm<sup>3</sup>, the main percentage was allocated to the urban supply with a 56,17% of the total (25% destined to the residential urbanizations), a 3,18% to irrigation of golf courses, and the remaining 40,65% to agriculture (Natera-Rivas, 2005). Human consumption has remained practically constant in that decade, accounting for 113,15m<sup>3</sup> per inhabitant per year (309,6liters per inhabitant per day) in 2009. This level of consumption is unsustainable, being well above the already high 247liters per inhabitant and per day, recommended according to the Hydrogeological Atlas data, for the Province of Malaga (Jiménez-Madrid, 2014).

Thus, the WCS is considered as one of the most unbalanced areas in terms of demand and water resources of the province. The overexploitation of its aquifers is alarming and it is joined by lower than average rainfall in recent years, questioning the guarantee of supply if the dynamics of growth of urban demand go on (which is derived from the increase in population, and the standard of higher consumption among tourists and climatic immigrants). To address this water deficit, the reuse of regenerated water in waste water treatment plants (henceforth WWTPs), as water for irrigation has been proposed. Along this line, between 2001 and 2003, about 3Hm<sup>3</sup> per year were used for irrigation of golf courses, which meant scarcely between 5% and 7% of the total purified water (Miranda-Páez, 2005). Currently, almost 20% of the total volume of purified water is destined to irrigate 34 of the 43 golf courses in the area (which has risen alarmingly in recent decades). To the still insufficient

reutilization of the reclaimed waters, there is also the added necessity of resizing of the WWTPs, which work above its capacity, surpassed by the continuous population growth.

### ***Generation of waste and electricity consumption***

In 2014, urban waste generation in the WCS amounted to 304.664 tonnes and electricity consumption reached 2.254.558MWh (53,3% in the residential sector and 33,4% in the commercial services sector) (MADECA, 2015). Based on the population census, 519.769 inhabitants (29,0% foreigners) as of January 2014, establishes a production of 586,15kg of urban waste per person, and a consumption of 2,31MWh of electricity for residential use, much higher than the 487kg of waste or the 1,33MWh consumed per resident in the municipality of Málaga, which is basically justified by the higher standard of consumption of tourists and climatic immigrants. In the case of waste, the figures also question the efficiency of local recycling and reuse measures.

### ***Ecological balance***

Adopting the ecological footprint as an indicator of the sustainability of human behavior over its territorial environment, the Western Costa del Sol reaches 4,6537 hectares per inhabitant (compared to the Andalusian average of over 3,5hectare per inhabitant), according to the population data and the demand for resources of the year 2000. The bioproducing area needed to attend to it, would be 24,16 times the total area of the coastal municipalities, identifying a situation of clear ecological deficit (Cano-Orellana, 2007).

Upon analysis of the carbon footprint, in order to determine the total amount of GHGs produced as a consequence of human activity, between 2000 and 2013, the average of emissions in the coastal municipalities amounted to 1.365.513Tons of CO<sub>2</sub> equivalent, and the sink capacity of 15.163Tons of CO<sub>2</sub> equivalent. For the purpose of comparison, in Malaga capital, emissions and carbon sink capacity amounted to 2.085.354 and 14.728Tons of CO<sub>2</sub> (REDIAM, 2015) equivalent, more than 1,5 times the emissions of the municipalities of the WCS, for a very similar carbon sink capacity.

This huge imbalance between emissions and absorption frees virtually all GHGs generated in this environment, mainly by road traffic, electricity consumption, waste treatment and wastewater. The reduced capacity of the coast as a sink for these gases derives from the deep artificialization of the coastal strip, with the consequent scarcity of arboreal masses and free soil, which are principal in charge of this function. This situation could be extensible to most of the municipalities along the Mediterranean coast of Andalusia.

Thereby, for the period 2000-2008, coinciding with the last real estate bubble in Spain, the carbon footprint of some municipalities of the WCS stands out, concretely, 6,08 Tons of CO<sub>2</sub> equivalent per inhabitant in Marbella, 4,6 in Mijas, or 4,5 in Torremolinos (Jiménez-Madrid, 2014).

### **Conclusions**

Currently, the peninsular Mediterranean coast is the most urbanized and populated area of the country, with the Western Costa del Sol (Málaga) as a paradigmatic case, in which the anthropized surface surpasses, in some of its municipalities, such as Marbella or Mijas, a 90% in its first 500m and a 80% if it is advanced to 2 Km. In spite of the excessive levels of urbanization reached, of the large number of existing vacant or secondary dwellings (which total 148.015 units in front of the 194.398 main houses, data from 2011) (MADECA, 2015),

and the potential risk of flooding due to rising sea levels, a large part of the vacant spaces is exposed to a possible, and legal, transformation into new urban land.

The fruit of this tourist-real estate activity, in the Costa del Sol region the population growth has remained practically constant since its origin, being difficult quantifiable the real population since to the population census, which currently exceeds half a million inhabitants. Beside, people who are not registered as residents, but residing in this coast, should be added. Inside of this group a growing number of climate immigrants could be include, as well as the seasonal population formed by tourists, thus exceeding one a million of real inhabitants during the summer months. In this respect, referred to 2003, The Regional Planning for the WCS (annulled in October 2015) had estimated 616.314 inhabitants as real population figures (facing only 290.200 residents registered) and, with the floating resident population, mainly tourists, would have reached close to one million inhabitants.

The result of these processes and unsustainable patterns of consumption and behavior (the ecological deficit and the GHG emissions of the municipalities that make up this coast prove it) are the loss of habitats and ecosystems as well as the deterioration of regulation or supply services, or cultural activities, that they provide. They call into question the guarantee of water supply and even of energy, the management of waste or the maintenance of their cultural heritage, due to the carrying capacity of this territory has been amply exceeded, especially during the peak time summer.

In addition to the disappearance of habitats and coastal ecosystems, the foreseeable effects of climate change on this coast, above described, have a direct and very negative impact on the quality of life and human health, as well as on its main socio-economic activity, tourism, which is especially vulnerable to the scarcity of rainfall and with them of drinking water; the rise of the level of the sea; and temperature increases. Phenomena, which in turn contributes to trigger, given that 5% of total global CO<sub>2</sub> emissions came from tourism, a 75% corresponds to transport (AR4, 2007).

In this regard, a sustainable tourism activity requires mitigation strategies such as revaluing and fostering proximity in the choice of destinations, as well as prioritizing the reduction of energy consumption, the efficiency, and betting on energies coming from renewable sources, especially in air transport and its low-cost format, which is the most responsible for GHG emissions linked to tourism. At the institutional level, the efficient use of airspace and thereby the reduction of fragmentation, or the establishment of emission rates, are some of the measures tested at EU level. Lastly, regarding to companies linked to tourism, *they must establish a code of good practices that include environmental planning criteria and predisposition to the application of regulatory measures, and be involved in the management of the destination* (Valls y Sardá, 2008).

*It can be concluded that the integrated regeneration of this space, must go hand in hand with the real awareness of the political class about the need for a change of the urban model of consumption in order to reduce its ecological footprint, of the citizen participation, and linked to the fight against climate change. Specifically:*

With the adoption of mitigation measures, on which the sustainability of tourism will depend, reducing the consumption of water and energy; promoting the generation of renewable energies; recovering and renaturalizing the coastal edges and the river channels, restoring their public character in cases in which they have lost it. Adapting buildings and its surroundings to the physical environment, with the use of bioclimatic strategies, the reduction of impermeable surfaces, the increase of green spaces, etc.

Identifying adaptation measures aimed at the protection and recovery of the coast and its ecosystems, beaches and dunes, traditional agricultural spaces, with the reintroduction of arboreal masses, etc.

With the adoption of protection, regulatory and planning measures, for the risk areas, in order to avoid the impacts caused by flooding; reducing the exposure of cultural and built heritage; modifying land uses, limiting new urban developments, and anticipating the progressive withdrawal or adaptation of existing buildings.

Integrated Coastal Zone Management (ICZM) with a supramunicipal vocation (in which all the agents with an interest in this coast participate in a coordinated way, and with the citizens playing a preferential role), would facilitate the successful implementation of these strategies against climate change, to be applied to the peninsular coastal strip of the Mediterranean and, particularly, to the WCS, strongly anthropized, favoring its integrated regeneration

## Productive Landscaping in Urban Built Environment

Jagadeesh Gorle<sup>1</sup> and Hema Rallapalli<sup>1</sup>

<sup>1</sup> School of Architecture, GITAM University, Visakhapatnam, India.

architectjagadeesh@gmail.com, hemasree.gsa@gmail.com

**Abstract:** Recent changes in the global climate pattern has witnessed increase in unusual rains and shifting weather patterns increasing the risk of food security. The demand for food in high density living areas is increasing the energy consumption for the transportation leading to higher carbon footprint. Moreover, in tropical countries like India where extreme weather conditions exist with summers being too hot and heavy rains flooding the cities during monsoons, the increase in concrete built forms and surface simplification are leading to the Urban Heat Island effect resulting in rise in local temperatures further increasing the energy consumption in built spaces. In this scenario, roofs with green vegetative covers act as good insulation while using waste water, gives a triple fold solution of maintaining air quality, reducing energy consumption and creating an alternative for food security by providing sustainable design solutions for multiple problems of urbanisation. In urban areas where land is one of the scarce resource, there is extensive potential for application of productive landscaping in cities, not only on land but also in the building components such as rooftops, fences, walls, balconies, property setbacks, etc. that adds a green envelop to these building components. In this paper we would be exploring the possibilities of integrating productive landscaping into urban design and built environment to achieve sustainable design solutions.

**Keywords:** Productive landscaping, urban agriculture, sustainable landscaping, food security, composting

### Introduction

The urban population in India is expected to grow to 404 million by 2050 (World Urbanisation Prospects, 2014) (See Figure 1). Many of our cities are ill equipped to handle such large-scale expansion.

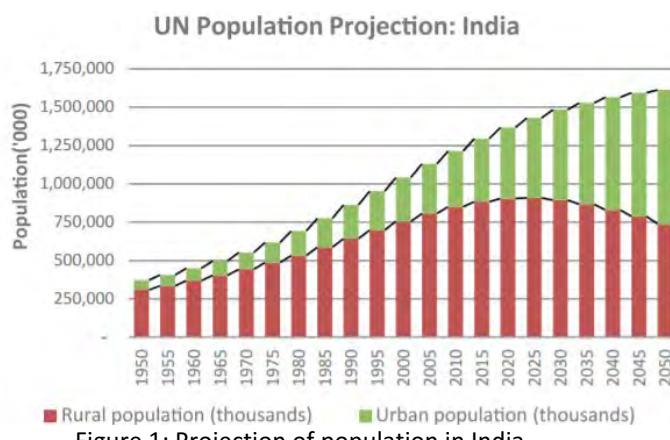

Figure 1: Projection of population in India

Resources are always limited and in a developing and highly populous country like India, resources are even scarcer. Population explosion results in the shortage of even the most basic resources like food.

## **Background: Issues and challenges of urbanisation**

There are a number of environmental, economic and social issues that are associated with urbanisation which needs to be studied and solved with a sustainable approach.

### **Environmental issues**

Climate change along with the El Nino effect, are expected to increase the frequency and intensity of current hazards, an increased probability of extreme events, spur the emergence of new hazards and vulnerabilities with differential spatial and socio-economic impacts. This is expected to further degrade the resilience and coping capacities of poor and vulnerable communities, who make up from a quarter to half of the population of most Indian cities (Satterthwaite, 2006). Hundreds of millions of urban dwellers in the Indian cities are at risk from the direct and indirect impacts of climate change. Without effective adaptation to climate change there will be very serious consequences for the most people residing in the cities in India.

Various climate models developed so far indicate following issues that would impact the cities (Bhat GK Raghupathi et.al. 2013)

- Temperature increase and higher variability leading to
  - Reduced comfort levels over longer periods across seasons
  - Increase in energy use for space cooling and heating
- Precipitation changes leading to
  - Drought, and extreme precipitation events
  - Changes in river hydrology causing floods, seasonal water scarcity
  - Cyclonic storms, storm surge and coastal flooding
- Heat island effects along with regional temperature increase
- Increasing demand of resources due to urbanisation i.e. for water, food, energy etc. leading to stress on urban ecosystem.

Since both urbanisation and climate change impacts are expected to simultaneously roll out in the coming decades, cities now are at a higher risk to the increasing severity of climate change.

### **Economic issues**

Mckinsey Global Institute (MGI) published a report “India’s Urban Awakening: Building Inclusive Cities, Sustaining Economic Growth” based on econometric model. During 2010-2030, urban India is expected to create 70 per cent of all new jobs in India and these urban jobs are expected to be at least twice as productive as equivalent jobs in the rural sector. If this demand is not met, both urban and rural areas are likely to face serious employment crisis.

Urban poor generally spend the major share of their earnings on food. Since the demand of food is higher in the cities, the cost of food is also higher making it harder for the Urban poor to meet their food needs. Poor urban dwellers, being largely net food buyers and depending mostly on markets for their food supplies, are particularly vulnerable to adverse food price shocks, and are consistently the group in society that suffers most from higher food prices. (See figure 2)

Figure 2: Diagram explaining the social, economic and environmental issues of urbanisation

### Social issues

In urbanisation, we see a constant influx of people from the rural areas in search of employment. Overcrowding of cities lead to a constant problem of scarcity of houses in urban areas leading to more and more slums. Impacts of inadequate housing conditions and basic amenities are an intricate issue involving variety of exposures that are physical, chemical, biological and social leading to various health and social issues. Increase in food prices make the urban poor the most vulnerable group to the necessity of food and nutrition. Food contamination is one major problem that takes a toll on the health of the whole urban population. Moreover, the environmental impacts of urbanisation like increase in temperatures, air and water pollution, lack of breathable air, etc. have serious effect on the health and wellbeing of the city dwellers.

### Productive landscaping as a solution to the many problems

As discussed in the earlier section, to meet the global challenges of the 21<sup>st</sup> century like urbanisation, climate change, food crisis, water crisis etc., we need to progress towards development with efficient use of available resources understanding the symbiotic relationship between urban planning, architecture, infrastructure, landscaping etc., for a culturally, economically, and environmentally productive urban realm. A one point solution to these many challenges is sought out to be urban agriculture. As quoted by Thomas Jefferson, "Agriculture is our wisest pursuit, because it will in the end contribute most to real wealth, good morals, and happiness."

The concept of kitchen gardens and localised food production is not new to the households of Indian sub tropics. It is an ancient practice where every household had some food producing plants and trees which were used for their own consumption and the excess produce was distributed in the neighbourhood. This practice also helped in maintaining the biodiversity of the region and have cleaner and healthier living conditions. However, overtime this practice became less with the cities becoming crowded and congested and the gardens being replaced by lawns and decorative plants. We reached a point that the current generation living in the cities think that growing their own food is not possible in the cities or they are not aware of how to do that.

Figure 3: Diagram explaining how productive landscaping is a solution to the issues of urban areas

Small scale and localised food production is possible in the backyards, gardens, lawns, balconies, indoors, roof tops, window sills and even walls. The major difference between rural and urban agriculture is that, in case of urban agriculture, the consumer is the producer so their production is made specific to their need which reduces waste. Urban agriculture will help the city to adapt to climate change and reduce its ecological foot print. Growing food in urban areas contribute to disaster risk reduction and adaptation to climate change by reducing runoff, reducing urban temperatures, sequestering CO<sub>2</sub>, while growing fresh food close to consumers reduces energy spent in transport, cooling, processing and packaging, whilst productive reuse of urban organic wastes and wastewater (and the nutrients these contain) reduces methane emissions from landfills and energy use in fertilizer production (See Figure 3).

Productive landscaping can also be socially productive. Urban farming provides employment to the city's slum dwellers. Urban farming also facilitates women empowerment, because women have a higher potential of becoming urban farmers as this activity can often be more easily combined with their other tasks in the household. Having community farms and community kitchens headed by women will make the process of food production, preparation and sale of healthy meals to the working community more streamlined and help them become entrepreneurs in the healthy food business. Community involvement in producing food will enhance the social fabric of the region as working together on something productive to the environment and themselves will give the urban farmers a sense of achievement through self-sustainability and unity. The activity involved such as watering and pruning also provides an individual some physical and/or psychological relaxation. Urban farms may also act as recreational areas for people to take walks, pick up fruits, buying fresh produce, educating children about how nature works by bring them in contact with farming, getting them involved in the farming activity etc.

Urban agriculture is a solution to reduce urban poverty, provide food security, decrease the dependence on food imports, and improve the quality of the food with sustainable practices. The importance of urban farming is increasingly being recognised by international organisations like UNDP, UN-Habitat and FAO (World Food and Agriculture Organisation) etc., however it is not widely practiced in India because of lack of know how. It is hoped that this paper will prove the importance and provide guidelines for the wider adaptation of productive landscaping in the urban built environment.

### **Methodologies for incorporating productive landscape in urban areas**

The main challenge with urban agriculture is the availability of land for cultivation. Therefore, we need to incorporate productive landscaping into the urban fabric where ever we have the possibility. Productive landscaping can be incorporated into the urban fabric at various scales: at building, street, neighbourhood and city levels. The potential and various design methodologies in maximizing the usage of the space are explained below:

- Productive Streets
  - Shared spaces /common spaces can be maintained by the communities at neighbourhood level
    - Use of fruit bearing trees instead of ornamental landscaping
- Areas in communities where land is available - vacant plots and large open spaces
  - Creating urban food forests in open spaces
    - Enrichment of contaminated soil using leaf litter from parks, avenue plantations, kitchen waste, etc., that can be converted to compost and used improve soil quality.
    - Softening the soil – modification to make it suitable for farming
    - Dig trenches for water percolation
    - Multi-layered diversified plants which increases the resistance towards pest attacks and natural disasters. Plants will be mutually benefit from the companionship compared to mono-cropping. This also requires less water because of high dense planting pattern there will be less evaporation from the soil (See Figure 4).
    - Mulching from the weed on site and dried leaf litter will retain the water in the soil for longer reducing the demand on irrigation.
- Areas in communities where land is a constraint – small spaces and building elements
  - Small spaces around houses and buildings
    - Replacing lawns with productive landscaping – Space can be optimised by going for modular units that can be multiplied as per the space availability (See Figure 6)
    - Use of vertical garden units where there is space constraint
    - Use of hanging pots
  - Rooftops
    - Reuse containers such as paint cans, water cans, buckets etc. to grow plants (See Figure 7)
    - Grow plants in plastic grow bags or used cement bags which are lightweight that do not add extra weight to the roof.
    - Creating raised soil beds on roof.
    - Use of vertical units using PVC pipes (See Figure 5)

- Balconies/Window sills
  - Can grow food producing plants such as green leafy vegetables, tomatoes, eggplant, okra etc in potted plants or grow bags
  - Use of vertical farming units
  - Use of hanging pots to grow food.
  - Use of balcony grills to grow climber plants.
- Walls
  - Climbers along the walls with support meshwork
  - Containers attached to wall
  - Use of trellises

Growing medium where soil is not available in abundance

- Use of Cocopeat
  - Naturally available material at affordable cost in Indian cities
  - Lightweight, so it can be used for balconies, window sills, terrace farming, green walls etc.
  - Because of the fibrous structure the moisture retention capacity is higher compared to the soil
  - It is loose which allows the plant root system to expand freely resulting in more healthy and productive crops
  - Adding vermi-compost will enhance the productivity of cocopeat medium
- Use of water for growing food (Hydroponics)
  - There is a high demand of water in urban areas therefore, we can use gray water (from kitchen, shower, sink, washing machine etc.) that is treated to the usable standard using simple mechanical process.
  - Collecting rainwater for irrigation of crops will reduce the burden on municipal sewage system.
  - Wetland crops can be grown along water streams and lakes
  - Water consumption can be reduced by going for polycropping instead of monocropping
- Improving the quality of the soil through composting organic material
  - With the process of composting we can convert the organic kitchen waste, dried leaves, grass clippings, wood waste, waste paper and cardboard into humus which increases the nutrients in the soil.
  - Adding earthworms or effective micro-organisms during the process of composting will further enhance the nutrient value in soil.

Figure 7: Showing the urban farming practices by few individuals in Visakhapatnam, India

## Conclusion

Local food production plays a large role in creating self-sufficient communities that are not dependent on food imports or on food that has travelled by road across the country. Productive landscaping, therefore is a holistic solution to our dependency on oil, energy consumption, carbon emissions in food transportation, reduction of urban heat island, health and economy. However, for large scale deployment of productive landscaping, we need the active involvement of the city dwellers and the local municipalities for creating conducive environment for production of food. Training and support services need to be provided for the enthusiastic urban farmers for wide deployment of productive landscaping. Further study is intended to be done on the economics and energy saving potential of productive landscaping in urban built environment.

## Correlation between air-conditioning usage and peak demand of electricity from Libyan homes

**Abdusalam Himdan, David Jankins, Edward Owens and Ali El Bakkush**

School of Energy, Geoscience, Infrastructure and Society, Heriot Watt University, Edinburgh, Scotland, correspondence email ah221@hw.ac.uk.

**Abstract:** Libya is a notable example amongst countries that use fossil fuels to generate electrical power in the world. Electricity in Libya is heavily consumed through the use of residential air conditioning, which comprises 36% of the total electricity generated at peak times on a hot summer day. In order to gain a general appreciation of electricity demand from cooling in Libyan domestic residences, a questionnaire was designed, comparing energy consumption and air-conditioning usage. This paper is based on the compilation of responses from the conducted survey. The questionnaire produced in this study, with 724 respondents, comprised of ten questions including building type, the number of air conditioning units used, the size of properties, and number of occupants. Moreover, the survey gave an indication of locations and the time at which air conditioning was used during the summer days , the result shows that houses with one and two storeys make up 61.3% of all housing types, meaning that the majority of Libyan people live in such buildings. Additionally the results show the impact of extreme use of air condition to the total electricity generation and the relation between the rate of increase of consumption and installed capacity of Libyan electricity.

**Keywords:** Libyan homes, Energy consumption, air-conditioning usage, Libya climate

### Introduction

In Libya, the climate is hot during summer time, so the need for cooling systems in summer are certain, especially in the southern region and coastal areas where the humidity is high. (El Bakkush et al., 2015). In the summer months, over 80% of buildings are using air-conditioners frequently within small volumes (Suleiman, 2011).

Local climate conditions have taken little notice due to cheap fossil fuel consumption in the country. As well as the introduction of mechanical air-conditioned technologies, the issue has gone out of hand concerning the environment. Energy consumption to allow comfort in buildings to be maintained cool has been huge.(Ahmad et al., 1984)

In the past, traditional buildings provided a relatively acceptable thermal comfort in winter and particularly in summer. These buildings are naturally ventilated and have a high thermal capacity. They are also equipped with a courtyard. However, in the present day the development of “modern” construction has been very fast with less care paid to the thermal quality of the buildings. Many recent buildings are not equipped with thermal insulation, and air tightness is very poor due to the lack of appropriate standards (Akair, 2007 p45).

According to the Libyan Housing and Infrastructure Board (HIB), Libya does not have its own specific criteria for housing construction, so the USA and British codes are used instead. These codes are seen as unsuitable for the Libyan climate and people's behaviour (AECOM, 2009). Furthermore, Suleiman (2011, p1928) stated that “there are no specific

energy conservation building codes to promote energy efficient buildings in Libya; however, there are some universal rules to implement energy conservation and environmental issues". Therefore, to reduce the electricity consumption in the residential sector and to increase the network efficiency, there is a need for adopting innovative technology approach in order to address these issues from an architectural perspectives (Roaf, 2012).

The objective of this study is to explore Libyan people's electricity consumption behaviour in conjunction with the housing occupancy and house type and design. Such information will be used to help investigate the correlation between air conditioning and peak electrical load in the Libyan residential sector.

### **Current Status of the Libyan energy**

The General Electricity Company of Libya (GECOL) was established in 1984 and it is responsible for all electricity sectors in Libya, including generation, transmission, distribution, and customer services.

Domestic energy use, which depends on multiple factors such as family size, lifestyle, the environment (location and climate), types of appliance in use, ownership, physical features of the house and human behaviour (Saleh et al., 2014), accounts for about 36% of the total energy consumption in Libya.

Air conditioning systems consume more energy than any other devices used in building services, and account for about 10-20% of the total energy consumption in developed countries (Alghoul, 2017). In Libya, about 18% of domestic energy consumption is used for temperature control in residential buildings, which amounts to approximately 6% of the total energy of all sectors. Hence, reduction in energy requirements by Heating Ventilation and Air Conditioning systems in buildings may lead to improved and more efficacious energy saving in buildings (Alghoul, 2017).

### **Generation annual growth**

According to the 2010 GECOL report, the country had 8,347 MW of installed capacity. Total generated energy was approximately 32.6TWh. With annual growth at 7.6%, this illustrates an average annual growth since 2003, as shown in Figure 1 (GECOL, 2010)

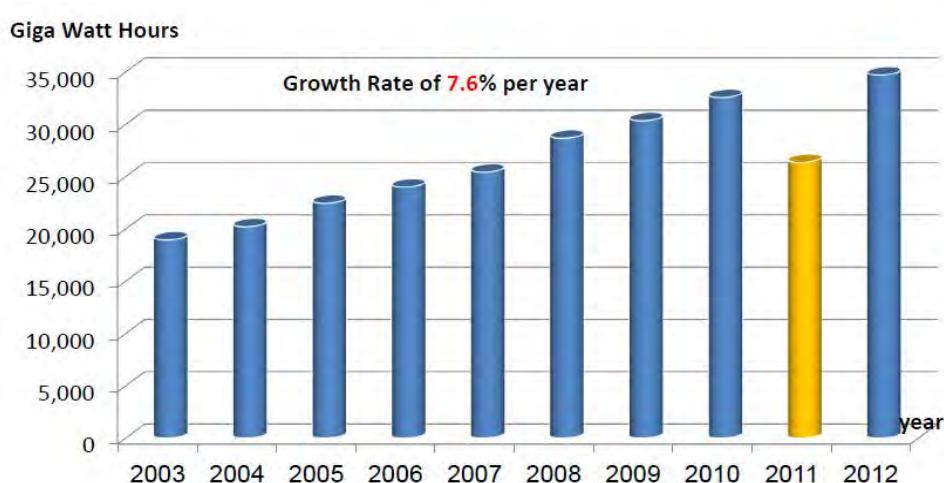

Figure 1. Energy production development 2003 – 2012 in Libya

Adopted from Current status of the Libyan power system and its future plans Power point presentation<sup>1</sup>

<sup>1</sup> [http://www.energyafrica.de/fileadmin/user\\_upload/Energy\\_Africa\\_13/Presentation\\_GECOL\\_Ashaibi\\_PAnel%204a\\_7th%20German-African%20Energy%20Forum.pdf](http://www.energyafrica.de/fileadmin/user_upload/Energy_Africa_13/Presentation_GECOL_Ashaibi_PAnel%204a_7th%20German-African%20Energy%20Forum.pdf)

The use of electrical energy in Libya is growing at a rapid rate. This growth in energy consumption is a result of the increasing urbanization occurring in the region, which is accompanied by an expanding population size, economy and degree of industrialization. Data collected over the last ten years in Libya has shown an increase in electricity consumption every year. By 2050, the government of Libya is expected to face more pressure to meet demands for the energy supply, especially in the residential sector with its cooling and heating needs. In the future, for these reasons, they must explore more efficient methods of energy use to overcome the increasing energy cost (Saleh et al., 2014).

### ***Type of Dwelling in Libya***

The Public Commission for Health Care Planning in Libya through Multi Indicator Cluster Survey (MICS) has reported that 65.4% of Libyan residents live in a one-storey house (MICS, 2003), many of which were constructed in the absence of technical data on the building materials (Suleiman, 2006). Another study by Dagdag and colleagues (2015) found that the majority of Libyan houses tend to be two- or three-storey buildings, consisting of about five rooms, and having flat roofs.

Typical construction materials include limestone bricks covered by plaster to form the external walls, and ground soft soil and marble tiles for the ground floor (Suleiman, 2011). Most use concrete and a small number use tiles, while those living in rural villages may resort to using materials such as fibre (Dagdag et al., 2015).

Installation of air-conditioning systems in the houses is a common feature due to the extremely high temperatures (Dagdag et al., 2015). During the summer months, excessive use of split-unit air-conditioning systems can be attributed to over 80% of the buildings (Suleiman, 2011).

### **Methodology**

The use of questionnaires as a method of collecting data has many advantages – the researcher is able to gain much information from many participants in a short amount of time. It is also cost effective and offers ease of access for both participants and researchers, who can subsequently quantify the results easily. The speed can be further improved by undertaking questionnaires electronically, which means a decreased time frame of waiting for results to be returned.

The questionnaire method was deemed to be most appropriate in order to give a general idea about Libyan domestic residences and the number of occupants and air conditioning use in order to compare between them and the energy consumption. For the questionnaire produced in this study, ten questions in the questionnaire ask about Libyan home types and how many air condition include also how the size of properties and how many people, kitchens, bathrooms, air conditioning units. Moreover, the survey gave indication about locations and the time of start using the air conditioner during the summer days, and time of stop using the air conditioner during the summer days, and month in the year start using air conditioning and finally, month in the year stop using air conditioning.

In spite of these benefits, there can also be several disadvantages. Naturally, people will have different understandings of questions and thus can interpret the meanings in a way which was perhaps not meant by the researcher. This can lead to answers not being given in the scope that was intended (Naoum, 2007).

For this particular questionnaire, a convenient sampling method called the “snowball” method was used, which allowed for quicker responses and wider spread among Libyans in different geographic areas of Libya.

The questionnaire was constructed on 30th of April 2016, and was then distributed electronically. Those contacted to carry out the questionnaire were asked to forward this on to others within Libya. By doing it individually instead of a group distribution meant more responses were received. The survey link was then shared on a social platform, Facebook, to maximise the response rate of students. Then, many individuals shared the link to their group of friends. This further maximised the response rate. The survey was closed on the 26th September 2016. The number of surveys distributed and responses achieved was 724, which gives a result as shown below.

Mohamed et al. (2015) conducted a study across Libya in 2013 through means of a questionnaire, which was written in Arabic and delivered to respondents for self-completion, in order to investigate the main avenues of domestic energy use in Libya. 823 questionnaires were distributed to a random sample from different household types and across different geographical areas with a 52% response rate (i.e. 429 valid questionnaires remained).

The findings regarding the estimated average energy (kW h) used by air-conditioning room in summer and spring are shown in the table below:

Table 1: Estimated average energy (kw/h) and cost (LD) to run appliances for one house (adapted from Mohamed et al., 2015).

Appliance	Rating	No. of appliances	Frequency of use per week	Hours used per day	Total kW h used per year
Air condition room in summer and spring	1000W	3	7	6	6480

## Results and Discussion

### House type

As Figure 2 illustrates below, the finding was that 41% of the participants live in a one storey house. Those who live in a double storey house were 21%. 14% of respondents reported living in a big villa. The rest of the respondents lived in flats: 1% in one bedroom flat, 6% in two bedroom flats, 10% in three bedroom flats, 6% in four bedroom flats and 1% in five bedroom flats.

Houses with one and two storeys make up 61.3% of all housing types, meaning that the majority of Libyan people live in such buildings. This result coincides with results from the MICS survey, which was conducted in 2003. In addition, the number of people living in these houses tend to be five or more, which implies that electricity usage will be excessive. Furthermore, the investigation for building materials for such houses resulted in large energy consumption due to having to meet the needs of the claimant (Akair and Bánhidi, 2007; Suleiman, 2011).

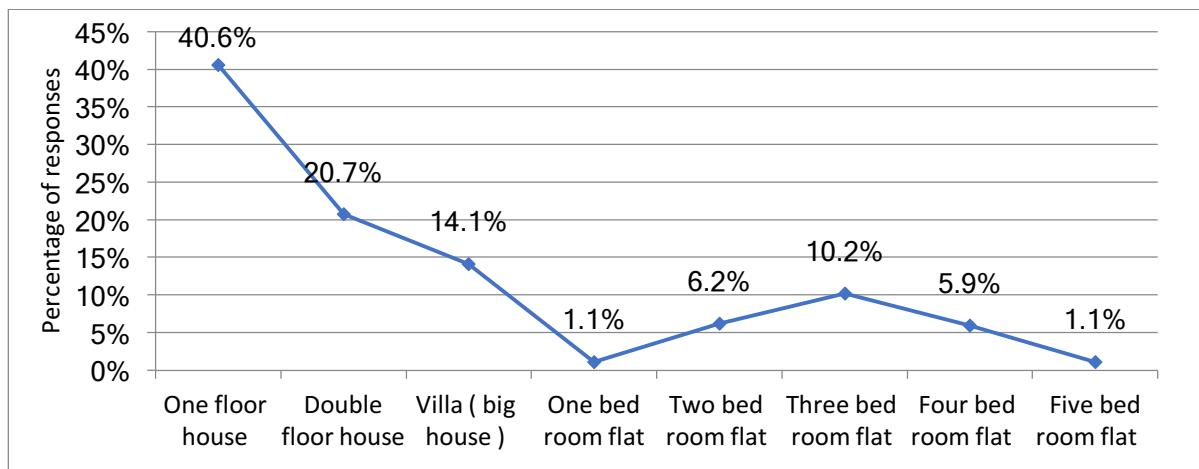

Figure 2.Type of building

### ***Use of air conditioning***

Figure 3 below shows that 78.7% have a number of air conditioning units ranging from 1 to 5, and Figure 4 below shows the peak time of electricity consumption.

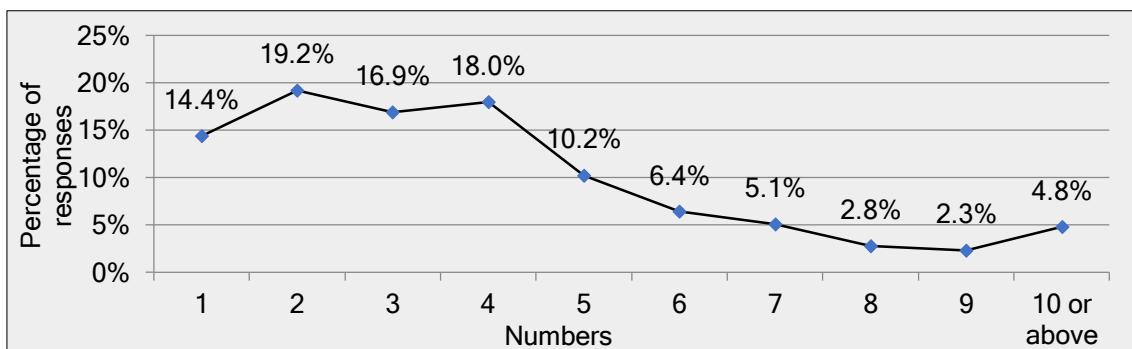

Figure 3. Number of air conditioning units

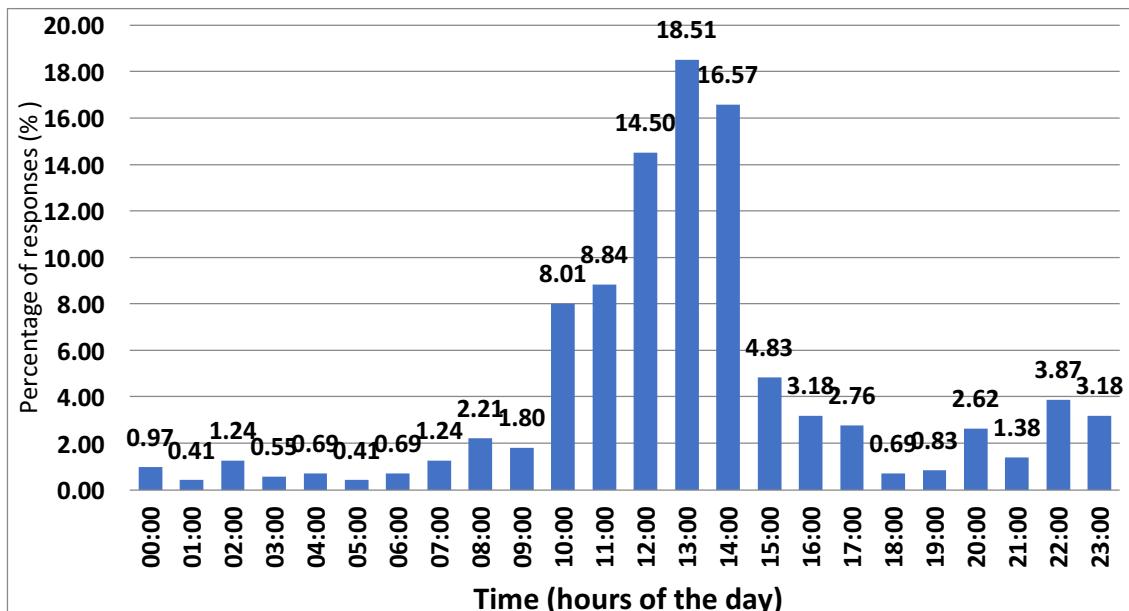

Figure 4. The start of using the air conditioner during the summer days

Therefore, if it is assumed that they have air conditioning units of size 12 BTU/h which will consume about 2.5 kW and estimated energy consumption (EEC) over 6 hours,

The result will be given as the equation below:<sup>2</sup>

$$\text{EEC} = \text{rate power of AC kw/h} * \text{period of operation} * \text{number of AC}$$

$$= 2.5\text{kw} * 6 \text{ hours} * 5 = 75\text{kwh}$$

The time of year that air conditioning was used most frequently was in May with 37% respondents stating this month. Between September and December there were no responses for when air conditioning is turned on, with 1% in January and February. In March 3% began air conditioning, 22% in April, 29% in June and 6% in July as shown in Figure 5. This indicates typical profiles of air conditioning profiles throughout the year.

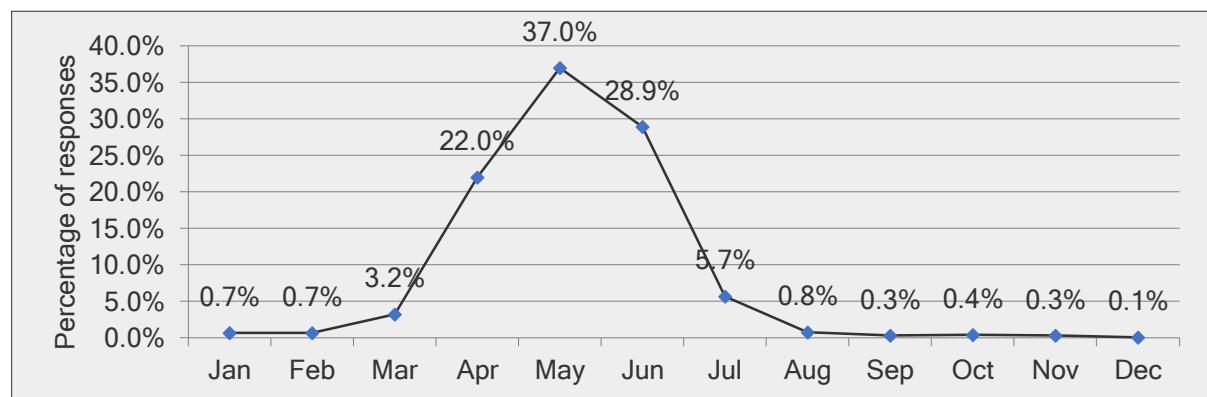

Figure 5. The start of using air conditioning in the month of the year

In Figure 6 below between January and August, respondent numbers were very low. The peak of responses indicated the end of using air conditioning in the month of October, with 45%. 25% responded in September and 17% in November.

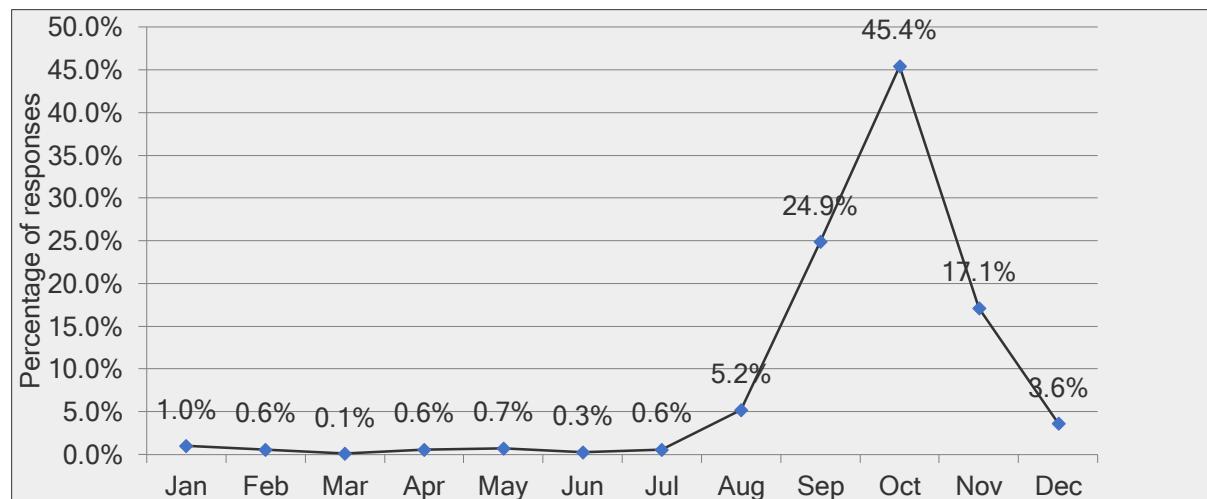

Figure 6. The end of using air conditioning in the month of the year

<sup>2</sup> <https://www.e-education.psu.edu/egee102/node/2106>

## **Conclusion and comments**

If Libyan housing continues to grow at the same rate of development, while GECOL generation rate remains the same, this will inevitably result in a shortage of energy supply that will be unable to meet with increasing demand. This demand, particularly with climate change a factor, is likely to be driven in part by cooling demand. It is therefore vital that we understand current cooling practices and, with that established, design (and retrofit) buildings to perform in a way that can reduce the energy used for this required service.

Future studies should therefore focus on adapting buildings with new technologies but also design features that reduce the need for that technology, employing more effective construction materials, shading and ventilation strategies that will aid in more efficient (and/or less) cooling. The work of this paper will form part of a PhD project by helping to specify a series of archetypal building models, simulated dynamically, to understand the potential of cooling reduction in limiting the growth of peak electricity demand in Libya.

## Uncertainty and sensitivity analysis of residential cooling energy against future climate in hot-humid Taiwan

I-Ting Lai<sup>1</sup>, Kuo-Tsang Huang<sup>1</sup> and Ruey-Lung Hwang<sup>2</sup>

<sup>1</sup> Department of Bioenvironmental Systems Engineering, National Taiwan University, Taipei, Taiwan

<sup>2</sup> Department of Industry Technology Education, National Kaohsiung Normal University, Kaohsiung, Taiwan

**Abstract:** Building cooling energy attributes a relatively large proportion to the total nation-wide energy usage, and the cooling energy is prone to be affected by the future temperature rise and increases the vulnerability of buildings. To formulate adequate strategies counteracting climate change for energy conservation, it is crucial to predict the future cooling energy variation trend. This study aims to quantify the uncertainty of future cooling energy use and to establish the relationship of building envelope parameters to the cooling energy increment. Monte Carlo method was applied to generate residential cases to encompass a variety of building characteristics of condominium. Each case was simulated via EnergyPlus. A global uncertainty and sensitivity analysis method was adopted. The results reveal that although the peak cooling load increases slightly, the annual cooling energy grows dramatically by 25.27%, 54.18% and 109.62% under RCP2.6, RCP4.5, and RCP8.5 respectively in the late 21<sup>st</sup> century since the large increment of the annual A/C operation frequency. The result of sensitivity analysis shows that the top three effective countermeasures to neutralize future cooling energy increment are lowering solar heat gain coefficient of the window, improving insulation of exterior walls, and reducing window-to-wall ratio in hot-humid and cooling dominated region.

**Keywords:** Climate change, hybrid ventilation, building energy consumption, adaptation measure

### Introduction

Energy usage in domestic buildings accounts for more than one-third of the annual total energy consumption in Taiwan, and a large proportion of the energy is mainly used in providing air-conditioning to satisfy the cooling demands (Yang and Hwang, 1993). With the increasing concern of global warming in the past few decades, it has also drawn great attention to the impacts of climate change on the cooling energy, which is highly influenced by the outdoor weather conditions. Wang et al. (2010) analysed the future residential building energy requirements in different regional climates in Australia. They summarized that cities in a cooling dominated region are more sensitive to the changing climate, and the high sensitivity of buildings should be considered during the planning of future energy requirements. As a result, to eliminate the potential threat posing from the changing climate by formulating adequate strategies, it is important to fully understand the possible cooling energy variation under future climatic conditions. In the United Kingdom, Tian and de Wilde (2011) investigated the uncertainties in the projection of the cooling and heating energy of an air-conditioned university building under climate change. In order to devise effective strategies for building energy conservation, Heiselberg et al. (2009) implemented sensitivity

analysis to assess the influence of each design parameter on the energy consumption of an office building in Demark. This research continued to introduce the uncertainty analysis in predicting the trend of residential cooling energy against future climate in hot-humid Taiwan. Three performance indicators are discussed separately to understand the variation of cooling energy in different aspects: (i) peak cooling load, (ii) annual A/C operation frequency, and (iii) annual cooling energy. Moreover, the sensitivity analysis was performed to determine the most effective passive design parameters, which could serve as the practical reference of strategies to counteract climate change.

## **Methodology**

### ***Downscaling method for future weather data***

Computer simulation tools are widely used in building thermal and energy performance analysis, while program EnergyPlus was adopted for hourly dynamic simulation in this study. To explore the future cooling energy variation, future weather data was originated from CanESM2, a global circulation model developed by Canadian Centre for Climate Modelling and Analysis, with three radiative forcing scenarios (RCP2.6, RCP4.8, RCP8.5). Then the future hourly-based typical meteorological years till 2100 were produced through morphing method proposed by Belcher et al. (2005) for cooling energy simulation purpose. Annual mean temperature variation in Taipei, Taiwan under climate change is shown in Figure 1. It is presented that annual mean temperature increases by 0.67°C, 1.7°C and 3.4°C under RCP2.6, RCP4.5, and RCP8.5 scenarios respectively in the late 21<sup>st</sup> century.

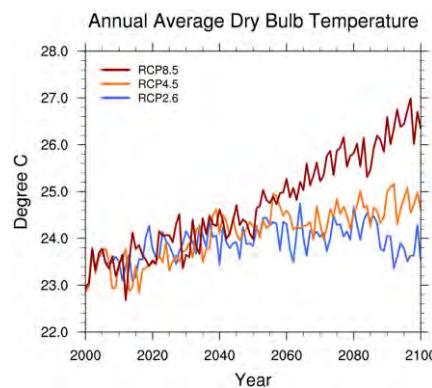

Figure 1. Annual mean temperature variation in Taipei (2000-2100).

### ***Generating simulated cases through Monte Carlo analysis***

The main purpose of this study is to develop appropriate strategies for building energy saving against future climate. Therefore, we should fully understand the trend of cooling energy consumption in advance through uncertainty analysis, aim of which is to discover the likely variation in the output due to the uncertain input. Then sensitivity analysis should be applied to identify the input parameters to which the estimated output of the system is more sensitive (Macdonald, 2002).

Passive design parameters affecting residential energy performance are various and complicated, such as building geometry, windows, and insulation of building envelope materials. The combination of these parameters and other factors, including outdoor climatic conditions, lack of specification of the system and global warming, contributes general uncertainty during the building simulation. Monte Carlo analysis (MCA) based on global

method was applied for sensitivity and uncertainty analysis, since it can be used to quantify the influence of the uncertain input parameters on the response of the output at once (MacDonald, 2009, van Griensven et al., 2006). When applying MCA, 1000 residential cases were generated through random sampling by creating a random number and scaling it to the target variable with its probability density function. In order to simplify the input information about building geometry, six typical apartment floor plans in Taiwan were selected and built when generating 1000 residential cases. The selected floor plans are shown in Figure 2. In which, B stands for bedrooms while L stands for living room. The probability density functions were assumed to be normally distributed for all parameters (except for orientation) represented in Table 1.

Figure 2. Six typical floor plans in Taiwan. B stands for bedroom and L stands for living room.

Table 1. Design parameters with coefficients.

Design parameters	Mean	Standard deviation	Units
Floor area	92.56	13.22	m <sup>2</sup>
Window-to-wall ratio (WWR)	0.35	0.07	-
U-value of window	5.5	0.5	W/m <sup>2</sup> -K
Solar Heat Gain Coefficient (SHGC) of window	0.70	0.05	-
Shading device	0.25	0.20	Shading depth / Window length
Thickness of thermal insulation of external walls	1.27	2.54	cm
Orientation	Eight direction with equal probability.		
Occupancy	4	1	Person
Lighting in living room	10	2.0	W/m <sup>2</sup>
Equipment in living room	9.0	1.8	W/m <sup>2</sup>
Lighting in bedroom	8.0	1.6	W/m <sup>2</sup>
Equipment in bedroom	4	0.8	W/m <sup>2</sup>
Coefficient of performance (COP)	3.3	0.2	W/W

### **Assumption for residential ventilation system and comfort criteria**

Usage of HVAC system energy has the largest contribution to building energy consumption. Therefore, it is essential to define the operating mode of ventilation system, prior to describing the annual cooling energy use of a typical residential HVAC system obtained from dynamic simulation. A split air conditioner is predominant among residential buildings in Taiwan. It operates similarly with mixed-mode ventilation, which is primary running in natural ventilation mode, whenever indoor thermal condition is overheating, air-conditioning is used instead. To assess and determine whether the mechanical cooling was in operation, an adaptive thermal comfort criterion suggested by the ASHRAE Standard 55 was adopted in the study. According to the criterion definition, the optimum indoor thermal comfort operative temperature ( $T_c$ ) is a function of monthly average outdoor temperature ( $T_{om}$ ), and is given in Equation (1). The upper limit of 80% acceptable comfort zone is defined as  $T_c + 3.5^\circ\text{C}$ .

$$T_{oc} = 0.31 \times T_{om} + 17.8 \quad (1)$$

### **Analysis of heating and cooling load under climate change**

On the basis of the simulation result, the variations of annual heating and cooling load between 2000 and 2100 under RCP8.5 with the highest greenhouse gas emissions is shown in Figure 3. It is clear that cooling load varies from 10 between 75 kWh/m<sup>2</sup> in 2000, and its maximum even reaches to 200 kWh/m<sup>2</sup> in 2100. Conversely, the range in heating load reduces. In comparison to the variation trend of cooling load, heating load is almost negligible. As a consequence, the main purpose of the study is to evaluate the effects of building design parameters on the annual cooling load.

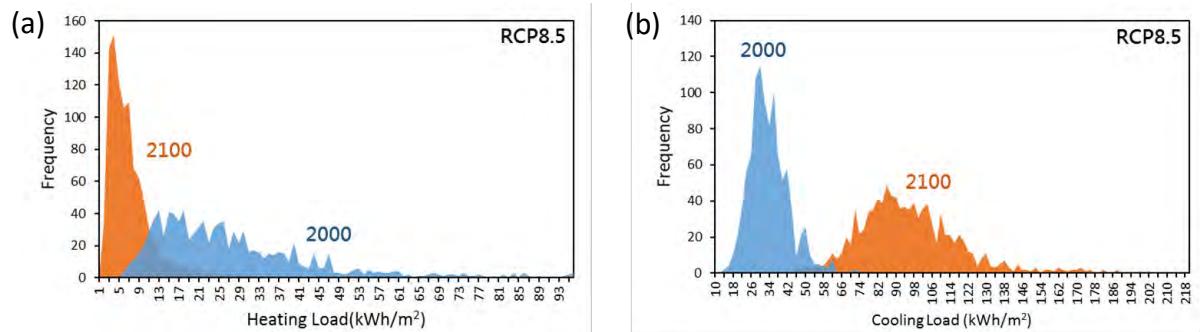

Figure 3. Variation of (a) heating and (b) cooling load between 2000 and 2100 under RCP8.5.

## **Results and discussion**

### **Uncertainty Analysis**

#### **Peak cooling load**

In order to assess the requirement of HVAC system under future climatic conditions, variation of peak cooling load would be the priority to be examined. As presented in Figure 4, the peak cooling load remains almost constant at 80 W/m<sup>2</sup> under RCP2.6, and slightly increases before 2060s under RCP4.5. Nonetheless, overall trend of the peak cooling load rises significantly under RCP8.5 compared to the other scenarios, and ultimately reaches to 92.7 W/m<sup>2</sup> (increases by 18.5%).

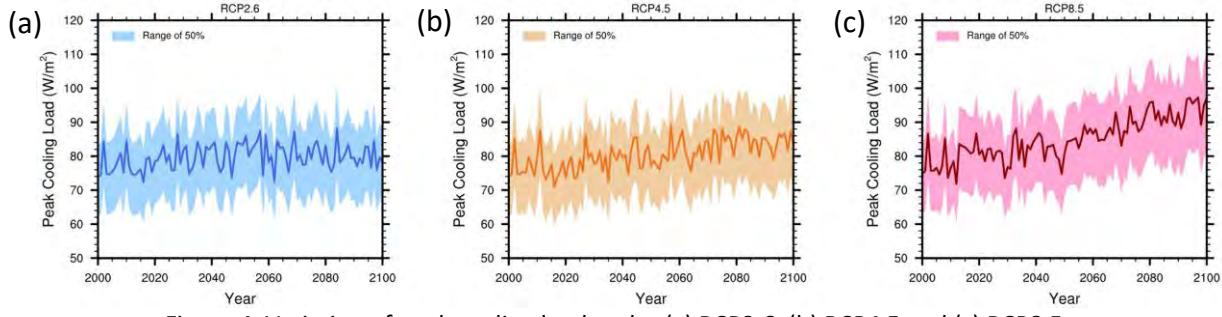

Figure 4. Variation of peak cooling load under (a) RCP2.6, (b) RCP4.5 and (c) RCP8.5.

#### *Annual A/C operation frequency*

With a purpose to investigate the usage of air conditioning system in response to global warming, annual A/C operation frequency would be analysed. We introduced “cooling day” as the calculation units to facilitate understanding. Due to different operating schedule for living room and bedrooms, and their corresponding annual A/C operation frequency (cooling day,  $CD$ ) were estimated separately, as shown in Equation (2) - (3).

$$CD_{Liv} = \frac{1}{hr_{Liv}} \sum_{i=1}^{365} t_{Liv,i} \quad (2)$$

$$CD_{Bed} = \frac{1}{n \times hr_{Bed}} \sum_{j=1}^n \sum_{i=1}^{365} t_{Bed,i,j} \quad (3)$$

Where  $t_{Liv}$  and  $t_{Bed}$  are the annual A/C operation frequency in hours,  $hr_{Liv}$  and  $hr_{Bed}$  are the occupancy schedule from EnergyPlus which equal to 16 hr/day and 13 hr/day respectively, and  $n$  is the number of the bedrooms in each case.

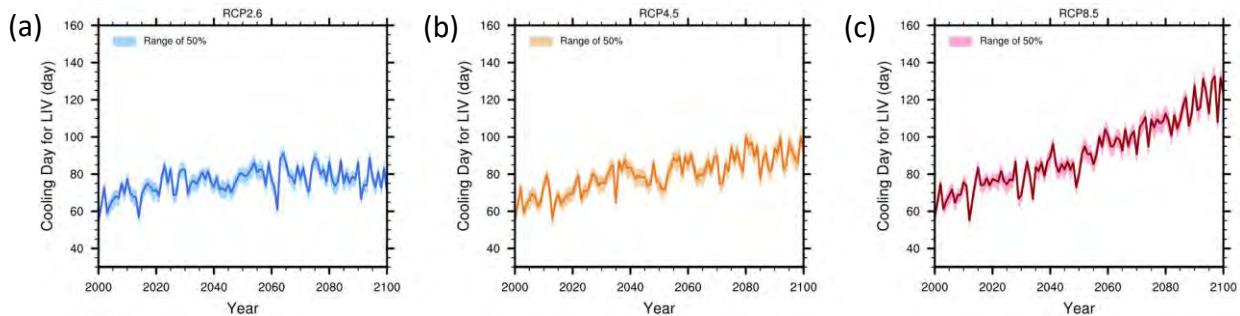

Figure 5. Variation of annual cooling day for living room under (a) RCP2.6, (b) RCP4.5 and (c) RCP8.5.

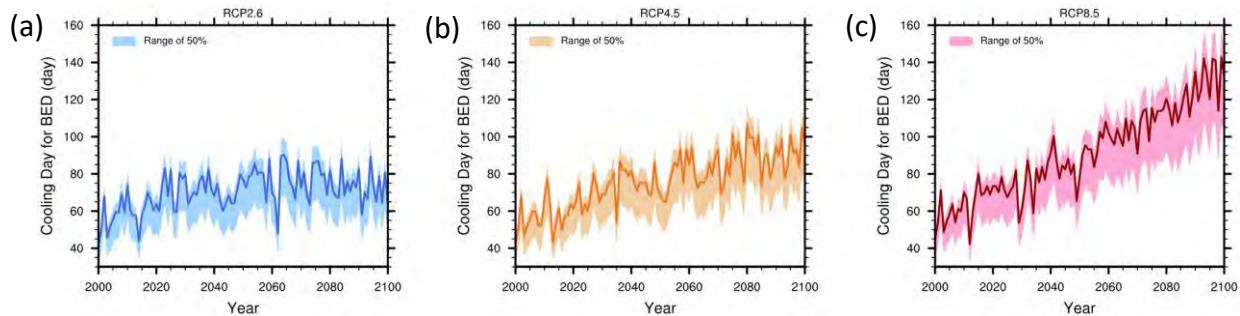

Figure 6. Variation of annual cooling day for bedrooms under (a) RCP2.6, (b) RCP4.5 and (c) RCP8.5.

Figure 5 shows the annual A/C operation frequency for living room, while Figure 6 shows the part for bedrooms. The annual cooling days for both living room and bedrooms increase before 2060s and drops eventually under RCP2.6, and as for RCP4.5, it rises just before remaining steady since 2070s. Obviously, a dramatic increment appears under the most extreme scenario, RCP8.5, and it increases to 115-120 days in the late 21<sup>st</sup> century (more than 68.7% and 104.5% compared to the present for living room and bedrooms respectively). It is speculated that the annual A/C operation frequency has a much higher growth rate than the peak cooling load under the future meteorological conditions.

#### *Annual cooling energy*

The general trend of the peak cooling load and the annual A/C operation frequency are learnt from the above analysis result. Then we start focusing on the potential impact on building enegy performance in terms of annual cooling energy. As shown in Figure 7, the long-term trend of the annual cooling energy follows to that of the annual A/C operation frequency. The figure illustrates that the cooling energy consumption is under control at 15.37 kWh/m<sup>2</sup> in the late 21<sup>st</sup> century under RCP2.6; in contrast to the former scenario, cooling energy consumption grows significantly to 26.74 kWh/m<sup>2</sup> under RCP8.5, which is almost twice as the amount of the present.

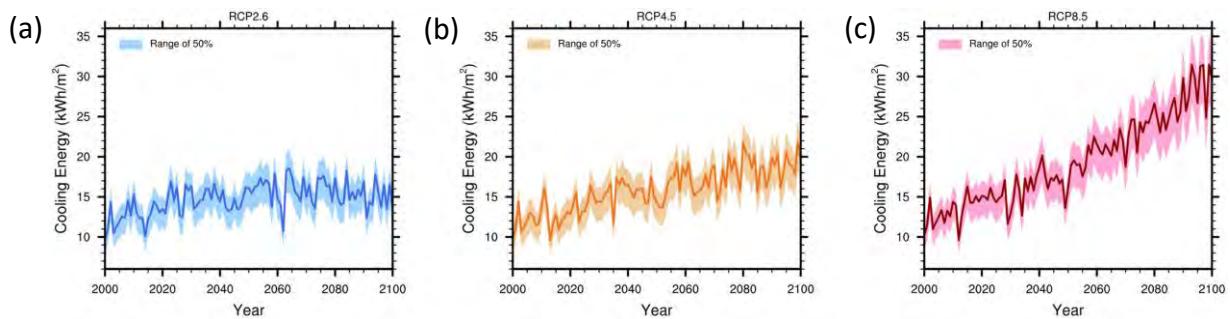

Figure 7. Variation of annual cooling energy under (a) RCP2.6, (b) RCP4.5 and (c) RCP8.5.

As displayed in Table 2, the increase of the peak cooling load is inconsiderable and does not exceed more than 20% among all the scenarios. Although there are both upward trends in the amount of the annual cooling day for living room and bedrooms, increment of the latter is more noticeable since most of the bedrooms are adjacent to external walls, and thus, the changing in outdoor climate could directly affect the increment. It could be summarised that at the end of the century, despite the slightly increment in peak cooling load, the annual cooling energy ultimately increases by 25.27%, 54.18% and 109.62% under RCP2.6, RCP4.5, and RCP8.5 scenarios respectively as the annual A/C operation frequency increases.

Table 2. Summary of the three indicators in different time slices under three scenarios.

Scenario	Peak Cooling Load (W/m <sup>2</sup> )			Annual Cooling Day (Day)				Annual Cooling Energy (kWh/m <sup>2</sup> )				
	RCP2.6	RCP4.5	RCP8.5	RCP2.6	RCP4.5	RCP8.5	RCP2.6	RCP4.5	RCP8.5	RCP2.6	RCP4.5	RCP8.5
Current (2000-2015)	76.97	77.16	78.24	66.74	66.33	68.43	56.94	56.63	59.86	12.27	12.21	12.76

## Sensitivity Analysis

A regression analysis of the annual cooling energy use on outdoor air temperature under climate change was performed. As presented in Figure 8, it reveals that the annual cooling energy consumption would increase by 5.01 kWh/m<sup>2</sup> per household as the outdoor air temperature increases by 1°C relative to 2000, under the hypothesis that all the design parameters remain unchanged during the whole 21<sup>st</sup> century. Therefore, it is crucial to develop counteracting strategies with the aim of maintaining the annual cooling energy usage at current levels.

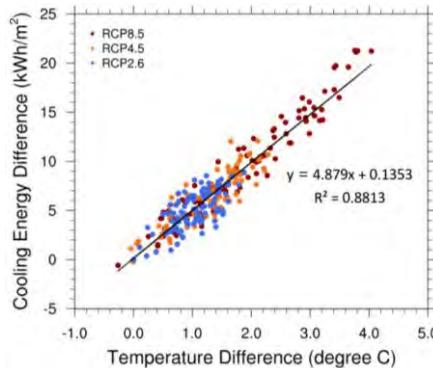

Figure 8. Regression of annual cooling energy use on temperature difference from 2000.

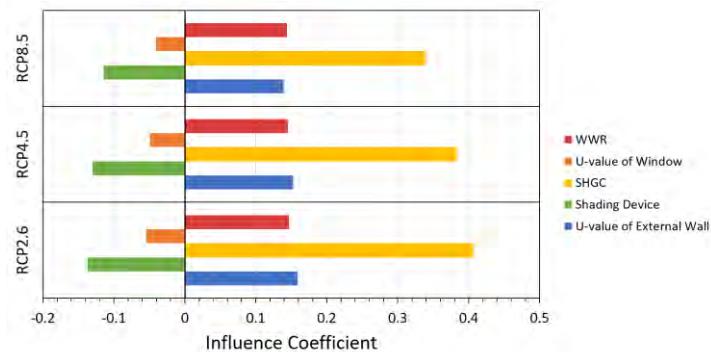

Figure 9. Result of influence coefficient for each design parameter under different scenarios.

To assess the influential passive design parameters which could be regulated and determine their levels of impact on cooling energy consumption, the sensitivity analysis was applied in the study. We selected and averaged the bottom 10% ( $IP_{0\sim10\%}$ ) and the top 10% ( $IP_{90\sim100\%}$ ) of each design parameter, as well as their corresponding annual cooling energy ( $OP_{0\sim10\%}$  and  $OP_{90\sim100\%}$ ), and then calculated the influence coefficient (IC) using the following equation based on the study from Lam and Hui (1996).

$$IC = \frac{\Delta OP \div \left( \frac{OP_{0\sim10\%} + OP_{90\sim100\%}}{2} \right)}{\Delta IP \div \left( \frac{IP_{0\sim10\%} + IP_{90\sim100\%}}{2} \right)} \quad (4)$$

If a parameter causes a change in cooling energy and the sensitivity of  $IP$  with respect to  $OP$  could be estimated in terms of the influence coefficient. The IC of each design parameter is shown in Figure 9. IC for each design parameter tends to decline under RCP8.5 since the outdoor climatic conditions with higher air temperature have a greater impact on cooling

energy use. Nonetheless, the range of variation for WWR is not wide enough (the largest value of WWR is 0.55), so the study could not reflect the insulation of the window properly in the result. Thus, it should be more accurately when selecting probability density function and coefficients for each design parameters.

It is apparent that the absolute values of IC for solar heat gain coefficient of the window, U-value of the exterior walls and window-to-wall ratio are the top three maximums. This means that introduction of improving insulation of exterior walls, and reducing window-to-wall ratio should be the major concern for architects and engineers during the design process of residential buildings, which consume relative low cooling energy. Moreover, low solar heat gain coefficient of the window is more important than low U-value of that during the selection of the glazing, since the influence of the former on the cooling energy reduction is much more than the influence of the latter. These countermeasures would contribute lower building energy consumption and increase the resilience of residential buildings in facing global warming.

## Conclusion

1. In Taiwan, since the demand on heating load of a residential building is negligible, cooling load becomes the dominant energy requirements and should be consider as the major problem to deal with when formulating adequate strategies.
2. Although the peak cooling load increases slightly, the annual cooling energy ultimately increases dramatically by 25.27%, 54.18% and 109.62% under RCP2.6, RCP4.5, and RCP8.5 respectively in the late 21st century owing to the large increment of annual A/C operation frequency.
3. If all design parameters remain unchanged, the annual cooling energy would increase by 5.01 kWh/m<sup>2</sup> per household as the outdoor air temperature increases by 1°C relative to 2000. Thus, passive design strategies must be adopted to save building energy usage.
4. Lowering solar heat gain coefficient of the window, improving insulation of exterior walls, and reducing window-to-wall ratio are the first three appropriate preferences of strategy.

## Energy and thermal performance assessment of existing residential buildings: the first step to introducing successful retrofitting strategies in Albania

**Jonida Murataj<sup>1</sup>, Rajat Gupta<sup>2</sup>, and Fergus Nicol<sup>2</sup>**

<sup>1</sup> School of Architecture, Oxford Brookes University, Oxford, UK

<sup>2</sup> Low Carbon Building Group, Oxford Institute for Sustainable Development, Oxford Brookes University, Oxford, UK

**Abstract:** This paper presents the findings of a study conducted in Albanian residential buildings. It aims to get insights of energy and thermal performance of the existing housing stock, as well as the effect that human behaviour has on the indoor environment. The methodology adopted comprised building surveys, occupant survey and continuous monitoring of outdoor and indoor environmental conditions during the summer and winter to cover for seasonal variations. 49 case studies were randomly selected to represent various Albanian housing typologies defined for this study. It is found that energy consumption was up to 97% over the baseline, and more than two third was consumed for heating the space in winter. The findings also indicate a disparity between the preferred thermal conditions and those experienced, especially in winter where residents found it very difficult to prevent the very high fluctuation of temperatures. Other occupants' behaviours associated with individual perceptions and cultural bearings are highlighted. Therefore, using these findings to inform and calibrate the baseline energy modelling will provide better estimations on energy savings for future retrofitting programmes.

**Keywords:** Energy performance, comfort, human behaviour, pre-retrofit survey, monitoring

### Introduction

Notwithstanding that energy retrofitting of existing housing stock offer a great potential in energy savings, several energy retrofitting programs have shown that they are lower than anticipated (Gupta and Gregg, 2012; Sunikka-Blank and Galvin, 2012), partly because of considerable assumptions and predictions used for energy modelling, due to a lack of data about various aspects of the building (Zero Carbon Hub, 2014). Furthermore, regional, social and cultural variation including differences in climatic conditions, income level, building materials and techniques, building stocks are complex and the boundaries are difficult to define and probably they have been underestimated (Kohler, 1999). Therefore, the model calibration with the real data on energy and environmental performance gathered through pre-retrofit monitoring of the building (Gupta and Gregg, 2016), including the possibility of integrating the occupants' behaviours into building simulations based on measured observations rather than assumptions (Guerra-Santin et al, 2016), is vital in minimising the performance gap between the expectations and outcomes.

Within this context, this paper investigates the energy and thermal performance of various archetypes in Albania through continuous monitoring of indoor and outdoor environmental conditions, building surveys and occupant survey, and examines the occupant's behavioural effect in achieving thermal comfort.

## Methodology

This research is part of an ongoing PhD study that aims to investigate the most effective retrofitting strategies for energy savings and improving thermal comfort in residential buildings in Albania. A socio-technical approach was used to collect quantitative and qualitative data from 49 households representing eight various archetypes of residential buildings in Albania, consisting of:

*Building surveys* to gather information regarding archetypes and energy use. Electricity bills were also obtained for 36 out of 49 dwellings.

*Questionnaire-guided interviews* to get insights of how and when the house is used, occupants' attitudes and habits, and other everyday practices in their home, as well as to assess their comfort sensation and preference in summer and winter.

*Continuous monitoring of the outdoor and indoor temperature in the living room and main bedroom of 49 dwellings in summer and winter*, to assess the thermal comfort in the house.

Based on dwellings statistics, the sample chosen for monitoring is closely representative of Albanian housing apart from semi-detached houses, which are under-represented.

Table 1. Statistics of residential buildings in Albania

Type	Albanian residential buildings		Dwellings		Sample	
	Frequency	%	Frequency	%	Frequency	%
Detached	88,804	80.5	88,804	33.9	17	34.6
Semi-detached	10,184	9.2	25,666	9.8	1	2
Terraced	4,351	3.9	14,142	5.4	2	4.1
Flat	6,944	6.3	133,291	50.9	29	59.3
Total	110,283		261,903		49	

Table 2. Frequency of key characteristics in the sample

Category	Description	Frequency	%
Year of construction	Pre-1960	4	8.2
	1961-1990	12	24.5
	After 1991	33	67.3
Construction type	Solid brick / stone external walls	8	16.3
	Concrete blocks	3	6.1
	Pre-fabricated	3	6.1
	Silicate brick	5	10.2
	Hollow brick	24	49
	Insulated walls	6	12.2
Ventilation / cooling scheme	Natural ventilation	3	6.1
	Mixed ventilation (natural + air conditioning)	46	93.9

## Energy consumption

Energy consumption data is used to get insight of air-conditioning usage during summer and winter. In almost all dwellings, electricity consumption increases during the winter months (November-March) with its peak in January and in summer in July, associated with heating and cooling respectively.

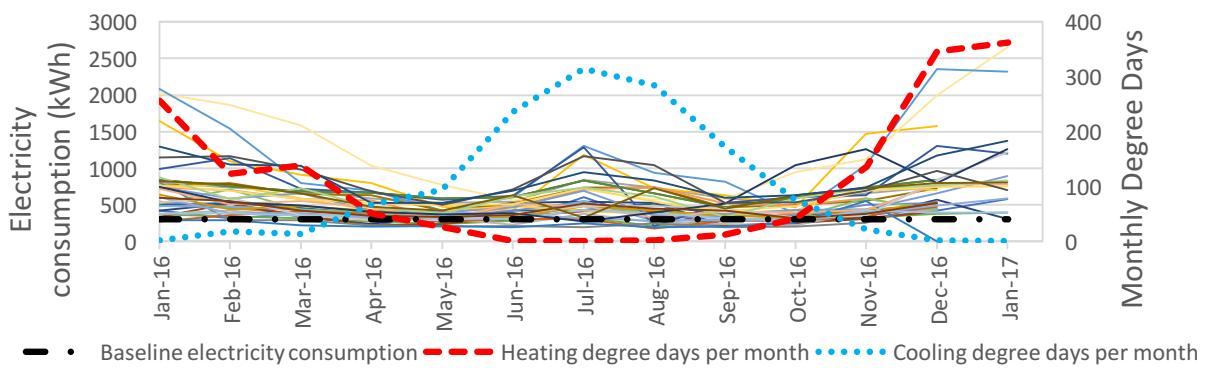

Figure 1. Electricity consumption from January 2016 to January 2017

Source of degree days: ([www.degreedays.net](http://www.degreedays.net), 2017)

43% of the dwellings are heated for half of the year and two of them are heated for as long as eight months of the year and most of the dwellings are cooled for three (20%) and four (45%) months of the year. Based on the baseline electricity consumption of 300kWh (ERE, 2009), needed in one household that does not perform heating or cooling with electricity, an estimation of electricity consumption used for heating and cooling of each dwelling in the sample.

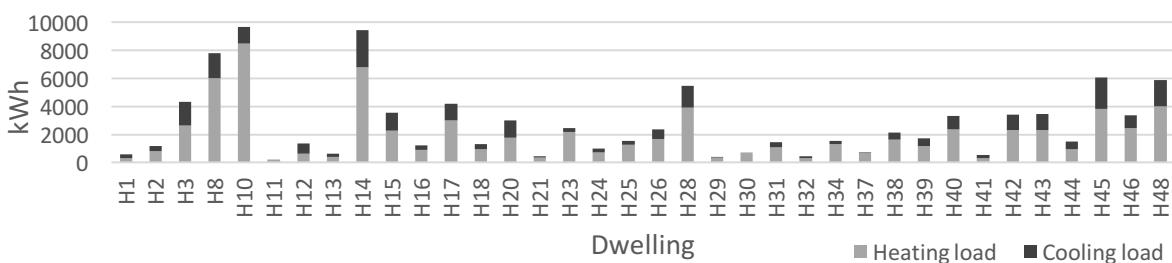

Figure 2. Estimated heating and cooling loads (kWh) based on electricity bills

Notwithstanding that energy data available include only electricity consumption, it can be noticed that most of energy consumed over the base load is for heating rather than cooling the homes. Furthermore, 65% of households also consider heating of their homes more important than cooling.

### Temperature variations and thermal comfort in summer

The indoor temperature of 49 living rooms and 42 main bedrooms were monitored from 30 June to 12 August 2016 at half-hourly intervals, to cover the hottest season of the year in the Albanian climate. The outdoor temperature ranged between 19.6°C to 41.1°C, while the indoor temperature ranged from 19.5°C to 36.5°C in living rooms and 19.5°C to 37°C in bedrooms. The indoor temperatures were well above the recommended figures from the guidelines (23°C -25°C) (CIBSE, 2006). Even more, half of the dwellings had indoor temperatures constantly over 25°C. The dwellings that experience the highest temperatures, had the largest temperature variation.

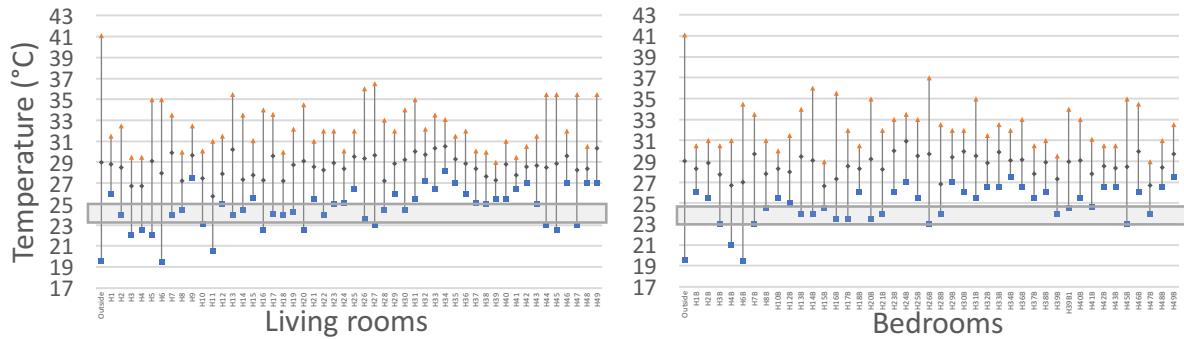

Figure 3. Minimum, maximum and mean temperatures for each dwelling during the summer

Subjective evaluation of the thermal environment was provided using a 7-point ASHREA scale for the thermal sensation evaluation and a 5-point scale for thermal preference. 86% of the households reported to feel warmer than neutral during the summer, from which more than 40% of them were feeling hot. Only 6% of the households required no change and approximately 60% wanted to feel much cooler.

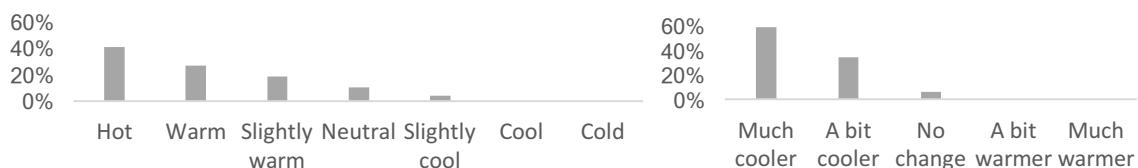

Figure 4. Percentage distribution of thermal sensation votes (left) and thermal preference votes(right)

The standardized indoor mean temperatures for each thermal sensation vote were calculated (Table 3), and it was found that occupants were feeling hot in an indoor mean temperature of 29°C (with a standard deviation of 1.1) and a maximum and minimum mean temperature of 30.5°C and 27.3°C respectively. The temperature range for the dwellings in which the households reported to be feeling warm or slightly warm were very similar. Interestingly, the occupants felt neutral for temperature close to the dwellings in which the resident were feeling hot. There were only two dwellings in which the occupants were feeling slightly cool, and indeed the mean, maximum and minimum temperatures were lower than in the other cases.

Table 3. Mean indoor temperatures of dwellings for each value of thermal sensation vote reported

#### How do you feel during the summer?

Slightly warm		Neutral		Slightly cool		Cool		Cold	
<b>Mean temperatures in living rooms</b>									
Mean	Max	Min	Mean	Max	Min	Mean	Max	Min	Mean
29.0	30.5	27.3	28.4	29.7	27.2	28.4	29.9	26.7	28.7
<b>Standard Deviation</b>									
1.1		0.8		1.2		0.5		1.0	

#### Temperature variations and thermal comfort in winter

The indoor temperature of 45 living rooms and 42 main bedrooms was monitored from 5 January to 16 February 2017 at half-hourly intervals, to cover the cold season. The outdoor temperature ranged between -5.5°C to 18.5°C, while the indoor temperature ranged from -

6°C to 29.5°C in living rooms and -5.5°C to 29.5°C in bedrooms. For most of the dwellings, the indoor temperature was below the recommended temperatures from the guidelines (22°C - 23°C) for living rooms and (17°C -19°C) for bedrooms (CIBSE, 2006). 19 out of 45 dwellings monitored did not reach temperatures 22°C or above. Some of the dwellings have registered temperatures close to the outdoor temperature, meaning that they have little or no heating at all and windows could possibly have been left open during the day. A very high temperature variation can be noticed in living rooms varying from 6.5 degrees (H39) to 33 degrees (H25), indicating a big problem in keeping the adequate thermal comfort in Albanian homes in winter. Moreover, the dwelling that had the largest indoor temperature variation, had recorded temperatures as low as 0°C to -6, which is the same as the outside temperature.

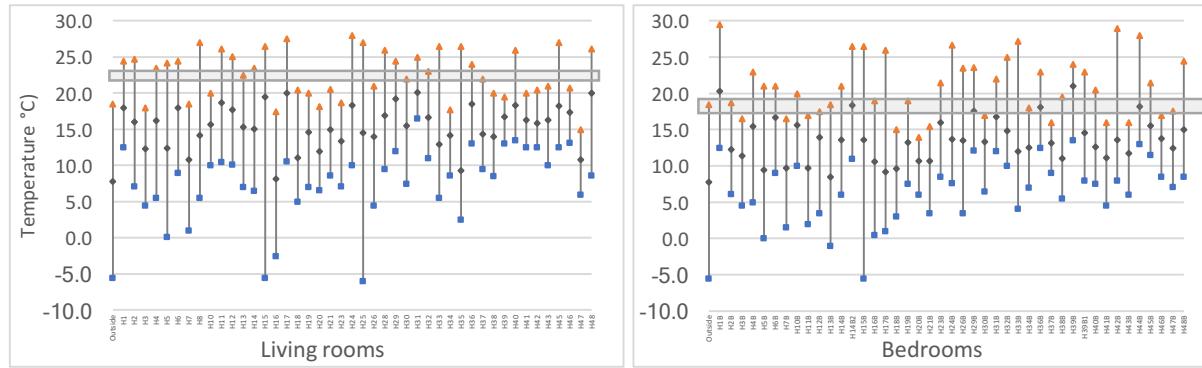

Figure 5. Minimum, maximum and mean temperatures for each dwelling during the winter

A considerable but low correlation ( $r=0.33$ ) is found between the mean temperature and the main construction material. More importantly, the dwellings that had applied wall insulation had higher indoor mean temperatures, which highlights the need of fabric improvement for improvement thermal comfort in Albanian homes.

75% of the households reported to feel colder than neutral during the winter, from which 39% were feeling cold. Nearly half of them (49%) preferred to feel much warmer and 37% preferred a bit warmer. Only 12% of the participants were feeling neutral during the winter and 4% preferred no change of temperatures.

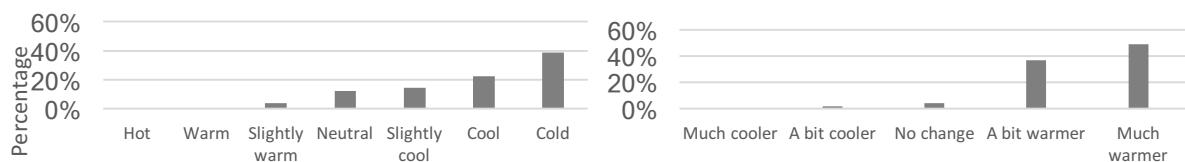

Figure 6. Percentage distribution of thermal sensation votes (left) and thermal preference votes(right)

Most of the occupants that were feeling cool or cold during the winter wanted the environment to be much warmer. Comparing the indoor mean temperatures for each thermal sensation vote (Table 4), it is found that occupants were feeling cold in an indoor mean temperature of 15.1°C (with a standard deviation of 3.1) and a maximum and minimum temperature of 20.1°C and 8.2°C respectively. However, there is not a large variation of indoor mean temperatures for which the occupants were feeling neutral, slightly cool or cool. The determinant factor for the thermal sensation votes distribution might be the value of the minimum mean temperature, which is higher for the dwellings in which the occupants were feeling slightly warm and neutral with values of 16.9°C and 10.8°C respectively.

Table 4. Mean indoor temperatures of dwellings for each value of thermal sensation vote reported

### Human behaviour effect

Focus should be in different practices and behaviours related to comfort to understand the energy consumption of households (Gram-Hanssen, 2010). Air conditioning was the most popular cooling type in the sample and still, maximum mean temperatures exceeded the value of 30 degrees. This was mainly because localised cooling or heating were performed in all cases, most of the time using convective cooling and heating, which produced relatively lower temperatures in living rooms than bedrooms in summer and vice versa in winter. Residents tended to open windows in the morning, evening and night, due to the cool outdoor air. However, the dwellings with higher variation of temperature, had on average four months of cooling and dwellings with shorter cooling period had an indoor mean temperature variation between five degrees to eleven degrees. The indoor mean temperatures during the winter are relatively lower in bedrooms than in living rooms because bedrooms were mainly unheated. In some of the dwellings, internal doors of the bedrooms that had direct access in living rooms were kept open to circulate the air. However most of the time it was a localised heating.

*"We can't afford to keep the electric oil filled radiator on all the time. So, we switch it on only when it is very cold and we cover it with a blanket, so we heat up quickly"*

Most of the households turned the heating off as soon as the occupants achieved a temporary thermal comfort, to save energy. One resident said:

*"We simply cannot afford to keep the air conditioning on all the time"*

Most of the dwellings start to be heated in November and the heating is greatly on until March or April. Most of the dwellings are heated in morning and evening which is the time when they are fully occupied and there are no indecent solar gains. Only seven dwellings were heated during the nights and there are noticed higher main temperature in bedrooms of these dwellings compared with the ones that are not heated during the night. Most of the households opened the windows in the morning just for fresh air exchange. In contrast, in most of the dwellings that were heated all day, the indoor temperature was controlled by opening and closing the windows. There is a low correlation factor ( $r=0.255$ ) between the type of heating and type of control. However, it is interesting to investigate whether certain control options are related to the types of heating. Indeed, using the convective cooling and heating systems can give the commodity to easily turn it on/off or change the temperature settings, while the heat produced from the wood stoves is more difficult to be controlled, making the resident opening the windows when it is too hot.

There are other considerations related to cultural norms for some of the families, especially those who live in detached houses (where the security issues are not a concern), to leave the door open for visitors and showing them their hospitality. Thermal preferences were also very different within some of the households. One female participant said:

*"I want fresh air all the time and keep the windows open all day in summer and mostly in winter. I don't care what my husband thinks or feels. He can get a blanket"*

Table 5: Standardized indoor temperature in living rooms by behavioral practices in summer and winter

## Discussion

It is revealed from this research that there were particularly bad thermal conditions in winter with very low temperatures and high fluctuation during the day up to 33 degrees. Convective cooling and heating was mainly used and it was used for longer period in winter than in summer, suggesting that heating was more crucial than cooling in Albanian houses.

Furthermore, cooling and heating were performed locally in all dwellings and for short periods of time during the day in most of them.

No significant correlation was found between indoor temperatures and building characteristics such as typology, year of construction and number of stories, apart from a weak correlation between indoor mean temperatures and the main construction material.

In summer, statistically similar temperatures were both reported as neutral and hot (around 29°C). However, only 10% was feeling neutral at this temperature, meaning that it could be related to individuals and their preferences. In addition, residents were feeling slightly cool for mean temperatures of 26.5°C. In winter, the occupants were feeling cold for temperatures 15°C and neutral for mean temperatures of 16°C. Economic factor was determinant for not being able to keep the house comfortable in summer and winter. However, cultural issues were associated with some behavioural practices which might be determined in achieving successful outcomes for future retrofitting projects.

## Conclusion

The analysis carried out for this research provides evidence of the energy and thermal performance of residential buildings in Albania, as well as occupants' thermal perceptions and preferences. It was found that heating the Albanian dwellings is more crucial than cooling and a way to achieve energy savings is to aim to decrease the duration in months, especially for heating. Furthermore, special attentions to be considered for unintended consequences such as overheating, which could increase the energy consumption for cooling. Given these findings, it is essential to use them to inform and calibrate the baseline energy models, prior to investigating any retrofitting strategies, to minimise the performance gap created by assumptions and predictions.

## **Impact of building envelope construction on thermal comfort: a parametric analysis of modern, low income housing in south-west Nigeria for current and future climates**

steve.sharples@liverpool.ac.uk

**Abstract:** Studies have shown that the biggest climate impacts will take place in the tropical countries of Africa. This paper examines how different building construction choices influence the thermal performance of contemporary low-income housing in the south-west Nigeria region for present and future climates. Climate-resilient and responsive dwellings need to be developed that can adapt to changing tropical climates whilst being socio-economically suited to their geographical context. This study examines the evidence of climate change in south-west Nigeria and how the region's contemporary low-income housing currently performs from energy and thermal comfort perspectives. Then, the study uses dynamic thermal modelling and current and future climate data sets to test, parametrically, how changes to the dwelling's envelope can be made to reduce climate change impact and improve occupant thermal wellbeing. As such, the typical south-west Nigerian family house type was modelled and parametrically optimised. The findings showed that some modifications to the walls, roofs and floors can help improve thermal comfort in present and future south-west Nigerian climates. The study concludes that improvements to thermal comfort and climate change resilience are realistically achievable by small modifications to a dwelling's envelope.

**Keywords:** Vernacular housing, climate-resilience, building envelope performance, parametric optimisation

### **Introduction**

Climate change is a phenomenon associated with industrialisation, urbanisation and the accompanying increase in greenhouse gas (GHG) emissions from the burning of fossil fuels (Thiele, 2013; Johnson et al, 2015). Despite these factors being associated primarily with the developed world, the Intergovernmental Panel on Climate Change (IPCC) identified the continent of Africa as being at risk from the impacts of climate change, with the threat of higher land temperatures, changes in precipitation and stresses on water availability (Niang et al, 2014). Nigeria will experience most of these predicted impacts and so strategies must be developed that make Nigeria more resilient to climate change. Ijeoma (2012) identified resilient housing as a key component of this strategy. Climate responsive architecture addresses climate change by trying to use passive measures to work with the prevailing climate and to reduce the need for fossil fuel energy. Climate-responsive design produces spaces, whether individual or communal, that adapt to contextual climates to create optimal living settings. In this study, a typical house in south-west Nigeria was investigated to exam its thermal performance under the existing climate. Dynamic simulations of the house

allowed thermal comfort conditions to be assessed, and by generating future climate scenarios for the same region it was also possible to estimate future comfort conditions in the house. Finally, some passive design alterations to the house were made and then the impacts of these changes on thermal comfort for current and future climates were investigated.

### **Nigeria and Climate Change**

Nigeria is a west-African country, and is the most populous country in Africa (CIA, 2015). It is also Africa's largest economy, presenting a platform for advancement in all sectors. Presently, it seems that there is still much room for investigations into climate change in Nigeria. AMCEN (2011) stated that Nigeria is the fourth highest emitter of carbon dioxide globally. Therefore, the country is important in discussions that consider the roles that African countries must play towards combating climate change. According to the CIA (2015), Nigeria is a party to the Climate Change-Kyoto Protocol, which was "*...an international agreement linked to the United Nations Framework Convention on Climate Change, which commits its parties by setting internationally binding emission reduction targets*" UNFCC (2014).

National awareness about climate change is being encouraged in Nigeria, and regions of the country are being incentivised about taking steps towards mitigating climate change. From reports of present and predicted floods in southern Nigeria, it is apparent that the country's coastal regions are at risk (AMCEN, 2011). Other predictions state that the increased flooding will be accompanied by droughts in rural areas, which may trigger rural-urban migration. Consequently, there will be rapid urbanisation, which implies higher levels of poverty, inadequate infrastructure and housing. South-western Nigeria's climate change can be addressed partly from the platform of architecture, by promoting the use of green and climate-responsive housing solutions in the region (AMCEN, 2011).

### ***South-western Nigeria's geography, climate and housing***

South-western Nigeria lies along the country's western coastline, bordered by the Atlantic Ocean (see Figure 1). The region comprises of six states, namely: Oyo, Ogun, Lagos, Osun, Ekiti and Ondo. The population of the region has been estimated at 32.5 million people and they account for about 21% of Nigeria's total population (AOAV, 2014). The Yoruba have dwelt in large urban communities in Nigeria's south-western regions for thousands of years (Laitin, 1986). The south-western Nigerian topography features mainly lowlands. The climate of the region is equatorial and tropical rainforests abound. There is a rainy season, which is caused by the wet south-west winds blowing from the Atlantic. This generally lasts from March till November. The dry season lasts from November till March and is caused by the Harmattan winds, which blow from the northern deserts (My Destination, 2014).

### ***South-western Nigerian housing and climate change***

Against the background of oil flares and waste sites it may seem that housing is a relatively negligible contributor to climate change in the region (AMCEN, 2011). However, national plans towards climate change mitigation emphasise that development takes in to consideration climate-responsive and climate-sensitive growth. When south-western Nigerian housing is studied, definite relationships between housing practices and the climate context can be established. Presently, typical modern and affordable housing available in south-western Nigeria possess a hip and gable roof, while featuring the use of glass sliding or louvered windows, reinforced concrete slabs and columns and metal roofing sheets. In many

such dwellings, the installation of electric appliances, such as air conditioning units or electric fans, and fluorescent tubes among others, are very necessary due to the climatic context (Olaniyan et al, 2013). As this borrowed architecture is climatically unsuitable, occupants resort to using electrically powered mechanical ventilation when indoor air temperatures are high. As such, petrol generators, which release carbon dioxide, are commonly used in the region. Thiele (2013) points out that burning fossil fuels, such as petrol, for energy will accelerate climate change. Accordingly, a large amount of qualitative research has shown that the degree of climate-responsiveness of modern south-western Nigerian housing is relatively low. Presently, there are efforts at understanding the climate responsiveness of housing design in this region objectively, and this study represents one such effort.

Figure 1. South-west Nigeria (source: <http://www.seedbuzz.com/knowledge-center/article/seed-supply-system-for-vegetable-production-at-smallholder-farms-in-southwe>).

## Methodology

### ***Thermal comfort and parametric optimisation***

This study primarily aimed to examine quantitatively thermal comfort and building envelope climate-responsiveness and performance in a typical south-western Nigerian family house. Thermal comfort predictions, derived from the computer modelling software DesignBuilder, were analysed and compared against different building envelope designs (set by tropical design standards). Hence, this study employed the parametric optimisation concept which involves searching for the best possible solution to a problem under the constraints of certain parameters (Lee, Han & Lee, 2016). This study focused on the relationship between air temperature and the building envelope under different climate scenarios, created by a unique specification of building envelope parameters without altering the general model. The operative temperature was considered for thermal comfort, especially as studies have revealed that humidity is generally a minor factor in determining thermal comfort (Mallick, 1996). In addition, the effects on the internal thermal environment due to climate change in south-western Nigeria were also investigated. The ASHRAE 55 adaptive thermal comfort standard served as the bench mark for this analysis. This standard stipulates that for optimum thermal comfort conditions the operative air temperature should be between 23°C and 29°C.

### ***Geographical context and climate of study***

Climatic data were generated by the software Meteonorm (Meteonorm 2015) for the south-western Nigerian city of Ibadan, which is built on seven hills and is approximately 150 km from the Atlantic Ocean. It is geographically located between latitude  $7^{\circ} 20'$  and  $7^{\circ} 40'N$ . The month of March - the warmest month - was chosen for the analysis. Meteonorm was used to generate both current and future weather data files for Ibadan up to the year 2050. Figure 2 shows the annual average temperature, indicating the magnitude of the predicted increase due to climate change.

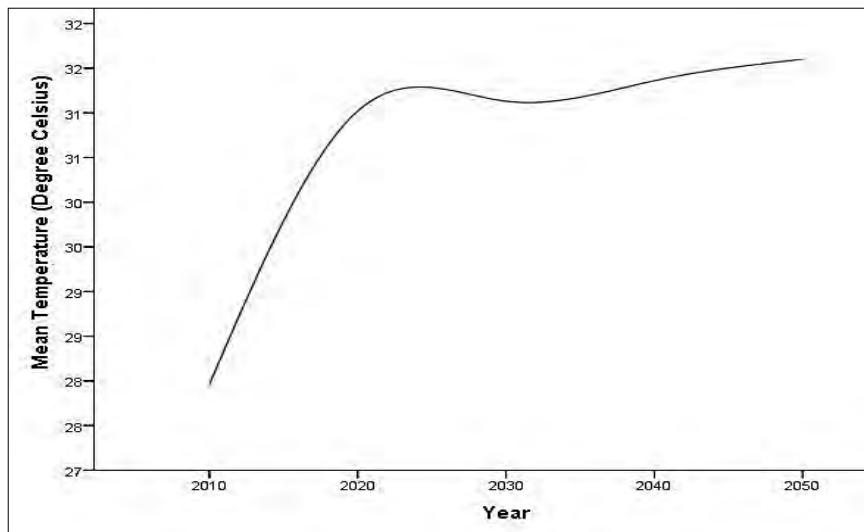

Figure 2. Ibadan's average annual mean air temperature now and up to 2050 (source: Meteonorm).

### ***House and materials***

A typical lower middle-class contemporary low-cost house was modelled using DesignBuilder (see Figure 3). The house had a total floor plan area of  $36m^2$  with a lounge ( $15m^2$ ), dining area ( $11m^2$ ), kitchen ( $11m^2$ ), bathroom ( $10m^2$ ) and two bedrooms (each  $16m^2$ ), and would typically accommodate 4 to 6 people. The base case model consisted of the basic envelope, with external walls made of 230mm cement/plaster mortar blocks; a floor of 126mm reinforced concrete slab with screed; and a pitched, uninsulated roof with a metal covering. No HVAC systems were used. Meteonorm climatic files were exported in an .epw format to DesignBuilder and indoor air temperature values were derived from the simulation analyses. Simulations based on the climatic contexts on a day during the hottest month of the year (March) were produced.

Based on weather data generated by Meteonorm, future weather conditions for south-western Nigeria over the next 35 years were generated to compare thermal comfort parameters now and in the future. The results of the simulation analyses show a rise in outside dry bulb temperature levels (see Figure 2). The building envelope performance was optimised for present (1991-2010 Meteonorm dataset) and future (2050 Meteonorm data set) climates. The month of March, the warmest month, was chosen for analysis. The validity of the DesignBuilder weather data values were checked against field measurements of external temperatures made by Adunola (2014) in Ibadan (Figure 4), and the agreement was satisfactory.

Figure 3. Base case model – floor plan and 3D model.

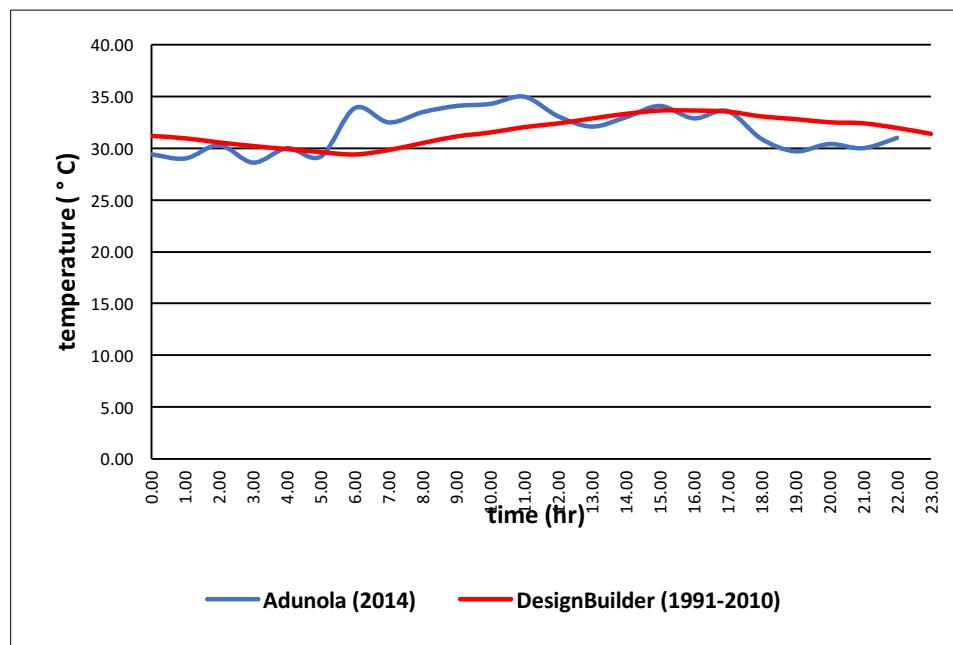

Figure 4. Validation of external temperature data for March (source: author's data analysis; Adunola, 2014).

## Results

A parametric analysis for the walls, floor and roof constructions was undertaken for the hottest month of March. This study considered that thermal comfort had been established when the operative temperature (average of indoor air and mean radiant temperature) was within the comfort zone ( $23^{\circ}\text{C}$  -  $29^{\circ}\text{C}$ ). For walls, Figure 5 shows that for the current SW Nigerian climate, hollow heavyweight concrete walls performed better than natural adobe or stone walls. However, operative temperatures with heavyweight concrete walls were still outside of the comfort zone (the shaded area in Figures 5 to 8).

Two composite floor types were assessed: reinforced concrete slab and concrete slab with timber joists. The reinforced concrete floor promoted temperatures closest to the comfort zone (see Figure 6). Here, during the hottest periods of the day (12:00 noon to 17:00) temperatures were still outside the thermal comfort range.

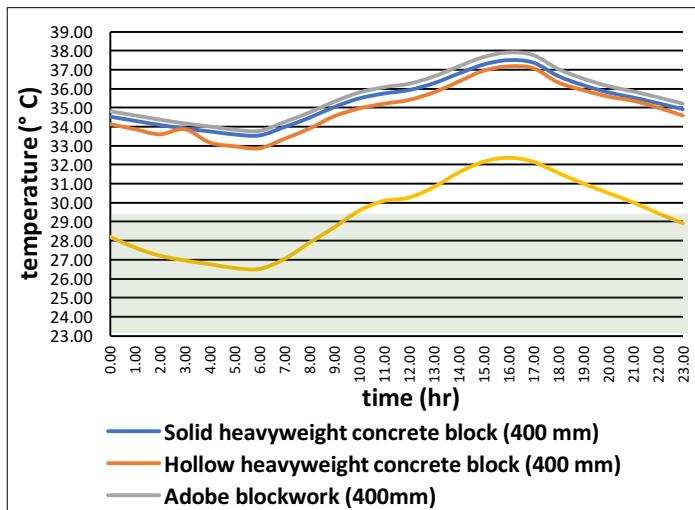

Figure 5. Hourly mean indoor operative temperature for different wall materials in March.

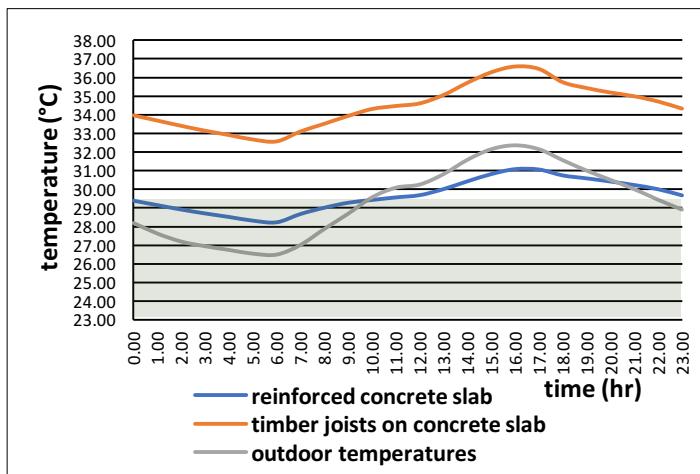

Figure 6. Hourly mean indoor operative temperature for different floor materials in March.

Two roofs were examined to optimise the roof performance. These were the hardwood-framed pitched roof and hardwood-framed flat-roof. With the hardwood-framed pitched roof, all the diurnal temperature ranges fell within the comfort range (see Figure 7). Finally, comparisons between the basic dwelling model for present and future climates revealed that the operative temperatures were outside of the thermal comfort range in both instances. However, the optimised building envelope delivered thermal comfort in present and future climates (see Figure 8 (a) and (b)).

### **Discussion**

The best-performing heavyweight hollow concrete block wall contradicts the claims of many studies that promote adobe walls for humid tropical climates (Tessema et al, 2013; Osasona, 2007). Optimisation of the floors also validated concrete as a suitable material for the climate as opposed to the timber material promoted by some studies (Atkinson 1950). For the roofs, a pitched roof undoubtedly performed best, as has been found by previous research (Jiboye & Ogunshakin, 2010). The interesting observation was the fact the concrete walls performed

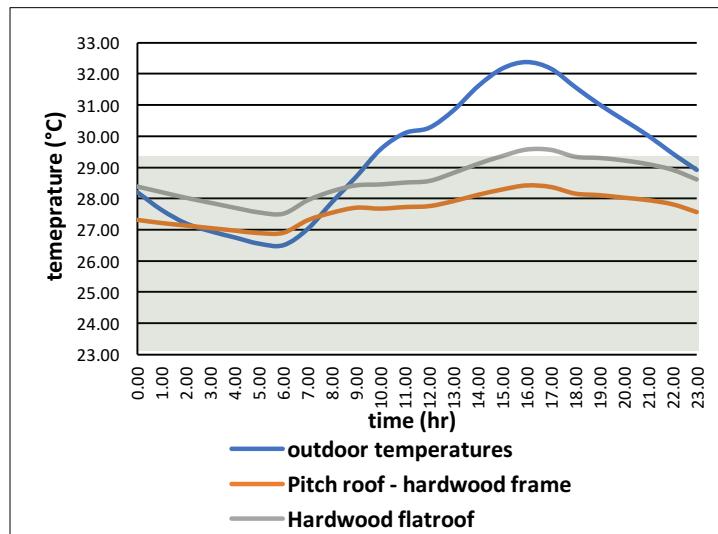

Figure 7. Hourly mean indoor operative temperature for different roofs in March.

better than adobe walls. Similarly, concrete represented a better option compared to timber, another indigenous building material. Therefore, there seems to be a limit to how much indigenous construction can be integrated effectively with modern construction.

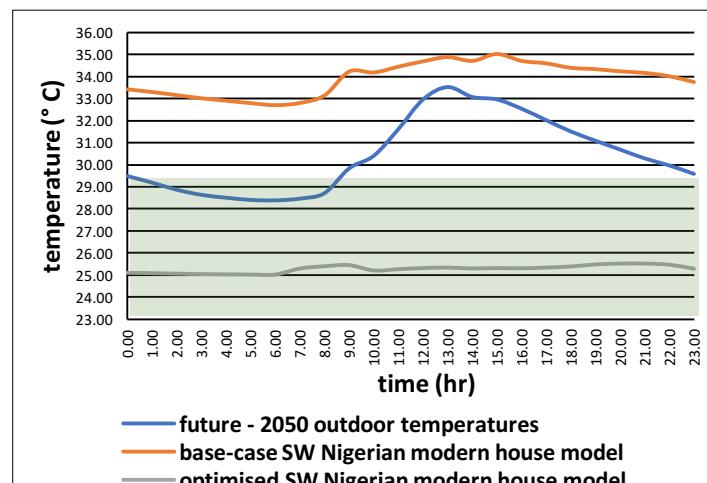

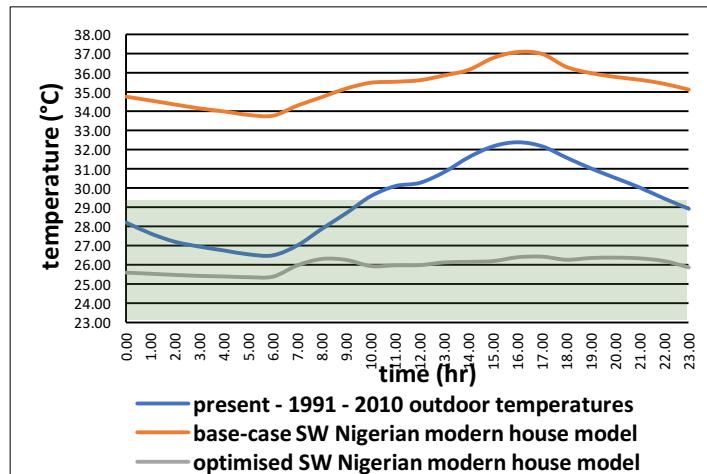

Figure 8. Comparison between optimised and unoptimized versions of SW Nigerian modern house model for present (top graph) and 2050 (bottom graph) climates.

## Conclusions and recommendations

Based on the results, it can be concluded that optimising a dwelling's envelope is a promising way of improving indoor thermal comfort for the present south-west Nigerian climate. Furthermore, the optimisation analyses indicate the ability of the building envelope to adapt to future climates. However, this study has only explored the relationship between temperature and the building envelope within the south-western Nigerian climate presently and in the future. Therefore, there is a need for more investigations into the effects of building envelope optimisation on other indoor environmental parameters, such as natural ventilation and air quality, in present and future climates.

## The Impact of Different Watering Strategies on the Cooling Effects of Pavement-Watering during Heat-Waves

Sophie Parison<sup>1,2</sup>, Martin Hendel<sup>2</sup>, Kristine Jurski<sup>3</sup> and Laurent Royon<sup>2</sup>

<sup>1</sup> Service Technique de l'Eau et de l'Assainissement & Laboratoire d'Essai des Matériaux, Mairie de Paris, Paris, France

<sup>2</sup> LIED (UMR 8236, CNRS), Université Paris Diderot, Paris Sorbonne Cité, Paris

<sup>3</sup> MSC (UMR 7057, CNRS), Université Paris Diderot, Paris Sorbonne Cité, Paris

**Abstract:** Pavement-watering is currently being viewed as a promising cooling technique for dense cities seeking short-term climate change adaptation methods. In this regard, the city of Paris has implemented a field experiment since 2013 in order to improve pedestrian's thermal comfort during heat waves, using the city's non potable water network. The campaigns conducted in 2013 and 2014 have demonstrated that pavement-watering has a positive impact on pedestrians' thermal comfort. In 2015 and 2016, different watering strategies were experienced, aiming to reduce the method's water consumption. In 2015, fewer statistically significant events were found in the morning with regard to the previous years, though the air temperature at 1.5m was reduced up to 1.2°C and by 0.6°C on average. Relative humidity and mean radiant temperature were also affected, resulting in a reduction of UTCI-equivalent temperature up to 2.8°C and by 1.2°C on average. Over the summer of 2016, the impact of the new watering strategy remains uncertain, due to several reasons. The impact of that change on the micro-climatic effects of pavement-watering is though discussed and future improvements are proposed.

**Keywords:** Pavement-watering, climate change adaptation, urban cooling, thermal comfort, urban heat island

### Introduction

In order to cope with climate change, cities have to develop innovative methods to deal with heat waves, that are likely to become both more frequent and intense in the upcoming years and that can cause excess mortality of the population (Robine, 2008). In this regard, the city of Paris has shown interest since 2013 in the implementation of a field experiment taking place on rue du Louvre, which aims to determine the effects of pavement-watering on pedestrians' thermal comfort (Hendel, 2015).

Our study is part of that process and proposes the quantification of the cooling effects of *in situ* pavement-watering during heat waves. To that purpose, two weather stations have been installed on rue du Louvre, one case and one control. Over the summers of 2013 to 2015, both the pavement and the road were watered. The campaigns carried out in 2013 and 2014 have demonstrated that pavement-watering leads to a 0.79°C maximal reduction of air temperature (0.31°C on average). Other parameters being also affected, the Universal Thermal Climate Index (UTCI)-equivalent temperature is reduced up to 1.03°C and by 0.42°C on average. In 2015, the watering frequency was reduced in the morning with regard to the previous years, while in 2016, only the road was watered instead of the both the road and the pavement. The purpose of those new watering strategies was to determine whether

pavement-watering cooling effects would still remain significant while reducing the amount of water used by the process.

Unfortunately, a dysfunction of our control weather station in 2016 on rue du Louvre forced us to use another control station, located in the Belleville district in Paris, 4.5 km away from the former. In addition to that, due to overall bad weather conditions in Paris in June and July 2016, almost all of the watered days on rue du Louvre occurred at the end of August, during which weather conditions met our requirements to trigger watering, unlike the previous years during which it mostly occurred during the months of June and July. Between those two periods, the net radiation overall look varies greatly on the Louvre site, leading to additional difficulties in the analysis of the 2016 data.

As a consequence of those two random hazards, the impact of the new watering strategy experienced in 2016 remains unclear. We here present an analysis of the cooling effects of pavement-watering in 2015 using both Louvre weather stations, and also a comparison between 2015 and 2016 using the Louvre case station and Belleville control station. The impact of the chosen watering strategy is then discussed and compared to the results obtained in 2013 and 2014, and further improvements are proposed.

## Methodology

The methodology applied for our field experiment is thoroughly described in Hendel (2015). It is briefly reminded hereafter.

### *Site location*

Local micro-climatic data was measured over the summers 2013 to 2016 on rue du Louvre, a north-south oriented street in the 1<sup>st</sup> and 2<sup>nd</sup> districts of Paris. Control and case weather stations are positioned approximately 200 m apart (see Figure 1). Due to a dysfunction of the Louvre control station in 2016, another control station was used, located in the Belleville district. This control station is located ~4.5 km away from the Louvre site and is positioned in an east-west oriented street. In previous studies (Hendel, 2015 & Hendel et al., 2016), this Belleville station was though used as a case station. For consistency, it will be though referred to as “Belleville control station” hereafter.

Figure 1. Station positions at the Louvre (left) and site locations across Paris' non potable water network (right) (Hendel, 2015).

#### **Watering strategy**

Pavement-watering was triggered if weather conditions met our criteria, based on a three-day Météo-France's forecast. The watering criteria, as well as the heat-wave criteria for Paris, are presented in Table 1.

Table 1. Weather conditions required for pavement watering and heat wave warnings in Paris

Parameter	Pavement-watering	Heat-wave warning level
Minimum air temperature	$\geq 16^{\circ}\text{C}$ (3-day mean)	$\geq 21^{\circ}\text{C}$ (3 consecutive days)
Maximum air temperature	$\geq 25^{\circ}\text{C}$ (3-day mean)	$\geq 31^{\circ}\text{C}$ (3 consecutive days)
Wind speed	$\leq 10 \text{ km/h}$	-
Cloud cover	sunny (< 3 oktas clouds)	-

On watered days, pavement-watering is ensured by the passing by of cleaning trucks using Paris' non-drinkable water, principally sourced from the Ourcq Canal. From 2013 to 2015, approximately 1mm of water was sprinkled every hour from 6:30 to 11:30 (in 2015, every two hours from 9:00 to 13:00, and in 2016, every one hour and a half from 7:00 to 11:30) and every 30 minutes from 2 pm to 6:30 pm on both the pavement and the road. In 2016, only the road was watered.

### Weather stations

A weather station diagram is illustrated on Figure 2. These are placed on the border of the pavement and measure air temperature ( $T_{\text{air}}$ ), relative humidity (RH) and black globe temperature at pedestrian height (1.5 m) as well as wind speed and net radiation at 4 meters above ground level. Instruments were protected from vandalism using a white-painted cage. Measurements were made continuously once every minute and were recorded using local day time (UTC+2).

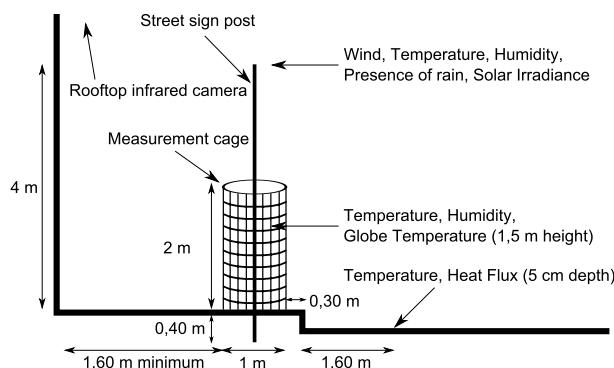

Figure 2. Weather station design and instruments used on rue du Louvre (REF)

### Interpretation method

To estimate the effects of pavement-watering, watered days are compared to reference days, for which weather conditions met our requirements (see Table 1) but watering was not triggered. In Hendel (2015), it was demonstrated that direct comparison between case and control station is not a valid method to determine the field effects of pavement-watering in cities, due to systematic case-control differences on reference days, i.e even when watering is not triggered.

For the analysis of the data, we therefore use a two-sample t-test for each minute to compare the average watered and reference day interstation profiles for each parameter. Therefore, we consider the difference between case and control stations on all reference days and on all watered days, but not the absolute values of the parameters themselves.

Notations chosen for the average profiles as well as the null and alternative hypotheses formulated for the t-test are presented in Table 2. The index “i” stands for the current considered minute while the letter “y” stands for the considered physical parameter for the test. A significance level of 0.05 is used, meaning that if the obtained p-value is lower than 0.05, the null hypothesis is rejected.

Table 2. Notation used for average profiles and hypotheses formulated for the t-test

Average watered profile	$X_i^{\text{wet}} = \langle y_i^{\text{case}} - y_i^{\text{control}} \rangle_{\text{all watered days}}$
Average reference profile	$X_i^{\text{dry}} = \langle y_i^{\text{case}} - y_i^{\text{control}} \rangle_{\text{all reference days}}$
Null hypothesis	$X_i^{\text{wet}} - X_i^{\text{dry}} \geq 0$
Alternative hypothesis	$X_i^{\text{wet}} - X_i^{\text{dry}} < 0$

Also, the mean radiant temperature ( $T_{\text{mrt}}$ ) (used to characterize the ambient radiative environment) was estimated from the measured parameters following the ASHRAE method (ASHRAE. 2001). To estimate the benefits of pavement-watering on pedestrians' thermal comfort, the UTCI is calculated using the simplified Bröde algorithm (Bröde. 2009).

## Results

Effects of pavement-watering on the air temperature in our different case studies are illustrated on Figure 3. All reference days from 2013 to 2016 were used (namely 28) for each analysis. Fig. a represents the effects of the 2015 strategy using Louvre stations (9 watered days in 2015), fig. b using Louvre case and Belleville control stations, and fig. c using Louvre case and Belleville control stations for the 2016 watering strategy (9 watered days in 2016).

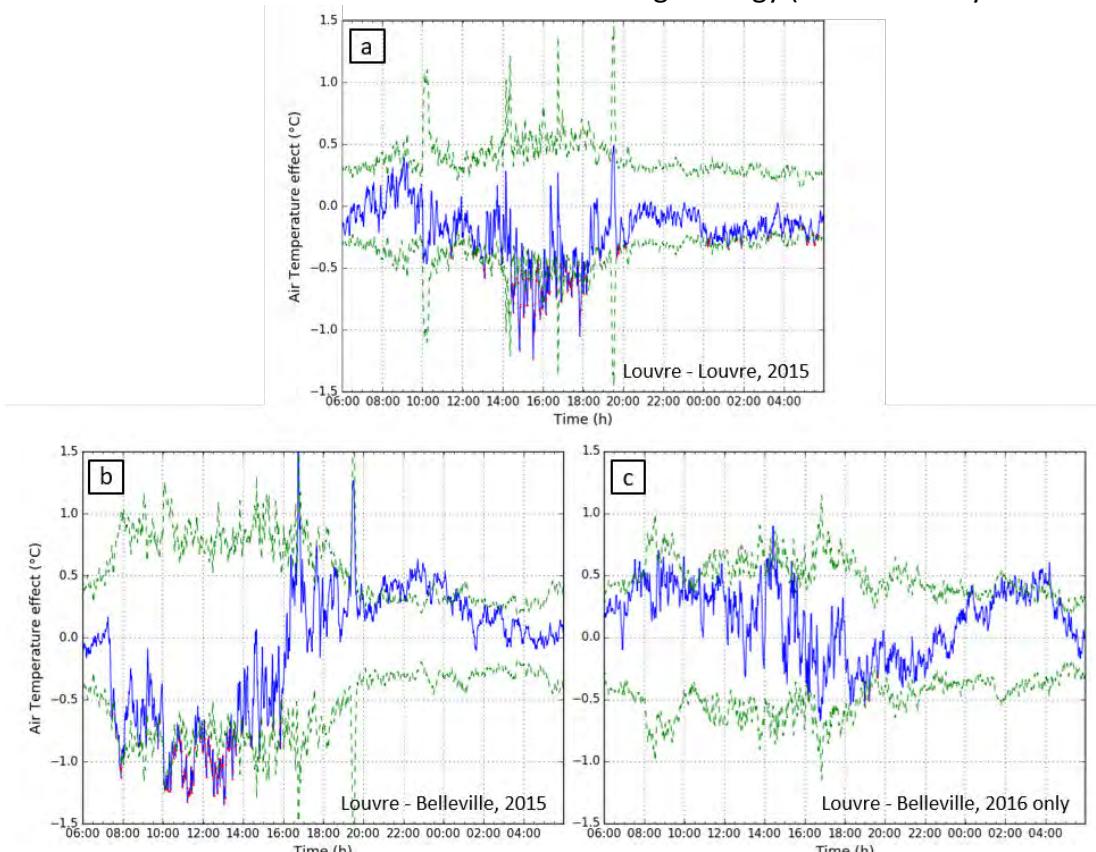

Figure 3. Average watering effects on the air temperature for the Louvre case and control stations over the summers of 2015 (a), for the Louvre case and Belleville control stations in 2015 (b) and for 2016 only (c)

Blue lines represent the average effect of watering while green dotted lines represent the margin of error of the t-test. Beyond this margin are statistically significant (stat. sign.) events, represented with red dots, for which  $p\text{-value} < 0.05$ , meaning that we are at least 95% confident that we wouldn't obtain such a value if the null hypothesis were correct.

On figure 3a, we notice that the impact of pavement-watering in 2015 is manifest. Mostly negative stat. sign. changes are exhibited for the air temperature, i.e the environment is made cooler thanks to watering. Though effects of watering are perceived throughout the whole day, maximum effects are experienced roughly from 14:00 to 19:00.

As compared to the effects obtained over the summers of 2013 and 2014 (Hendel et al., 2016), we notice that the cooling effects of watering in the morning seem to be lessened in 2015, due to the change of the watering frequency (once every 2h in 2015 against once every hour before). Indeed, fewer stat. sign. events are detected from 9:00 to 12:00.

On figure 3b, Belleville control station was used to analyse the 2015 data in order to give better insight of the impact of this analysis method on our results. On this figure, we note that the amplitude of maximum stat. sign. effects are marginally increased, which supports the hypothesis that the watered area on the Louvre site may influence the dry area, as stated in Hendel (2015). To address that issue, new analyses shall be conducted using a matched-pairs t-test for example. Nevertheless, only few stat. sign. events are detected, unlike what is seen on fig. 3 a. This can partially be attributed to the enlargement of the margin of error for the t-test, due to the major differences in insolation patterns between those two stations as compared to both the Louvre stations, all things equal otherwise. Solar irradiance on the Louvre stations and on Belleville control station is presented on Figure 4.

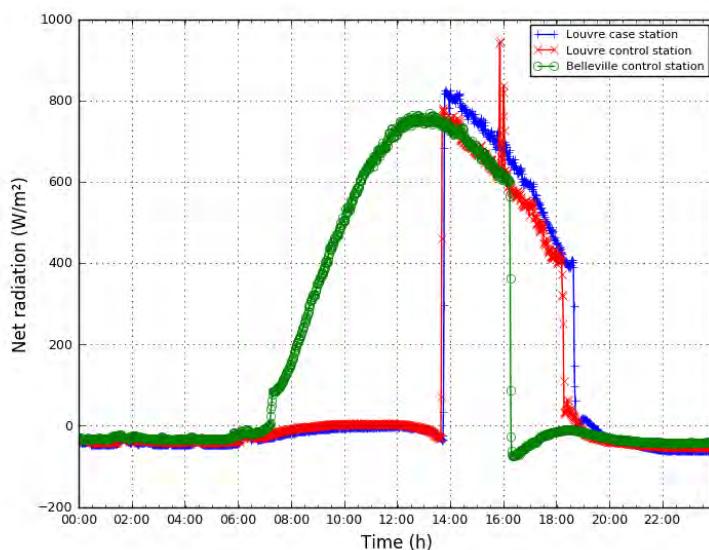

Figure 4. Solar irradiance at Louvre stations and at Belleville control station on the 6<sup>th</sup> of June 2015

On Figure 4, we notice that solar irradiances between the Louvre stations are highly consistent with each other, unlike the Belleville control station. The Belleville station being located in an east-west oriented street, in June, it is illuminated from 8:00 whereas illumination starts at 14:00 on the Louvre. In the afternoon, Belleville and Louvre stations are shaded at respectively 16:00 and 18:00. As a consequence, though figures 3a and 3b are obtained using the same data (only different control stations), the noticeable impact of watering appears at two different moments, namely roughly from 14:00 to 18:00 for fig. 3a and from 10:00 to 14:00 for fig. 3b.

Finally, concerning figure 3c, the impact of watering in 2016 is seemingly less important than what is observed on figure b for 2015 using the same stations. We indeed find out that almost no stat. sign event is detected. This might be the consequence of the use of the Belleville control station (leading to an enlargement of the margin of error with regard to the analysis conducted with both Louvre stations, as previously seen) as well as of the impact itself of watering the road only. Also, most of the watered days occurred in June/July from 2013-2015, while it mostly occurred in August in 2016, where solar irradiance is quite different from the beginning of the summer.

Average and maximum values of stat. sign. events in each case are summarized in Table 3, duration and hour of occurrence of those events are exposed in Table 4, and finally, p-value and mean effect of a 24h t-test are shown in Table 5.

Table 3. Average and maximum values of stat. sign. effects of pavement watering for 2016 and for 2015 using Louvre-Belleville crossed stations, and using Louvre stations only

Parameter	2016 (Louvre case, Belleville control)		2015 (Louvre case, Belleville control)		2015 (Louvre case and control)	
	mean	max	mean	max	mean	max
T <sub>air</sub>	-0.44°C	-0.55°C	-0.81°C	-1.08°C	-0.57°C	-1.23°C
RH	+2.29%	+4.23%	+2.61%	+5.08%	+1.87%	+3.8%
T <sub>mrt</sub>	-1.52°C	-15.3°C	-7.92°C	-12.7°C	-1.39°C	-8.92°C
UTCI	-0.97°C	-3.61°C	-2.46°C	-3.52°C	-1.16°C	-2.84°C

Table 4. Duration of stat. sign events and occurrence hour of maximum stat. sign. Event for 2016 and for 2015 using Louvre-Belleville crossed stations, and for 2015 using Louvre stations only

Parameter	2016 (Louvre case, Belleville control)		2015 (Louvre case, Belleville control)		2015 (Louvre case and control)	
	duration (h/d)	h. of max	duration (h/d)	h. of max	duration (h/d)	h. of max
T <sub>air</sub>	0.15	19:00	3.22	10:12	3.36	15:30
RH	5.52	15:05	6.93	10:24	4.80	15:30
T <sub>mrt</sub>	5.52	16:36	1.50	12:59	4.2	17:50
UTCI	0.9	16:36	0.85	11:24	2.03	17:50

Table 5. p-value and average 24h stat. sign. effects for 2016 and 2015 using Louvre-Belleville crossed stations, and for 2015 using Louvre stations only

Parameter	2016 (Louvre case, Belleville control)		2015 (Louvre case, Belleville control)		2015 (Louvre case and control)	
	p-value	mean	p-value	mean	p-value	mean
T <sub>air</sub>	-	-	-	-	0.0236	-0.20°C
RH	0.018	+0.65%	0.0093	+1.90%	0.0018	+0.77%
T <sub>mrt</sub>	-	-	0.0219	-4.28°C	0.0300	-0.48°C
UTCI	-	-	-	-	not stat. sign.	not stat. sign.

In Table 3, we notice same order of magnitude for stat. sign. events for 2015 between the two analyses, except for mean effects on mean radiant temperature and UTCI, much greater when using Belleville control station. This can be explained when looking at Table 4, where we notice that durations of stat. sign. events are much smaller when using Belleville control station. As seen before, in this configuration, the impact of watering is only detected in the morning. Since fewer stat. sign. events are detected using Belleville control station, mean values are thus brought closer to maximum events values, and tend to increase as a consequence.

Concerning 2016, for the same reason we observe similar effects in Table 3 as compared to 2015. Nevertheless, in Table 4, we note that stat. sign. events for 2016 last less than an hour, except for relative humidity and mean radiant temperature, which happen to be greatly influenced by watering. We therefore conclude that the impact of watering in 2016 is extremely tenuous.

Finally, in Table 5, we observe the 24h average effect of watering and the associated p-value. Empty cells mean that no 24h-average effect was found, and “not stat. sign.” mean that a cooling effect was indeed found but the associated p-value were greater than the confidence interval (0.05). In 2015 using both Louvre stations, a stat. sign. value is found for each parameter, meaning that watering has a great impact of the environment since it is perceived on a 24h average. With Belleville control station, no stat. sign. effects were found for the air temperature and the UTCI. For 2016, no stat. sign. effect was found for the mean radiant temperature either.

## Conclusion

Different watering strategies were conducted in 2015 and 2016 compared to 2013 and 2014. The campaigns carried out in 2013 and 2014 have demonstrated that watering the road and the pavement lead to a reduction of UTCI-equivalent temperature up to 1.03°C and by 0.42°C on average.

In 2015, watering frequency was reduced in the morning with regard to the previous years. The analysis of this data showed overall equivalent results, with a reduction of the UTCI equivalent temperature up to 1.23°C and by 0.57°C on average. Nevertheless, in the morning, fewer statistically significant events were found, meaning that this new watering frequency do have a small impact on the cooling effects exhibited thanks to pavement watering.

Those results were also analysed using a control station located elsewhere. Analysis revealed effects with the same order of magnitude, but a deterioration of the significance level, leading to the detection of much fewer statistically significant events. This observation can be attributed to the poor match of solar irradiances between the meteorological stations used.

Finally, the latter analysis was compared to the 2016 watering strategy, where only the road was watered, in order to reduce the method’s water consumption. Almost no stat. sign. effects were found for this case. Given the difficulties encountered in 2016, it is complicated to conclude if the watering strategy itself is inefficient, or if those results are the consequence of multiple factors. Indeed, using the Belleville control station instead of the Louvre’s has proven that it lessens the average detected effects and their duration. Also, the watered days in 2016 occurred in August whereas it mostly occurred in June and July before. The insolation between those two periods may vary, which has its importance on our comparison. Finally, given that the station is placed on the pavement, the strategy itself is expected to have a little impact on the results.

In any case, given the impact on the 2015 data on the results using the Belleville control station, using two stations with such a poor solar irradiance match seems to be unappropriate.

To better quantify the effect of the 2016 strategy, future campaigns will still focus on the reduction of the water consumption of pavement watering. Future results will be added to those already existing, leading to better statistics for our analyses.

## **Formulating a methodology to study adaptability in buildings to climate-change: climate-responsive adaptability in Indian conditions**

**Aysha Saifudeen<sup>1</sup>, Monto Mani<sup>1</sup>**

<sup>1</sup> Centre for Sustainable Technologies, Indian Institute of Science, Bangalore, 560012, India

**Abstract:** India is famous for its diversity, and is the identified high-risk of climate change. The diversity in climatic zones makes it a challenge in identifying any adaptation measures, as no one-solution would fit all. Climate-change would put the existing habitations to withstand changes in the periodicity, occurrence, and intensity in temperature, humidity, rainfall, and wind, all of which have originally influenced the design of vernacular buildings. Studying building adaptability, in terms of design and material configuration could provide a valid basis to verify the inherent preparedness of a habitation to impending climate-change and in devising active measure to mitigate vulnerability. The main objective here is to formulate a methodology to study adaptability of buildings, focusing on their climate-responsiveness. This would include the design of the building in response to the specific climate, geographic location, and the material configuration defining the building elements. The focus would be on passive and/or naturally ventilated dwellings, with an assessment on current/future demands on energy for maintaining thermal comfort. Besides prospective variations in climate classification in view of climate change, the proposed methodology would attempt to map the climate change repercussions in the physical manifestations and comfort requirements of a building for various climate zones.

**Keywords:** Climate change, Building adaptation, Climatic zone, Building comfort requirement

### **Introduction**

Climate change is imminent, on going, expected to occur more rapidly, and unpredictably than earlier expected. It is defined as the change in state of climate, recognized by changes in the different climatic parameters that persist for a long duration, due to either natural processes or external forces. Human induced reasons such as burning of fossil fuel, deforestation etc. causes global warming. It is the regional variation of climate due to rise in temperature, acting globally (Sands 1992), (V. Ramaswamy 2006). The independent analyses carried out by NASA and the National Oceanic and Atmospheric Administration (NOAA) has recorded the warmest surface temperatures during 2016, since 1880. The temperatures in 2016 were 0.99 degree Celsius warmer than the global average of mid-20<sup>th</sup> century mean. The entire year with eight of the twelve months were the warmest on the records. The average surface temperature of earth has increased about 1.1 degree Celsius since late 19<sup>th</sup> century. This is largely due to the various human driven emissions into the atmosphere (GISTEMP Team 2016),(Hansen et al. 2010) (IPCC 2014).

### **Climate change and habitations**

Climate change is affecting the habitations worldwide. A study on five bird species of south western United States shows that there is high risk of lethal dehydration due to increase in hourly temperature (Albright et al. 2017). The health of human beings is also highly sensitive

to the change in weather patterns and various aspects of climate. Habitations, particularly in the developing countries, are most prone to climate change directly as well as indirectly. If the variations in climatic factors such as temperature, humidity, precipitation or the occurrences of heat waves, drought, flood, fire etc. are the direct effects, indirect effects include the crop failures, shifting patterns of diseases, population migration due to prolonged drought etc. (Mertz et al. 2009).

### **Climate change and Built environment**

Built environment is also undergoing significant impact due to climate change. Based on the climatic zone, there will be considerable variation in energy use and energy demand. There will be changes in the use pattern of heating and cooling equipment, which can alter the economy pattern as well. There will be probable sways on the comfort levels of the occupants based on the changes in weather parameters. Climate-change would put the existing buildings to withstand changes in the periodicity, occurrence, and intensity in temperature, humidity, rainfall, and wind, all of which have originally influenced the design of vernacular habitations. However, many researches discuss the impact of buildings on climate change, such as air pollution, CO<sub>2</sub> emission, urban heat island, surface run-off and change in wind direction, very few discuss on the other way around. Nevertheless, a test was carried out on a small office building to show the scope of using building performance simulation tools in assessing the potential impact due to climate change. The prospective alterations in comfort levels, energy use and demand, effects on heating and cooling equipment, emission impacts, etc. is being discussed (Drury B. Crawley 2003).

### **Building adaptation**

According to James Douglas, “building adaptation include any work to a building over and above maintenance to change its capacity, function or performance”. Adaptability is the key attribute of adaptation where a building’s ability to absorb any scale of change. Building adaptation can be in different ways based on the purpose; reuse of space according to human needs, otherwise called adaptive reuse, the transformation of buildings due to anticipated changes or flexibility of built spaces to changing needs (Douglas 2006).

### **Methodology**

Building adaptation can be in two ways, spontaneous or involuntary and unsupernatural or voluntary. The term ‘Building adaptation’ in this study, is any unsupernatural or voluntary intervention to adjust a building to suit the changing conditions with respect to climate. This would test the ability of the built environment to withstand higher temperatures, drier or wetter seasons, and altered wind-regimes in providing favourable living conditions, and test short and long-term structural and durability resilience. Studying building adaptability, in terms of design and material configuration could provide a valid basis to verify the inherent preparedness of a habitation to impending climate-change and in devising active measures to mitigate vulnerability. The current scope is limited to predominantly vernacular dwellings, with an assessment on current/future demands on energy for maintaining thermal comfort. Even though the vernacular dwellings are more attuned to prevalent climates, the methodology is expected to be applicable to modern dwellings as well.

India is famous for its diversity, and is the identified high-risk of climate change (IPCC 2014). The diversity can be clearly seen in the various zones identified such as, hot and dry,

warm and humid, moderate, cold and sunny, cold and cloudy, and composite climates (Nayak & Prajapati 2006). The diversity in climatic zones makes it a challenge in identifying any adaptation measures, as no one-solution would fit all. The Table 1 below provides the general adaptation techniques available, with respect to the variation in climatic factors that form the basis for further studies. This is prepared in view of the probable changes occurring to the climatic factors of different climatic zones as mentioned in the other tables of this study. For example, a region belonging to the moderate climatic zone may shift to warm and humid climate. Then, the mechanisms adopted for comfort may become inadequate. The Table 1 discusses the potential adjusting mechanisms to achieve comfort in terms of occupant physiology, clothing, and buildings.

In this research, the authors are also trying to develop the prospective variations in the existing climatic zones of the country, due to climate change. It include the variations in the physical manifestations of a building, changes in the existing climate classification, and change in the building comfort requirement features during both heat loss and heat gain. The tables 2, 3 and 4 are adapted from the book chapter in press for the Encyclopaedia of Sustainable Technologies by Elsevier. The Table 2 shows both climate classification and climate change implications in physical manifestations of the buildings, corresponding to the increase and decrease in mean monthly temperature. The Table 3 and Table 4 shows the climate classification along with the building comfort requirement features, to resist heat gain and to promote heat loss respectively during the change in mean monthly temperatures. However, a reclassification of the climatic zones is challenging, as it is uncertain, but it forms the basis for this study of building adaptation due to climate change. This would include the design (and geometry) of the building in response to the specific climate and geographic location, and the (local) material configuration defining the building elements (walls, roof, fenestration, etc.) that determines the thermal performance of the building in appropriately regulating indoor thermal comfort.

## **Discussion**

We can see that, hot and dry zone requires a revision in classification, as the conditions are intensified due to increase in mean monthly temperature. Both cold & sunny and cold & cloudy zones require a revision in classification as the conditions are aggravated due to decrease in mean monthly temperature. The study observes that due to increase in mean monthly temperature, the regions belonged to moderate and composite zones has shifted to warm and humid zone, whereas the regions belonged to cold & cloudy and cold & sunny has shifted to moderate zone. There will be corresponding modifications to the building physical manifestations and the comfort requirements due to heat loss and heat gain.

## **Conclusion**

Climate change is occurring unpredictably worldwide. The different climatic zones in India are also facing severe changes on the various climatic factors such as temperature, humidity, wind, precipitation, and solar radiation. Therefore, it is necessary to add building adaptation as a major requirement among the other functional features of a built environment. The present study has looked at the role of building adaptation in the scenario of climate change. It has formulated a methodology to study the adaptability of buildings focusing on climate responsiveness. It has brought in, the prospective variation of existing climatic zones, with the modifications in physical expressions of a building along with the building comfort requirements, to both resist heat gain and promote heat loss.

Table 1: Adaptation techniques available with respect to the variation in climatic factors

Climatic factors with variation		Occupant Physiology/psychology	Clothing	Buildings
Temperature	High	Behavioural thermoregulation	Insulated, loose-knit, unlined/half lined, light colored fabric with low clo value	Mechanical air conditioning, evaporative cooling, fan or wind induced ventilation, natural ventilation
	Low	Increase metabolic rate to maintain warmer skin temperature	Close-knit, thicker weaves, lined, dark colored, tight-fit fabric with high clo value	Natural ventilation, mechanical heating, passive solar heating
Relative humidity	High	Lessen activity density	Breathable, loose-fit fabric with low clo value	Mechanical air conditioning, fan or wind induced ventilation, natural ventilation, dehumidifiers
	Low	Increase sweating capacity	Close-knit, lined, tight-fit fabric	Natural ventilation, humidifiers
Wind	High	Control room openings	Close-knit, thicker weaves, lined fabric with high clo value	Natural ventilation
	Low	Control room openings	Breathable, loose-fit, loose-knit fabric with low clo value	Fan induced ventilation
Precipitation	High	Mechanical shielding	Water repellent fabric with low clo value	Shading devices
	Low	Less shielding		Rain water harvesting
Solar radiation	High	Mechanical shielding	Breathable, more skin covered clothing with high clo value	Shading devices
	Low	Less shielding	loose-fit, loose-knit fabric with low clo value	Increased openings

**Abstract:** Thermal comfort is crucial to ascertain the energy consumption in buildings and is a key factor for decision-making in the design of sustainable building envelopes. This paper presents a methodology to assess the performance of construction systems quantitatively on the basis of overall yearly thermal comfort. A framework is proposed to deal with the risk from climate change temperature increases in the UK. A dynamic thermal model with five of the most commonly used construction systems for dwellings was chosen for simulation in London, UK, for current, short term, medium term and long-term climate scenarios using the software Designbuilder. The research investigated the effect of thermal mass and insulation thickness on the behaviour of widely used construction systems based on annual thermal comfort. The study reveals that high level of thermal mass and insulation thickness do not necessarily provide maximum comfort hours in high performance construction systems for future climates.

**Keywords:** Climate Change, Thermal Mass, Insulation, Thermal Simulation

### Introduction

Buildings that can respond to future climate change are less likely to be obsolete, and so future thinking in the early design stages of a building is an essential principle of sustainable development. One of the key parameters to decide energy consumption in buildings and, consequently, to determine possible future optimization is the thermal comfort of occupants. The potential impacts of changes in the UK climate on the built environment have become widely recognized, with possibly the most important feature of these changes being the impact of higher air temperature on building thermal performance. Tabatabaei, et al. (2015) considered the importance of alleviating climate change consequences by passive design features to offset temperature rises. The study also recognized that thermally lightweight homes could cause levels of discomfort by creating higher room temperatures. The research work emphasized that masonry houses, with inherent thermal mass, can result in less energy consumption over their lifetime compared to a similarly designed lightweight timber frame house. A study by Orme et al. (2007) indicated that in lightweight well-insulated houses an outdoor temperature of 29°C might cause overheating, with air temperatures of more than 39°C inside the building. The aim of this study is to quantify the thermal response of some wall construction types to climate change risk. Five of the most commonly used wall construction systems for dwellings were chosen, and all met the German Passivhaus (PH)

standard requirements – a standard that can reduce building carbon emissions by up to 80% in the UK (AECB, 2017).

## Methodology

Five common construction systems, including traditional and modern methods of construction (MMC), were selected and configured to achieve a U-Value of  $0.1 \text{ W/m}^2\text{K}$ . These constructions were used to investigate the effect of thermal mass and insulation thickness on comfort levels using the dynamic thermal simulation software DesignBuilder (DB) that employs EnergyPlus as its calculation engine. The admittance factor, i.e. building fabric response to a swing in temperature (CIBSE, 2006) was taken as a thermal mass performance indicator. The selected construction systems meant low, medium and high thermal mass performances were considered. Current and future weather data for London were used to evaluate the behaviour of the construction systems. Future climate data for three timelines (2020, 2050 and 2080) in London were generated by the ‘CCWeatherGen’ morphing procedure (SERG, 2016). CCWeatherGen morphs Chartered Institution of Building Service Engineers (CIBSE) TRY (Test Reference Year) files into future EPW files based on projections from the UK Climate Impacts Programme (UKCIP). EPW is the weather file format used by DB.

## Climate change

Lisq (2006) emphasized that “*the possible impacts of climate change on the building stock being built over the next few decades must be addressed today*”. Figure 1 illustrates the psychrometric charts for London in 2011 and 2080, with the comfort zones shown. These charts demonstrate likely temperature increases as well as likely thermal discomfort.

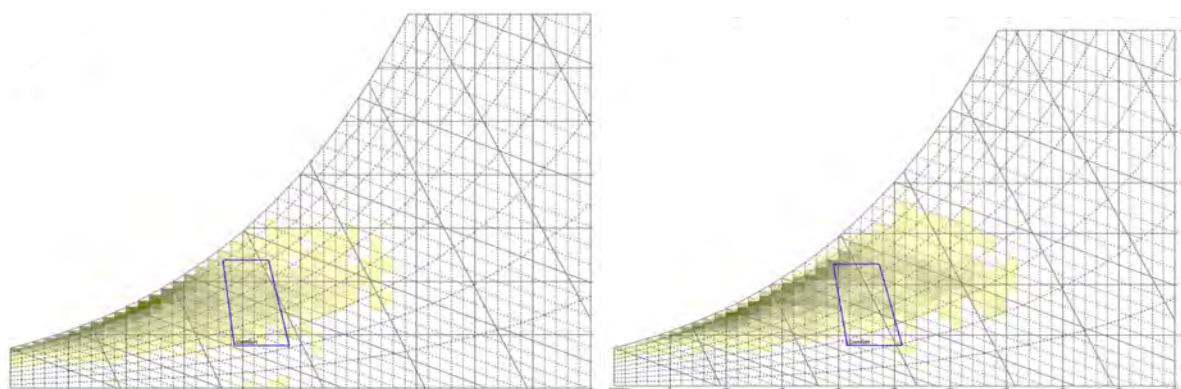

Figure 1. Psychrometric charts for London 2011(left) and London 2080 (right), showing comfort zones

London’s temperatures are expected to increase by around  $5^\circ\text{C}$  between 2011 and 2080, with levels of thermal discomfort also rising. Consequently, temperature increases may increase occupant vulnerability to overheating. Reducing this vulnerability will require improvements in both building energy performance and occupant thermal comfort. This paper examines the impact different construction choices can have in tackling the potential risk of overheating in future dwellings.

## Wall construction types for UK housing

This research considered five commonly used UK wall construction systems. The selection criteria were:

- Recent utilization in the UK housing industry

- Method appropriate for UK housing
- The potential of achieving the Passivhaus standard (set at 0.10 W/m<sup>2</sup>K U-Value)

The building model used for the simulations was a simple, single storey single zone room measuring 8m x 8m x 3.2m high with a centrally located south-facing triple glazed window 2m x 3m wide. The infiltration rate was set at 0.25 air change per hour (AC/H). Mechanical ventilation was considered and U-Values of 0.1 W/m<sup>2</sup>K for the roof and floor and 0.8 W/m<sup>2</sup>K for a triple glazed window were assumed. The wall constructions examined are shown in Table 1.

### **Thermal comfort**

Several studies have proposed a temperature range of 18-26°C as likely to be within the human comfort zone (Gupta & Gregg, 2012). ASHRAE 55-2004 identified thermal comfort as a subjective response and defined it as the '*state of mind that expresses satisfaction with existing environment*' (ASHRAE, 2004). Therefore, it seems that a precise value cannot be assigned to thermal comfort. '*State of mind*' largely depends on residents' perceptions and expectations. ASHRAE-55 is based on a the static heat balance approach, which includes four environmental variables (dry bulb air temperature, mean radiant temperature, relative humidity and air velocity) and two human variables (activity and clothing level). For simplification and quantification purposes, this paper used this standard as a reasonable way to assess the thermal comfort/overheating results.

### **Results and discussion**

DesignBuilder was used to analyse the thermal performance of the wall systems. The generated London weather data used a high emission scenario from the year 2011 until 2080. Predicted levels of total annual discomfort hours are shown in Figure 2 and given in Table 2.

Figure 2. Total annual discomfort hours in London for four climate periods

Table 1. Wall construction systems used for the simulations

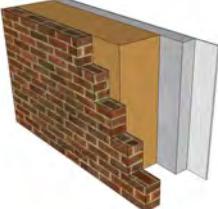

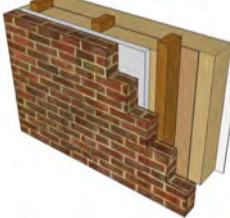

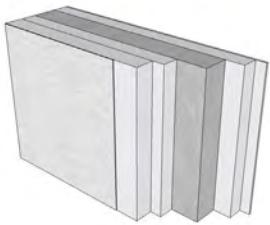

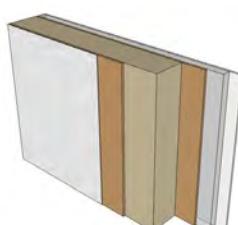

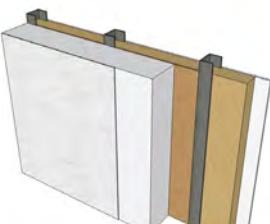

Construction Systems	Details
 Brick and Block BB	From Out to in: 110mm Brick Outer Leaf, 300mm Phenolic Insulation, 100mm Aerated Concrete Block, 10mm Lightweight Plaster Decrement factor (0-1): 0.23; Time Constant (Hrs): 7.7 Admittance ( $W/m^2K$ ): 5.3; U-Value ( $W/m^2K$ ): 0.1 Thickness (mm): 520
 Timber Frame TF	From Out to in: 110mm Brick Outer Leaf, 50mm Air Gap, 140mm Rockwool, 10 mm Plywood, 200mm Rockwool, 12.5mm Plasterboard Decrement factor (0-1): 0.2; Time Constant (Hrs): 3 Admittance ( $W/m^2K$ ): 1.54; U-Value ( $W/m^2K$ ): 0.1 Thickness (mm): 522.5
 Insulating Concrete Formwork ICF	From out to in: 5mm Rendering, 120mm Extruded Polystyrene (EPS), 100mm Extruded Polystyrene (EPS), 160mm Heavyweight concrete, 100mm Extruded Polystyrene (EPS), 12.5mm Plasterboard Decrement factor (0-1): 0.47; Time Constant (Hrs): 5 Admittance ( $W/m^2K$ ): 2.96; U-Value ( $W/m^2K$ ): 0.1 Thickness (mm): 497.5
 Structural Insulated Panel SIP	From out to in: 5mm Rendering, 15mm Softwood board, 200mm Extruded Polyurethane (PUR), 15mm Softwood board, 50mm Air Gap, 12.5mm Plasterboard Decrement factor (0-1): 0.81; Time Constant (Hrs): 2.4 Admittance ( $W/m^2K$ ): 1.16; U-Value ( $W/m^2K$ ): 0.1 Thickness (mm): 297.5
 Steel Frame SF	From out to in: 5mm Rendering, 200mm Extruded Polystyrene (EPS), 10mm Plywood, 90mm Rockwool, 12.5mm Plasterboard Decrement factor (0-1): 0.36; Time Constant (Hrs): 4.9 Admittance ( $W/m^2K$ ): 1.39 ; U-Value ( $W/m^2K$ ): 0.1 Thickness (mm): 317.5

Table 2. Total discomfort hours by year and wall type

Year/Wall	BB	ICF	SF	TF	SIP
2011	2284	2289	2284	2260	2284
2020	2500	2504	2502	2493	2498
2030	2552	2552	2551	2540	2545
2050	2648	2647	2645	2623	2638

### Thermal mass effect

For all periods in London the results from the simulations showed a slight advantage for timber frame (TF) compared to the other wall constructions. Table 1 shows that brick and block (BB) had the highest admittance factor, which demonstrates a high level of thermal mass. However, maximum discomfort hours for most of the times was observed for BB. The behaviour of the steel frame (SF) and insulating concrete formwork (ICF) are almost the same as BB. However, as the climate warms so the performance of the structural insulated panel (SIP) reduced compared to the other systems. The systems all had the same U-Value, and so the thermal mass does not seem to provide a benefit in terms of reducing annual discomfort hours.

### Insulation effect

The study reduced the amount of insulation thickness in each construction (i.e. increased the U-Value) to observe the impact of insulation thickness on the overall performance. Figures 3 to 6 demonstrate the results of this insulation reduction for each construction system.

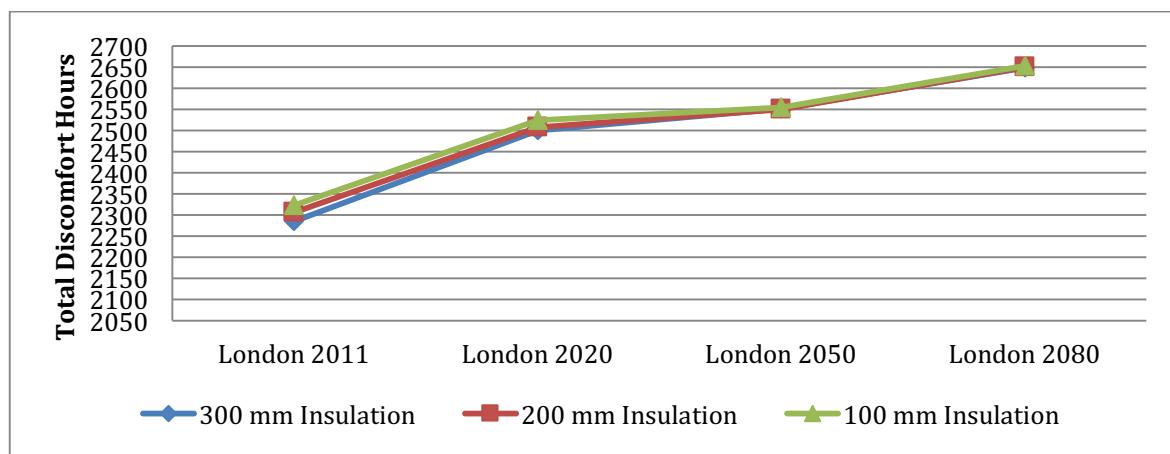

Figure 3. Comparison of insulation thickness effect in BB construction, London

Figure 3 suggests that for the brick and block BB wall, reducing the insulation thickness (from that which gave a 0.1 U-Value) to 200mm and 100 mm (U-Values of 0.13 and 0.2 respectively) does not give significant differences in annual discomfort hours. For the ICF wall (Figure 4), the maximum insulation thickness (320mm) for the 0.1 U-Value provides a small comfort advantage for current weather data compared to the 200mm (0.15 U-Value) and 100mm (0.28 U-Value) insulation thicknesses. However, this benefit narrows and then disappears during the following decades.

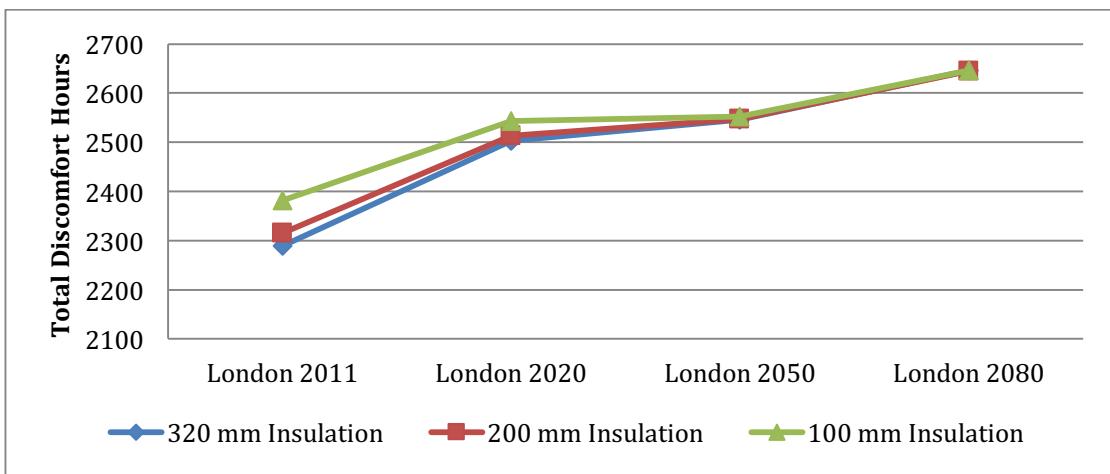

Figure 4. Comparison of insulation thickness effect in ICF construction, London

The TF wall (Figure 5) demonstrates a similar trend to the ICF wall, with an initial small comfort benefit for London 2011 weather data as the insulation thicknesses are reduced (U-Values of 0.15 and 0.24 W/m<sup>2</sup> K for 200 and 100 mm thicknesses respectively). However, as with the ICF wall, the benefit is soon lost.

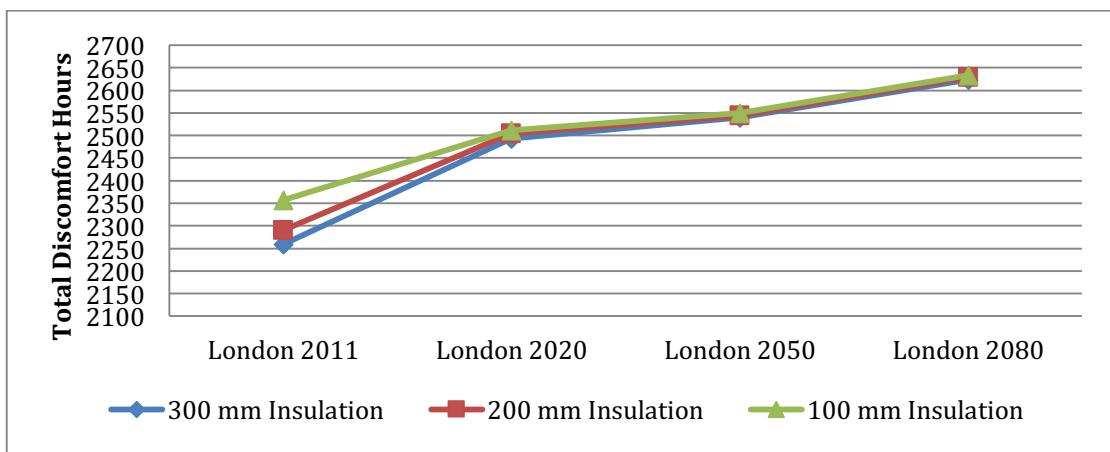

Figure 5. Comparison of insulation thickness effect in TF construction, London

For the SF and SIP systems (Figures 6 and 7), a 100mm decrease in insulation (0.1 and 0.14 U-Values respectively) has a negligible effect on total discomfort hours for any period.

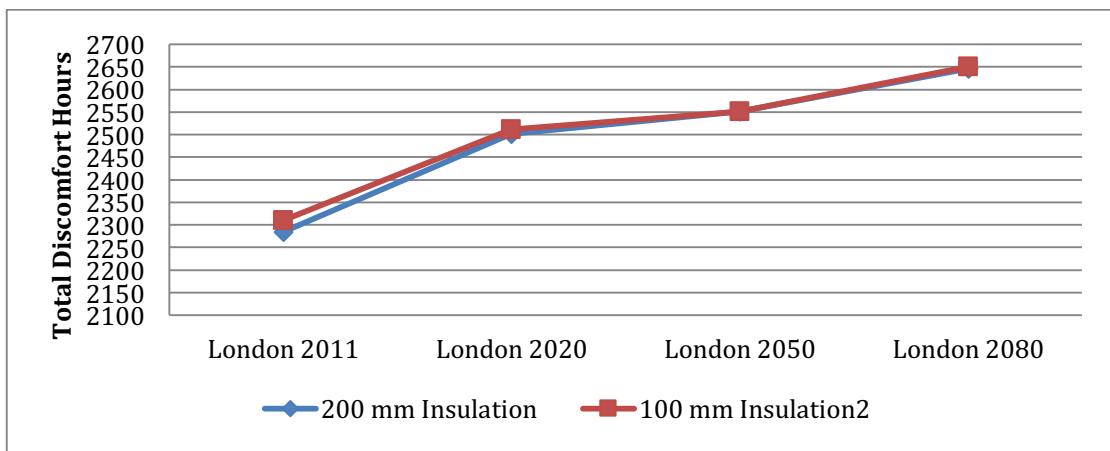

Figure 6. Comparison of insulation thickness effect in SF construction, London

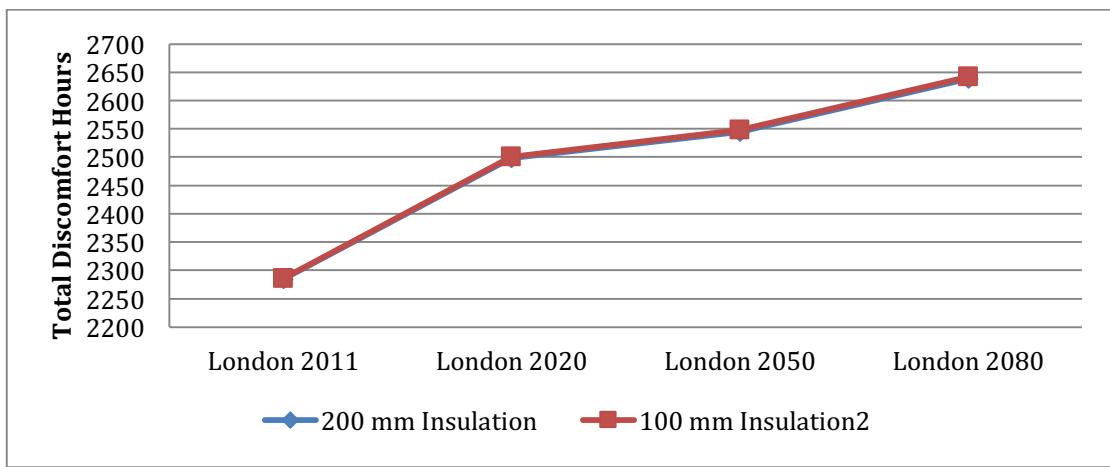

Figure 7. Comparison of insulation thickness effect in SIP construction, London

In general, it seems that any changes in insulation thickness that increases U-Values up to about 0.3 W/m<sup>2</sup>K will not impact on total annual discomfort hours. It should be mentioned that reducing insulation thickness is likely to decrease the overheating risk and increase the overcooling risk for UK summers and winters respectively. However, this study has considered only the total annual hours of discomfort, adding together both cold and hot discomfort hours to find the annual total.

This point is illustrated in Figure 8. The y-axis shows the number of hours during a year that a certain temperature was experienced in the room for the ICF wall with two insulation thicknesses. So, the ICF room with 100mm insulation experienced 100 hours at 11°C temperature while the 300mm ICF wall had nearly zero hours at 11°C. Even though the overall discomfort hours over a year are close for both ICF constructions, the distributions of the hours in each temperature band are not similar.

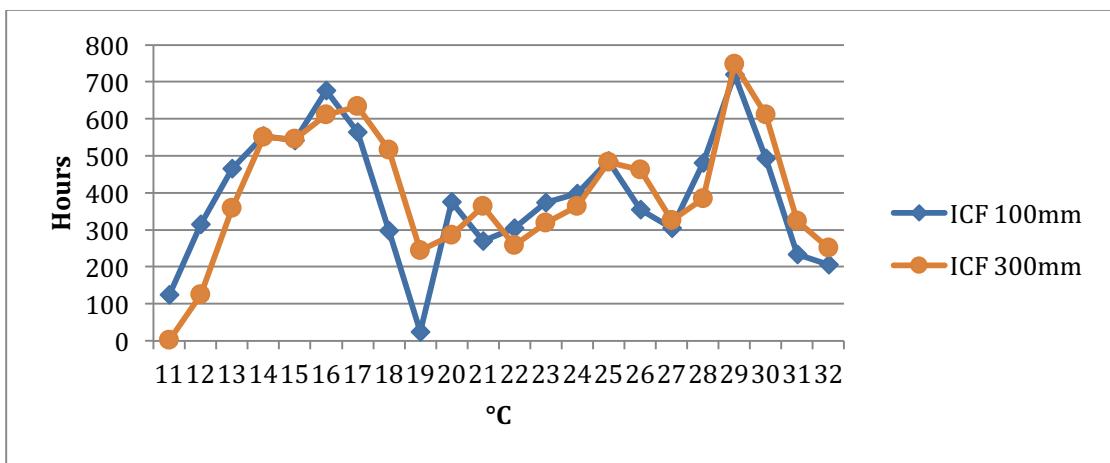

Figure 8. Hours at each temperature band interval for an ICF wall with 100 and 300mm of insulation

## Conclusion

This study has examined the effects of construction type, thermal mass and thermal insulation on annual thermal discomfort hours for different climate periods in London. The results for a simple house form suggest that the annual discomfort hours are relatively insensitive to the type of building system used. The number of discomfort hours increase in a warming future, but with little difference in total discomfort hours between the differently constructed spaces. Timber frame shows a slightly better performance compared to the

others, but no one “correct” construction can be recommended to decision-makers. This finding agrees with a comfort study by the Three Regions Climate Change Group (TRCCG, 2008) of 1960s houses and flats in London, East and Southeast of England. The Group concluded that ventilation strategies, solar control and cooler floors were more effective approaches to improving comfort in UK housing compared to increasing insulation levels.

It appears that a preferred building materials/details can be chosen without worrying that it might be a risky choice for future discomfort. However, there is the caveat that looking at total annual values of discomfort hours can obscure the balance between the ‘hot’ and ‘cold’ discomfort hours. More research is needed to disaggregate the hourly types of discomfort as the energy used to meet a heating demand per °C can be provided much more efficiently and economically than the energy needed to meet the same per °C cooling demand.

## Adapting to a Warmer Climate – Affordable Low-carbon Retrofits and Occupant Options for Typical Australian Houses

John James Shiel<sup>1, 2</sup>, Behdad Moghtaderi<sup>1</sup>, Richard Aynsley<sup>3</sup>, Adrian Page<sup>1</sup>, John M Clarke<sup>4</sup>

<sup>1</sup>Priority Research Centre of Frontier Energy Technologies and Utilisation, University of Newcastle, Callaghan, Australia, correspondence email: jshiel@westnet.com.au

<sup>2</sup>EnviroSustain, NSW, Australia

<sup>3</sup>Building Energetics, QLD, Australia

<sup>4</sup>CSIRO Climate Science Centre, VIC, Australia

**Abstract:** This paper describes the cost-effectiveness of adapting Australian houses and occupant behaviour to reduce room temperatures and heating and cooling requirements in a warming world. We used CSIRO's Australian Climate Futures framework and Belcher's "morphing" technique to project the 2050 climate; a novel Standard Effective Temperature (SET\*) thermal comfort approach where occupants modify their behaviour and tolerate higher temperatures; a do-it-yourself (DIY) retrofit approach to find the most cost-effective retrofits simulated for typical Australian houses; and combinations of retrofits with small, medium and large simple payback periods (SPPs) to suit occupant categories. The most effective strategies were modifying occupant behaviour; partitions to reduce the conditioned volume; ceiling and roof insulation; gap sealing; and retrofits to suit the type of house construction (such as wall and under-floor insulation, and internal brick walls for added thermal mass if there was a concrete floor). The research suggests that deeper retrofits may be needed than those provided by the large SPP retrofit combinations in 2050 to adapt to high indoor temperatures, even after changing behaviour regarding higher air speeds and lighter clothing.

**Keywords:** cost-effective retrofits, existing houses, carbon emissions, extreme climate change, occupant adaptation

### Introduction

Adapting a household for climate change means changing occupant behaviour or retrofitting the house for the projected effects of regional climate changes that may occur over the remaining life of the house (e.g. for higher house temperatures, greater wind speeds or bigger floods).

Global temperatures are rising at a potentially catastrophic rate (Nuccitelli 2016). The number of storms, floods and temperature-related natural disasters have increased from 300 to 900 over the past 35 years, with many hundreds of billions of dollars in property damage since 1980 alone (MunichRe et al., 2015, pp. 43–44). Sir Nicholas Stern has now stated that he had greatly underestimated the damages from climate change, following the poor response of global leaders (ClimateWire and Narayanan, 2013).

Australia has agreed to keep global temperature increases well below 2 °C, implying a zero-emissions economy by 2050, but has one of the world's worst-performing building stocks per capita, and where residential buildings are responsible for around 13% of all Australia's emissions. Since around 30% of the 2050 residential stock exists now and houses

make up 80% of residences, it is important to retrofit existing houses for climate change (Shiel, 2017).

Improving the performance of the envelope in the housing industry is difficult due to the number of stakeholders, low energy efficiency of older houses, and a lack of relevant knowledge, of both owners and building contractors.

Since improvements are more likely if convenient, easy and affordable (Bond et al., 2011), the aim of this paper is to find cost-effective low-carbon retrofits and behaviour-change strategies to lower the effective temperatures felt by household occupants. These adaptation strategies may also mitigate climate change by lowering energy use and therefore carbon emissions.

## **Methodology**

### ***Climate Change***

We undertook climate change modelling with the Climate Futures tool (CSIRO, 2016) to find the most appropriate general climate model (GCM) based on 1) the representativeness of the ‘Maximum Consensus’ case, 2) model skill and 3) availability of requisite variables (Clarke et al., 2011; J. J. Shiel et al., 2017).

Although two scenarios were examined for 2050, only one is reported here, namely the Extreme Climate Change scenario. (The Scarce Resource scenario results are reported in (J. Shiel et al., 2017)). The Extreme Climate Change scenario is a future of “business as usual” (Peters et al., 2013, p. 5) with a plentiful supply of fossil fuels, and corresponds with RCP8.5, where RCP is a Representative Concentration Pathway (RCP) (van Vuuren et al., 2011).

We generated plausible Reference Meteorological Year (RMY) Adelaide climate data for 2050 (Shiel, 2017) using:

- Belcher’s “morphing” technique (Belcher et al., 2005) with the selected GCM, and
- the Adelaide 1990 RMY climate file dataset from NatHERS.

### ***Retrofits***

The characteristics of the existing houses modelled are provided in Table 1, and these were chosen to match typical Australian house constructions e.g. with external walls of weatherboard, cavity brick, and brick veneer (DEWHA, 2008; Shiel, 2017).

Table 1 – House Characteristics for the three existing houses H1 – H3

	<b>House 1</b>	<b>House 2</b>	<b>House 3</b>
<b>Era</b>	1950s	1980s	2010s
<b>Area</b>	112m <sup>2</sup>	187m <sup>2</sup>	223m <sup>2</sup>
<b>Ext. Walls</b>	Weatherboard	Cavity brick	Brick veneer
<b>Int. Walls</b>	Plasterboard	Single Brick	Plasterboard
<b>Floor</b>	Timber floor	Timber floor	Concrete slab
<b>Garage</b>	None	Single car	Double car
<b>Ceiling insulation</b>	None	None	R1 K·m <sup>2</sup> /W
<b>Roof</b>	Tile	Tile	Metal
<b>Ceiling Height</b>	2.74m	2.4m	2.4m
<b>Eaves</b>	450mm	600mm	600mm
<b>Windows</b>	Timber single-glazed windows	Aluminium single-glazed windows	Aluminium single-glazed windows

Seventy retrofits were modelled for each house including partial air-conditioning; perimeter insulation; weather-stripping; adding thermal mass; and other measures such as low-e window films and external vegetation.

We used the NatHERS AccuRate software to calculate the required energy for comfort for the retrofits; estimated their do-it-yourself (DIY) cost and carbon savings for a split-system air-conditioner in Adelaide; and ranked the retrofits by simple payback period (SPP). Retrofits were combined for three sets of costs that had small, medium and large payback periods to suit occupant categories of tenants; of owners and landlords; and of householders who would like to carry out deep retrofits (J. Shiel et al., 2017).

### ***Occupant Behaviour Changes***

For occupant behaviour change, we rely on a previous study (J. J. Shiel et al., 2017) of the effects on energy savings of an alternative Standard Effective Temperature (SET\*) comfort approach, for the same warming climate scenarios for 2050. It suggested that dwelling occupants could be comfortable at higher temperatures by changing their behaviour regarding air speed and clothing.

The effective temperature felt by occupants with this alternative SET\* approach depends on the six parameters: air temperature, radiant temperature, air speed, humidity, clothing and metabolic rate, with a wider comfort temperature band than used in NatHERS.

## **Results**

The results reported here are for the Adelaide region (“Southern & SW Flatlands (East)”) Extreme Climate Change scenario in 2050, with an air-conditioner and DIY costings.

### ***Climate Change***

HADGEM2-ES was found to be the most appropriate GCM and the annual average of the mean monthly increase for temperature was projected to be 1.8 K from 1995 to 2050 (CSIRO, 2016; J. Shiel et al., 2017).

### ***House Retrofits***

Figure 1 shows the single retrofit carbon savings by payback period for House 2, which shares characteristics of House 1 (e.g. a timber floor) and House 3 (a garage with concrete floor) and illustrates the general trend of single retrofits. It has a table that ranks the House 2 cost-effective retrofits by payback period, and similar retrofits are colour-coded as shown in Table 2. Furthermore, the size of carbon savings provide a general indication of how effective each retrofit is in keeping the temperatures of all the conditioned rooms in the NatHERS temperature comfort band.

Table 2 shows the indicative costs and carbon savings of cost-effective single retrofits for House 3, and includes only the retrofits for Houses 1 and 2 where they are in common. The older House 1 has more cost-effective retrofits than Houses 2 and 3 (Shiel, 2017).

Figure 2 shows the carbon savings and SPPs for various combinations of retrofits for each house to suit occupant categories. The retrofits that make up the large SPP combination for each house are provided in Table 3, and the small and medium SPP retrofit combinations are mostly subsets of these sets of retrofits (Shiel, 2017).

## Adapting to Indoor 2050 Temperatures

Figure 3 shows the effects of the large SPP set of retrofits on the free running, or naturally conditioned temperatures of houses 1 and 3, for the living room and bedroom one, on the hottest day in 2050.

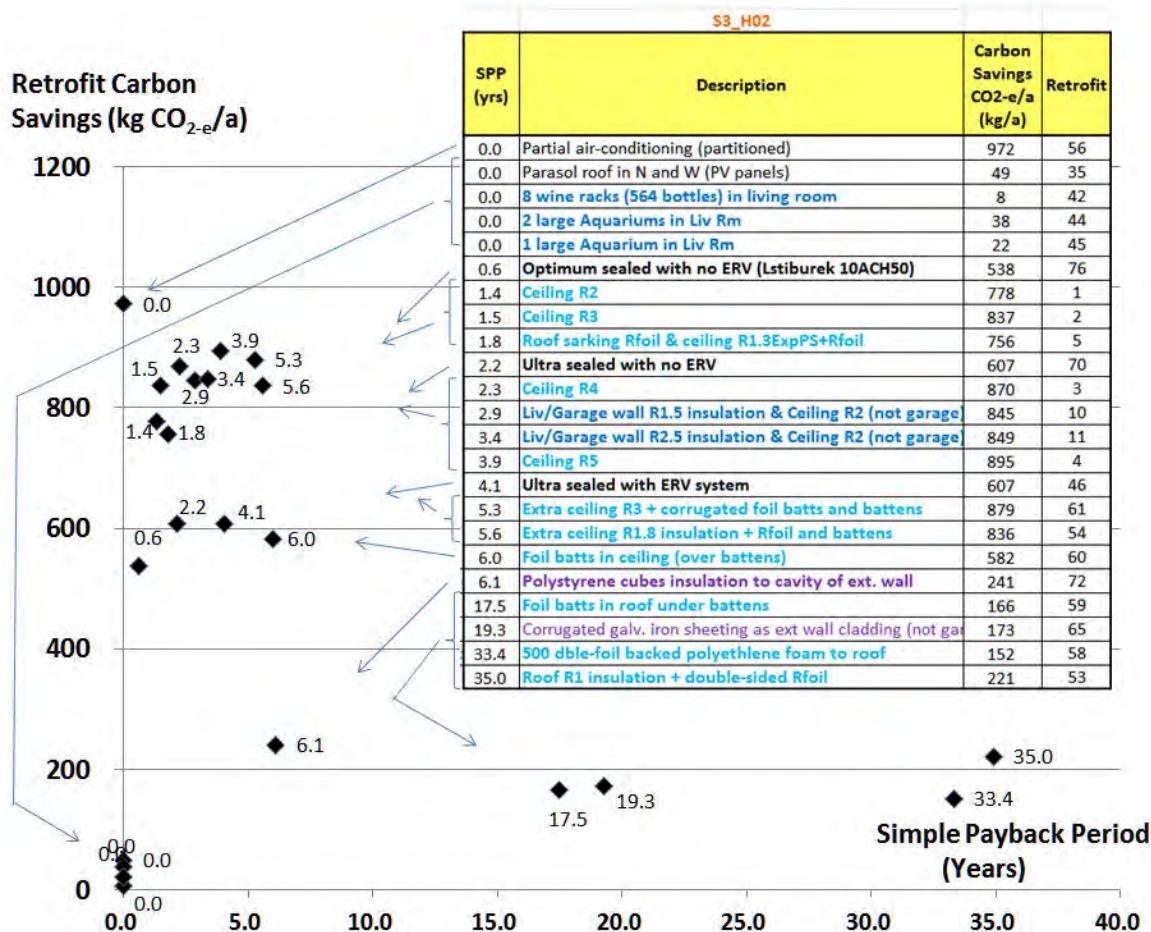

Figure 1 - The carbon savings by payback period of cost-effective do-it-yourself (DIY) retrofits for House 2, a 1980s cavity brick and timber floor house. The values are labelled with their SPPs, and the table is ranked by SPP and colour-coded as in Table 2. The other house results are in (Shiel, 2017).

## Behaviour Change

The SET\* comfort approach provided an extended comfort temperature band for free-running thermostat values in Adelaide of 14.2 °C to 34.8 °C based on modified air speed and clothing levels where the occupants would effectively feel like it was 16 °C to 28 °C (J. J. Shiel et al., 2017).

## Discussion

Before adapting a house for climate change, a life-cycle household carbon and costing analysis should be carried out, especially with housing shortages in Australia (Iyer-Raniga, 2010).

## Single Retrofits

The most cost-effective retrofits to lower Australian house temperatures are partitions to reduce the conditioned volume, ceiling and roof insulation, optimum weather-stripping e.g. by Lstiburek in (Aynsley and Shiel, 2017), and those that suit the type of house, e.g.

- wall insulation for the weatherboard and cavity wall houses with timber floors;
- under-floor insulation for the old weatherboard house; and
- added thermal mass with internal walls where there is a concrete floor.

Some retrofits with little effect were included because of the DIY costing approach, where they were assumed to be at zero cost, e.g. if part of a hobby or already part of the house such as aquariums or photovoltaic panels (Shiel, 2017).

Table 2 –Cost-effective single retrofits of House 3 and where these are shared with Houses 1 and 2. The retrofits are colour coded for roof and ceiling (light blue), walls (purple), floors (brown), thermal mass (dark blue), sealing (bolded black) and other (black).

### **Importance of Thermal Mass**

An envelope with low diffusivity (where diffusivity is conductivity divided by thermal mass) is needed to maintain comfortable free running internal temperatures in temperate climates (Barrios et al., 2011). So having the appropriate level of thermal mass is an important retrofit to keep future energy requirements low, in addition to the right levels of radiation and insulation (Baggs and Mortensen, 2006).

Thermal mass retrofits were cost-effective for the two houses with attached concrete floor garages by adding an insulated internal garage brick wall. The brick wall retrofit was included as DIY because some householders can undertake this retrofit and it was an important retrofit while contractor costs were included for a few other retrofits, such as the ERV system (Shiel, 2017).

### **Combined Retrofits**

For retrofit combinations, the partial air-conditioning retrofit was not used, since it does not have a temperature-lowering adaptation effect, but can be useful in lowering emissions.

Retrofit combinations with a small payback period of three years may suit tenants, those with little disposable income, those who may not be staying long in the house, or those in old houses that will only experience mild effects of climate change. Those with a

higher level of disposable income could carry out the medium level of SPP retrofit combinations, whereas households keen to carry out deep retrofits could use the retrofit combination with a large SPP.

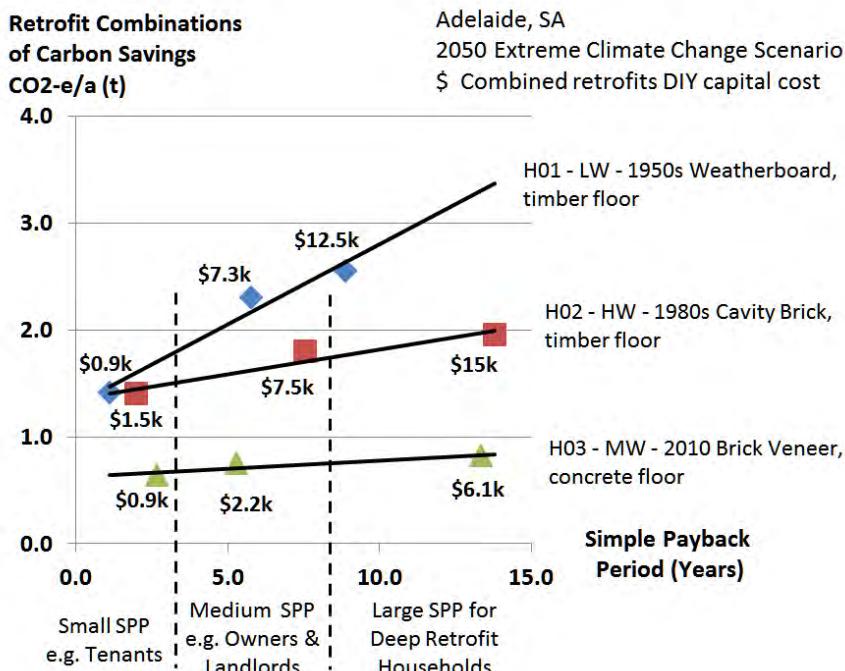

Figure 2 - Carbon savings by SPP for combinations of retrofit by house type and era (with 1950s weatherboard or light-weight walls – LW; 1980s cavity brick or heavy-weight walls – HW; and 2010 brick veneer or medium-weight walls – MW) with degree of retrofit (small, medium and large) to suit occupant categories. The dollar label refers to the DIY capital cost of the retrofit SPP combination.

### **Adapting Houses and Occupant Behaviour for 2050**

Figure 3 indicates that the living room free running temperatures after the large retrofit combinations in Table 3 will reach 43 °C for House 1 and 41 °C for House 3, a reduction of up to 7 K and 6 K respectively.

Table 3 – The retrofits making up the combinations of the large payback periods, to suit deeper retrofit households as shown in Figure 2 (retrofits are bolded if in common).

House 1	House 2	House 3
<b>3 - Ceiling R4 Insulation;</b> 16 - Underfloor 90mm gap & 1500 bubble Insulation with dbl-sided Rfoil; 26 - 5m high deciduous trees to North windows; 32 - Low-e film applied to windows; <b>35 - Parasol roof in N &amp; W roof;</b> <b>42 - 8 wine racks (564 bottles);</b> <b>44 &amp; 45 - 3 large Aquariums;</b> 49 - 1.4m dia Ceiling fans; 53 - Roof R1 insulation; 55 - Green ivy on North & West walls; <b>59 - Foil batts in roof under battens;</b> 62 - Foil batts stapled under floor; 67 - Carpet to timber floor; <b>72 - Polystyrene cubes insulation to cavity of ext. wall;</b> 76 - Optimum sealing (Lstiburek 10ACH <sub>50</sub> ).	5 - Roof sarking Rfoil & ceiling R1.3 expanded polystyrene + Rfoil; <b>10 - Add Liv/Garage brick wall with R1.5;</b> 18 - R2.5 polystyrene batts under timber floor; 34 - Low-e film tint to non-North windows; <b>35; 42; 44 &amp; 45; 59;</b> 58 - 500 dbl-foil backed polyethylene foam to roof; 60 - Foil batts in ceiling; 62 - Foil batts underfloor; <b>65 - Corrugated galv. iron sheeting as ext. wall cladding;</b> 72; 76.	3; 10; 35; 42; 44 & 45; 59; 65; 74 - Polystyrene cubes to full 140mm cavity of ext. wall; <b>76</b>

In Figure 3, for bedroom one in House 3, the maximum night temperature after retrofits is 34 °C, lowering the maximum temperature by 2 K. However, for House 1 the bedroom one temperatures are actually higher after the retrofits, due to the bedroom's location on the western side and the retrofits preventing heat escaping at night (e.g. perimeter insulation and greater sealing).

Household occupants can adapt with behaviours such as using higher air speeds and wearing lighter clothing to tolerate 34.8 °C during the day and 30.4 °C at night to feel like it is 28 °C and 26 °C respectively, with night comfort under high temperatures deserving more research (J. J. Shiel et al., 2017). However, when temperatures exceed 35 °C, there is a high risk of heat stroke as heat exchange with the environment is greatly diminished (Hanna and Tait, 2015, p. 8050), particularly for infants and elderly.

Figure 3 – The change in living and bed room free running temperatures after the combined retrofits of the largest payback period for the hottest day in 2050. These are for House 01 (1950s weatherboard) and House 03 (2010 brick-veneer), where the external maximum temperatures for day and night were 46 °C and 36 °C respectively, with maximum corresponding relative humidity levels of 20% and 38% respectively.

### Cool Retreats

These results suggest that deeper retrofits are required to lower temperatures, and that there should be a greater focus on retrofitting rooms to become cool retreats. This includes changing room types and ventilation strategies e.g. moving bedrooms away from the western side, having separate living spaces for winter and summer, as well as specific retrofits and technologies to keep one room cooler (Aynsley and Shiel, 2017; Roaf et al., 2005; Saman et al., 2013).

### Conclusion

The key findings are that:

- Many cost-effective retrofits can be found for older timber-floored Australian houses to adapt to a warmer future, with a fewer number identified for more modern houses with concrete floors.
- Retrofit combinations for small, medium and large payback periods were found to suit different occupant categories, with up to a 7 K reduction in room temperatures in 2050.
- Large payback period retrofit combinations as well as occupancy behaviour change may still be insufficient for Adelaide in 2050 for the Extreme Climate Change scenario, requiring deeper retrofits and special room modifications as cool retreats.

<sup>2</sup> Environmental Modelling Group, Institute of Geography, Johannes Gutenberg-Universität Mainz, Mainz, Germany, h.simon@geo.uni-mainz.de; m.bruse@geo.uni-mainz.de

**Abstract:** Starting from previous studies concerning the impact of vegetation in urban microclimate (effects on air temperature, mean radiant temperature, surface temperature, humidity, wind speed and direction) for the city of São Paulo, Brazil, this study aims to achieve: (1) a 3D parametrization of Brazilian trees using the module Albero on ENVI-met model V4, considering local leaf density and canopy structure collected during fieldworks; (2) the calibration of the model based on field measurements carried out locally on urban parks; (3) the simulation of different green distribution scenarios. The method includes field measurements of air temperature, humidity, globe and surface temperature, as well as registering other data that characterizes local microclimatic conditions (wind speed and direction, global solar radiation, sky view factor), and the comparison between measured and simulated data on ENVI-met V4. After that, a base case and other parametric scenarios were proposed to incorporate different greening strategies inside dense urban blocks. According to the simulation results, for different tree canopy characteristics, a maximum reduction of up to 1,6K in air temperature and 13,6K for surface temperature were found, when comparing the base case to the street trees scenarios, indicating a more homogeneous distribution of the vegetation effect on microclimate.

**Keywords:** urban vegetation, urban microclimate, ENVI-met, leaf density

### Introduction

The process of urbanization has changed the relationship between society and the natural environment. The direct consequence of this process is the change in the characteristics of urban surfaces (Stone, 2012). Thus, urbanization results in changes in physical properties of surfaces, including water content, thermal capacity, conductivity, albedo and emissivity, causing a reduction in evaporation rates (Voogt and Oke, 2003).

The lack of vegetation influences the increase of the air temperature due to the heating of the surfaces (floors, facades and roofs) throughout the day and the reduction of evaporative surfaces that perform heat exchange. In addition, other factors also contribute to this effect: change in the geometry of the urban fabric (height and width ratio of the canyon), use of materials that store part of the sensible heat due to its thermal properties and emission of anthropogenic heat generated by burning fossil fuel (Oke, 1978).

According to Stone (2012), three main strategies need to be considered to mitigate warming in large urban areas: (1) planting trees and planning new configurations using vegetation (green roofs, green walls, sky gardens); (2) increasing the albedo, incorporating

techniques to reduce the heating of the roofs or replacing surfaces coatings with more reflective materials; (3) implementing of energy efficiency programs committed to reduce greenhouse gas emissions.

At the microscale, trees have been shown to be particularly beneficial in lowering urban temperatures and improving human thermal comfort due to both evapotranspiration and shading. Important determinants of the intensity of cooling from vegetation include tree location, size and canopy coverage, planting density and irrigation management and as much as 80% of the cooling effect of trees is from shading (Coutts *et al.*, 2013).

Starting from previous studies concerning the impact of vegetation in urban microclimate (effects on air temperature, mean radiant temperature, surface temperature, humidity, wind speed and direction) for the city of São Paulo, Brazil, this study adopted the model ENVI-met, that considers the density of leaves to simulate the micro scale interactions of surface-vegetation- atmosphere. With the new advancements on ENVI-met, trees are represented by clusters of LAD cells, forming a bigger entity with a three-dimensional geometry (3D-plants) and are managed by a special editor program called Albero (Simon, 2016).

This study aims to achieve: (1) a 3D parametrization of Brazilian trees using the module Albero on ENVI-met model V4, considering local leaf density and canopy structure collected during fieldworks; (2) the calibration of the model based on field measurements carried out locally on urban parks; (3) the simulation of different green distribution scenarios, analysing the outcomes of microclimate variables.

## **Method**

The method includes field measurements of air temperature, humidity, globe and surface temperature, as well as registering other data that characterizes local microclimatic conditions (wind speed and direction, global solar radiation, sky view factor) and the comparison between measured and simulated data on ENVI-met V4. After that, a base case and other parametric scenarios were proposed to incorporate different greening strategies inside dense urban blocks.

On-site measurements were carried out to monitor representative local hot weather conditions. Subsequently, by the results of the local microclimatic data and vegetation characteristics, computer simulations calibrated ENVI-met V4, based on the comparison of measured and simulated data, with a more detailed 3D modelling studies that considers the existing vegetation at an urban park.

After simulation results, analyses were carried out to indicate a better use and distribution of vegetation as a strategy to mitigate urban warming in a subtropical changing climate.

## **Area of Study**

The city of São Paulo is located in Southeast of Brazil (23°32'S, 46°37'W). According to IBGE (2015), the population is almost 21 million inhabitants in the metropolitan area, distributed in an overall area of 8051km<sup>2</sup>, where 2200 km<sup>2</sup> of the Municipality is an urbanized area in which 65% of population lives today.

São Paulo has a humid subtropical climate with mild and dry weather conditions during winter. Summer is moderately warm with average temperatures varying between 19°C and 28°C, and annual rain varies between 1250 to 2000mm (IBGE, 2015).

This work was carried out testing a greenery increase in the surrounding blocks of Tenente Siqueira Campos Park (Trianon Park), which is located at Paulista Avenue, considered an important axis for cultural and financial activities in the city center. This area, according to data from the Municipal Environmental Agency (SVMA, 2011), is part of the Subprefecture of Sé, with an average rate of  $6,18\text{m}^2$  of green area per inhabitant, contrasting with other nearby neighborhoods such as Pinheiros subregion, with  $22.5 \text{ m}^2$  of green area per inhabitant.

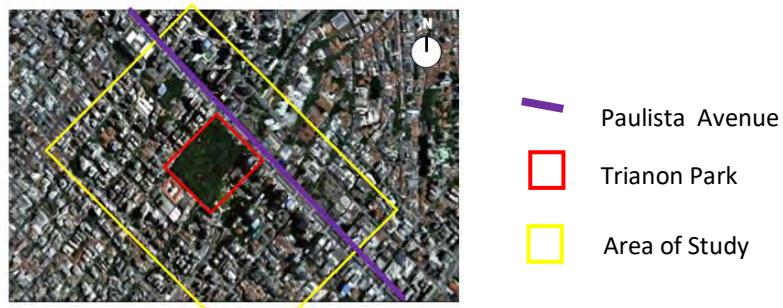

Figure 1. Area of study surrounding Trianon Park

### **Field Measurements**

Climate monitoring was carried out for four consecutive days, during the period from April 2<sup>nd</sup> to 5<sup>th</sup> 2016. In the Bela Vista borough, along Paulista Avenue, two areas were chosen for the measurements: one inside Trianon Park (P1) and another one in the courtyard of an office building (P2). In the point 1, a meteorological station was placed over open soil covered with small plants and under high dense trees. In the point 2, the meteorological station was placed over a concrete pavement with gravel and located in a dense building block without vegetation (Figure 2).

One of the purposes of the measurements was to compare microclimatic data (air temperature, humidity, solar radiation, surface temperature, wind speed and direction) registered in a dense urban park area surrounded by high-rise buildings without vegetation. These data were essential for the calibration process in ENVI-met model.

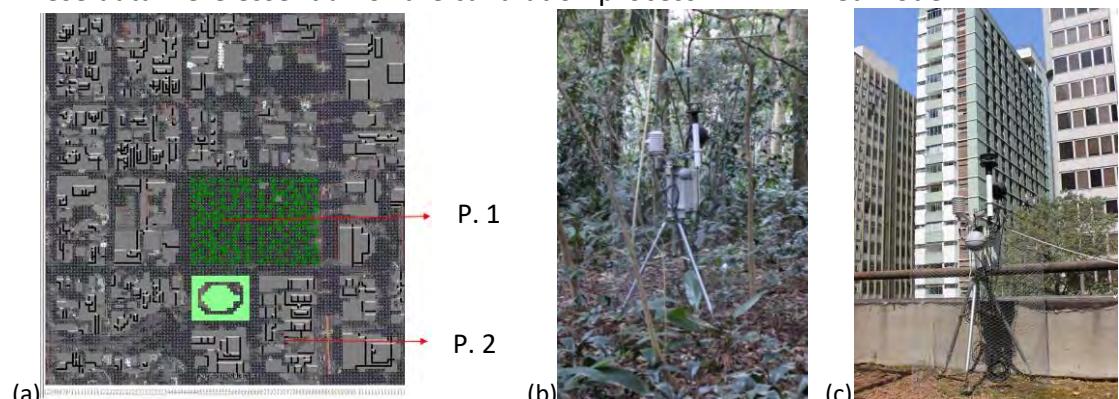

Figure 2. (a) Location of two points for microclimatic measurements; (b) Meteorological station at Trianon Park (Point 1); (c) Meteorological station at Paulista courtyard (Point 2).

### **ENVI-met V.4 model simulations**

The ENVI-met is a three-dimensional model to simulate the interactions between surface-vegetation-atmosphere for urban environments with resolutions of 0.5m to 10m in space and up to 10 seconds in time. In this way, it allows analysing, in a micro-scale perspective, the

interactions between the urban design and the microclimate (Bruse and Fleer, 1998; Huttner, 2012; Simon, 2016).

This prognostic model is based on the laws of fluid dynamics and thermodynamics. Includes simulations for: airflow around and between buildings; process of heat and water vapour exchange on the surface of the floor and facades; local turbulence and its dissipation rate; parameters of heat exchange with vegetation; dispersion of pollutant particles; and biometeorological parameters such as the predicted mean vote (PMV) and physiological equivalent temperature (PET).

In order to evaluate the microclimate benefits of vegetation, a numerical model was implemented to calculate the main factors related to vegetation: transpiration, evaporation, sensible heat flux, turbulent heat and steam fluxes; stomata resistance, leaf energy balance and water balance of the soil-vegetation system. It considers not only the shading effect of the trees, but also the physiological process of plants, based on the A-gs model (Jacobs, 1994) to calculate stomata conductance (Bruse, 2004).

In ENVI-met V4, besides the 1D plants database, a toolbox called Albero was also implemented with a more sophisticated way to define the new 3D plant geometries. It offers data management, plant generation and modification and it is directly integrated into the new ENVI-met database system (Bruse, 2017). For this study, Albero was used to edit and create new trees that could approximate to the characteristics of the existing trees in São Paulo.

### ***Parametrization of tropical trees with Albero***

This model considers the parameter Leaf Area Density – LAD<sup>1</sup> to calculate plants' physiology. According to the ENVI-met 3D plants database, there are 14 types of vegetation, which have specific characteristics according to the following aspects: CO<sub>2</sub> fixation type (C<sub>3</sub> or C<sub>4</sub> plants), leaf type, short-wave albedo, height of the plant, root zone depth, root area density profile (RAD) and leaf area density profile (LAD).

In previous versions, 3D-plants did already allow the remodelling of the distribution of LAD cells and thus the shape of a tree. The cells themselves, however, were not part of the tree but instead acted as individual leaves. With the new advancements, LAD cells are now part of a bigger object, which allows the evaluation of a plant as an organism (Simon, 2016).

In Albero, different to the 1D vegetation, it is possible to define the center of the plant (tree) and ENVI-met build up the tree in the model with a grid resolution of 1m x 1m to define trees. The advantage of the new editor is that the trees can be visualized in 3D and the geometrical form is automatically adjusted based on your model resolution (Simon, 2016). On the other hand, it requires more handwork to design the trees from the scratch or to change values from each cells (Bruse, 2017).

Using Albero, three type of trees were created: T1 with sparse canopy form (Figure 3a), T2 with spherical canopy form and uniform distribution inside the crown (Figure 3b) and T3 with spherical canopy form and leaf density concentrated in the outer part of the crown (Figure 3c). In all typologies, trees are 20m high, diameter of 17m, and leaf density starting 4m above the ground to avoid obstruction for wind flux at pedestrians' level. The average LAD considered was 1,2 m<sup>2</sup>/m<sup>3</sup>, based on LAI measurements at Trianon Park with hemispherical images method (Shinzato *et al.* 2013).

<sup>1</sup> LAD is a parameter defined as the total one-sided leaf area (m<sup>2</sup>) per unit layer volume (m<sup>3</sup>) in each horizontal layer of the tree crown (Lalic and Mihailovic, 2004).

The new typologies created were used during the calibration process of the ENVI-met model, in order to obtain the adjustment of the measured and simulated curves at Trianon Park.

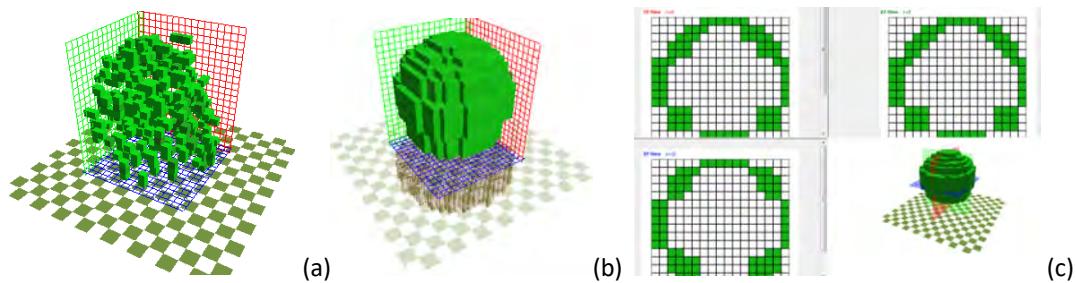

Figure 3. Tree typologies using Albero; (a) sparse canopy form; (b) spherical canopy; (c) spherical canopy with LAD in the outer part of the crown.

#### **Calibration Process in ENVI-met V4**

Simulation of the study area (base case scenario) in ENVI-met V4 was built with input area domain formed by two central blocks representing Trianon Park with 165m x 120m (19.800m<sup>2</sup>) each and 18 blocks around the park. The total area for the modelling was 490.000m<sup>2</sup> with a grid of 200 x 200 cells and each cell with dimension of 3,5mx 3,5m. Five empty cells were added in the border of modelling area and no nesting grid cells were considered. The vertical model had 30 grid cells with 2,5m each.

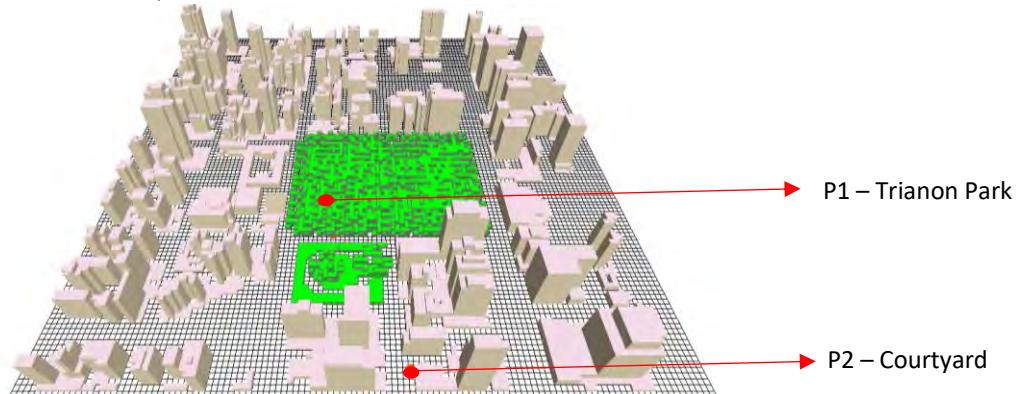

Figure 4. Base case scenario with 2 receptors coinciding with the meteorological stations located at Trianon Park (P1) and Paulista Courtyard (P2)

In order to compare the results of a numerical simulation with measured data or to simulate a specific meteorological development it is necessary to force the simulation by adjusting the variables at the inflow boundaries of the model. With "forced (closed)" boundary condition, the values of the 1D model are copied to the grid cells at the inflow boundary of the model (Huttner, 2012).

The simulations used full-forcing feature, which enables the model to run with predefined boundary conditions for air temperature, wind speed, wind direction, relative humidity, direct radiation, diffuse radiation, longwave radiation and cloud cover. Microclimatic data were obtained from onsite measurements and radiation data from Micrometeorology Group in the Institute of Astronomy, Geophysics and Atmospheric Sciences - IAG at the University of Sao Paulo.

For the input data, the soil temperature for the upper layer was measured using Campbell 107 temperature probe and humidity was estimated from results of Simple Biosphere Model – SIB2, provided by Laboratory of Climate and Biosphere – LBC Group in the Institute of Astronomy, Geophysics and Atmospheric Sciences - IAG at the University of Sao

Paulo. The specific humidity at 2500m was obtained from local Campo de Marte Airport<sup>2</sup> (ca. 3.3km North of the site).

The calibration process was important as the adjustment between the simulated data considered two distinct conditions: one with dense vegetation (P1) and another area without vegetation (P2). The phase with the sensitivity tests simulated scenarios with the three typologies of trees created, adjusting values of LAD, albero and soil moisture.

Simulations ran for 24h, starting on April 4<sup>th</sup> 2016 at 5h and the Figure 5 shows the best results for air temperature achieved during calibration process. For the Trianon Park, the tree typology T3 with LAD of 1,7 m<sup>2</sup>/m<sup>3</sup> in the outer part of the crown had the closest results with the field measurements inside the park.

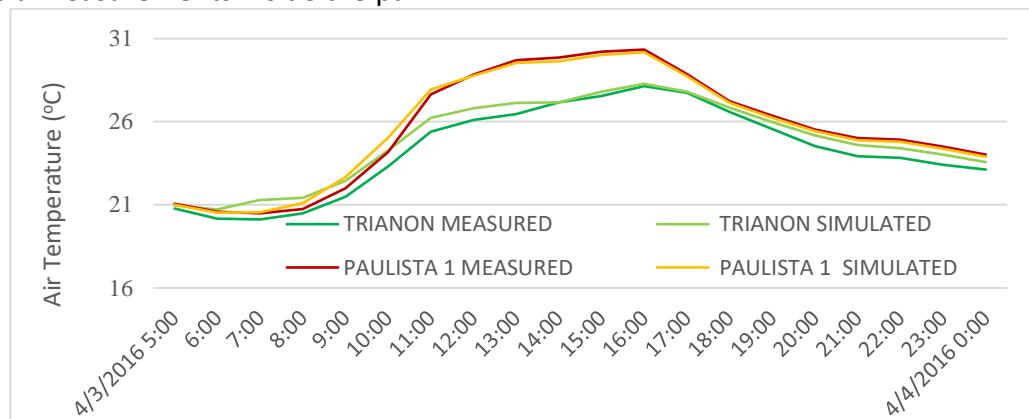

Figure 5. Results for simulated air temperature in ENVI-met and the data measured for meteorological stations - model calibration process.

Based on simulation results, the average difference between air temperatures under dense trees (T3) and the surroundings is up to 1,6 K. The specific humidity under the tree canopy was 12,5 g/kg, while inside the blocks it was 10,90 g/kg. For surface temperature, the vegetation showed an average difference of 10,2K between green spaces and the street. According to the Figure 5, there was a high agreement between ENVI-met simulation results and on-site measurements. Regarding the spatial distribution, results showed that the maximum effect of vegetation in air temperature occurred under the canopies, but the cooling effects could influenced up to 250m in leeward side of the park (Figure 6).

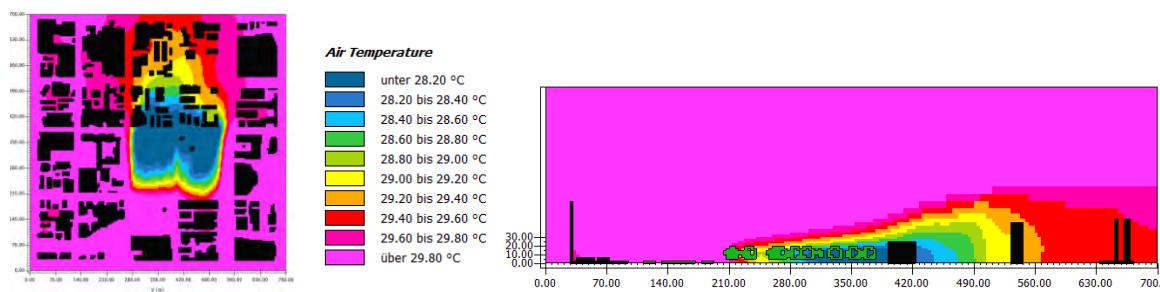

Figure 6. Simulation results for air temperature at Trianon Park – on April 3<sup>rd</sup> 2016 at 15h.

### Simulations with new green areas

According to the results of the calibration process, the vegetation effect was restricted to the location of the park. In this way, a new scenario was created in order to verify the effect of vegetation by increasing the green areas area inside every block. The configuration of each

<sup>2</sup> Available from the homepage of atmospheric soundings by University of Wyoming. Access on <http://weather.uwyo.edu/upperair/sounding.html>

block was maintained and the vegetation were placed only in unbuilt areas between buildings (Figure 7a).

The proposed new green areas were formed of dense tree groups with grass covering the open soil. Based on the T3 typology, which had rounded canopy with LAD of  $1,7 \text{ m}^2/\text{m}^3$  in the outer part of the crown (20m height/ 14m diameter), two other tree typologies were created: T4 with LAD of  $1,5 \text{ m}^2/\text{m}^3$  (15m height/ 11m diameter) and T5 with LAD of  $1,2 \text{ m}^2/\text{m}^3$  (10m height/ 7m diameter). The trees of the park were replaced by grass to avoid influencing the results on the surroundings.

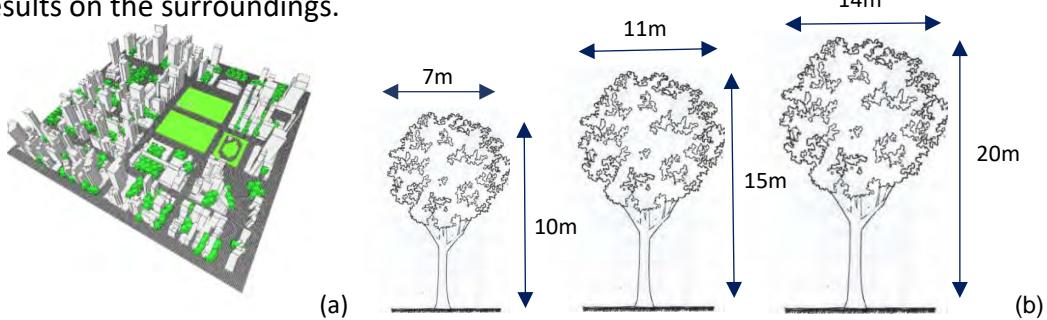

Figure 7. (a) Scenario with trees inside the blocks; (b) Trees typology: T5, T4 and T3, respectively.

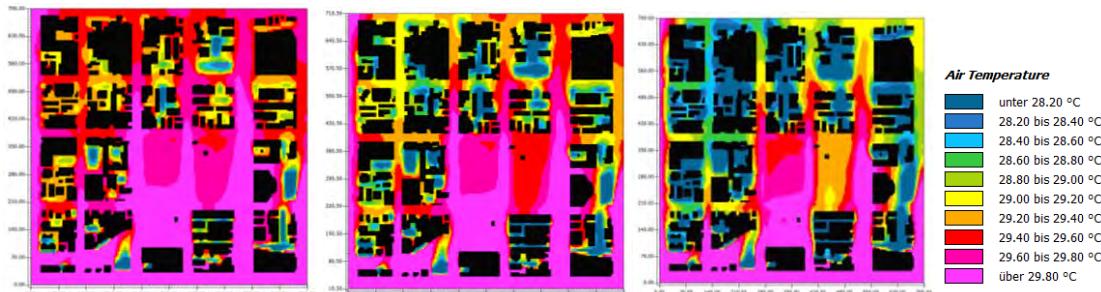

Figure 8. Results for air temperature with typology T5, T4 and T3, on April 3<sup>rd</sup> 2016 at 15h – z=1.25m.

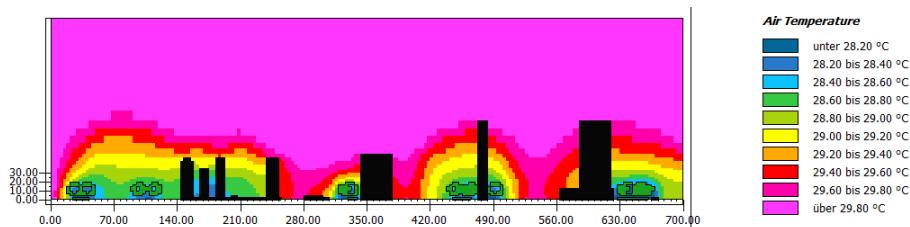

Figure 9. Results for air temperature for trees inside the blocks (grass + T3 LAD  $1,7 \text{ m}^2/\text{m}^3$ ) – Section axes x-z at grid 123 (432.25 m).

The cooling effect of vegetation depends on urban configuration, soil characteristics, leaf density and green areas distribution. The maximum reduction in air temperature under the trees was 1,6 K, on April 2016 at 15h, represented in dark blue spots in Figure 8.

In those areas, the specific humidity under canopy was 12,5 g/kg and the lowest value registered inside the block was 10,6 g/kg. For surface temperature, simulations showed differences up to 13,6 K and for mean radiant temperature MRT, the reduction was up to 10,5K.

Comparing the three scenarios, the maximum effect in air temperature occurred in 20% of the total unbuilt area using T5 trees, while the groups of T4 had 75% and 90% with T3 typology. In this sense, spatial configuration of the maximum effect with T3 trees was more pronounced and homogeneous than the other two situations.

## Final Considerations

After the calibration process between measured and simulated data in ENVI-met 4, with full-forcing feature and the new resources of the Albero module for 3D trees, simulations of the study area were developed with the inclusion of new green areas in the built-up blocks surrounding Trianon Park. According to the simulations, for different canopy characteristics, results indicated a very good agreement between the ENVI-met model and the local measured data, with a maximum reduction of 1,6K in air temperature and 13,6K for surface temperature, when comparing the base case to dense trees inside the blocks (T3 typology).

The cooling effect from Trianon Park on surrounding urban area was up to 250m in leeward side of the park, while small green areas simulated could reach up to 30m. However due to a better vegetation distribution, the cooling effect of small green areas was well distributed and more homogeneous than one single park.

From the analysis of the results, it could be seen that greening the unbuilt areas between buildings can be an effective strategy to ameliorate the microclimatic conditions at Bela Vista borough, in downtown São Paulo, considering the potential of vegetation in reducing urban warming, especially in the daytime.

## Acknowledgments

**Abstract:** This paper is concerned with the implications of flooding in Bogotá (Colombia) by focusing on a specific typology of flooding -surface water flooding- resulting from excess of surface water runoff as it occurs in the Colombian capita. In particular, the paper considers some of the main alternative strategies that can be used to reduce the risk of surface water flooding and pays specific attention to the benefits of Sustainable Urban Drainages (SUDS). The suitability of SUDS in the urban context is tested through an approach focusing on the city block scale and its surfaces' characteristics. Technical and social elements of SUDS are critically analysed and accordingly, a comparative analysis is performed to test different adaptive strategies scenarios for a case study in quartier Carimagua in the inner urban area of Bogotá. Carimagua barrio has been found to be able to effectively mitigate the excess of surface water runoff, and by so to meet some of the challenges associated with climate change. On this basis, it is defended that the city block can cope with not only its own surface water runoff but also to compensate as active catchment for other parts of the city where adaptation might not be feasible.

**Keywords:** climate change, flooding mitigation, urban resilience, permeability, sustainable urban drainages.

### Introduction

This paper will focus on the drainage capacity of neighbourhoods of Bogotá to give some answers to the risk of flooding caused by climate change phenomenon. For this reason, this paper engages with future climate change and specifically with predicted increased risk of flooding, with specific focus to test flooding mitigation techniques in the increasing urbanised land of Colombia, and Latin America in general.

From 2010 to 2011 La Niña phenomenon affected Colombia and caused economic losses caused by flooding, related to the destruction of infrastructure and urban areas. A paradigm shift in water management is recognized as a necessary step for adaptation to climate change and crucial for furthering the sustainability agenda in Bogotá. On this regards, research conducted (Hoyos et al; 2013) emphasized the importance of both the spatial context as well as the variables related to hazard exposure and social vulnerability (figure 1). Melgarejo et al. (2014) stress this point in view that extreme weather events are becoming disaster management systems in the city.

Effects of climate change in Colombia have been modelled (IDEAM et al; 2015) and a generic change in temperature and rainfall is expected to increase the climatic variability effects of El Niño and La Niña, which have an exacerbated impact in Colombia and Latin America in general. In the Cundinamarca region, where Bogotá is located, it has been predicted an increase in average temperatures by 2100 to up to 2.3°C against today values.

Also it has been predicted a change in the precipitation patterns: an increase in rainfall to up to 30% in the province of Bogotá North, with values between 10% and 30% compared to today's values (IDEAM et al; 2015). Some of the effects of such changes are expected to affect the farming sector due to both changes in temperatures as well as infestation associated with increased rainfall. Also, infrastructural sector (transport and energy) are expected to fail (IDEAM et al; 2015) with potentially devastating effects on population (when this is associated with population security).

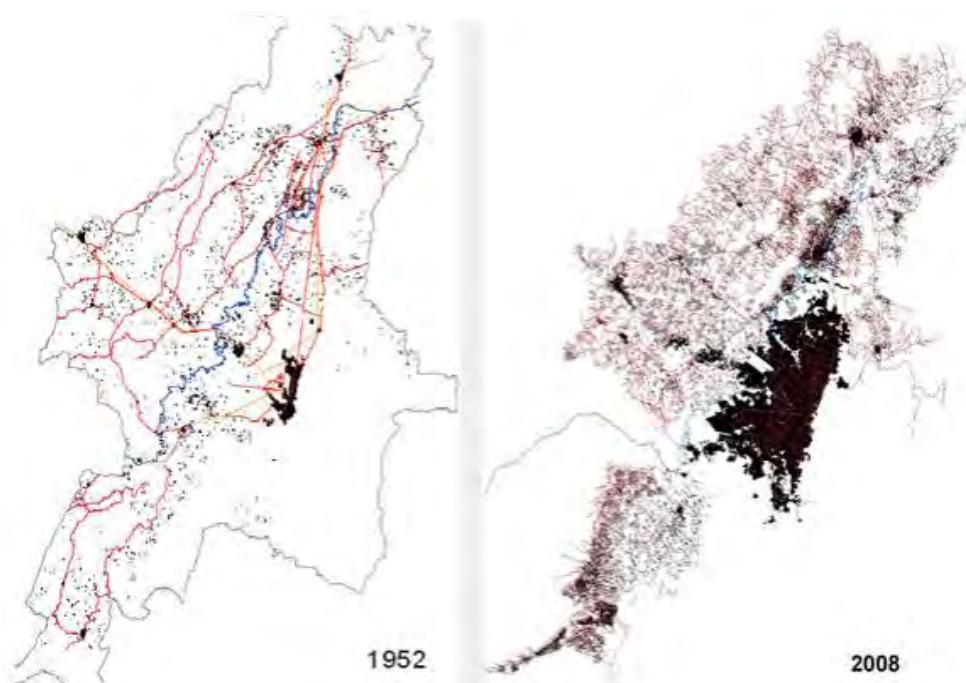

Figure 1. Land urbanisation and density evolution of Bogotá (Niño, 2012).

The Colombian disaster risk management ministry (UNGRD), in cooperation with other international organisations, are implementing the project "Strengthening the risk management capacity of Floods" in order to create directives to cope with excess rainfall and the necessary standards to control this kind of events, by means of identifying four flooding risk scenarios: (a) first, ponding water, (b) second, flooding, (c) third, electrical storms (d) tree-falling. These scenarios are connected to three climate phenomena, i.e. hailstorm, landslides and gales (INDIGER, 2016).

To mitigate these changes, and specifically with the predicted increase rainfall, an adaptation technique is required. Techniques available to mitigate with the excess water runoff are the sustainable urban drainage systems (SUDS), which are non-piped drainage systems that minimise the impact of surface water runoff (rainfall that cannot infiltrate the soil). According to Toledo (2012), SUDS that are most sustainable and suitable to urban environment are green roofs and pervious surfaces. Pervious surfaces effectively reduce surface water runoff and pollution to a significant extent.

On the other hand, green roofs represent a cheap, relatively good option to reduce surface water runoff. In fact, they reduce surface water runoff to a more limited extent when compared to previous surfaces, but they can add benefits not only regarding pollution reduction, but also regarding biodiversity, wildlife, amenity, health, reduction of urban heat island effect.

Related, green roofs increase the life of roofing materials, reduce the urban heat-island effect (Ritchie & Thomas, 2013) and reduce the energy demand (GLA, 2011). This paper aims at contributing to the development of an adaptation strategy within Bogotá by producing a strategic test of adaptation to flooding strategy that effectively mitigates with the predicted increase of rainfall in the Province of Bogotá.

## Methods

To analyse closely this phenomenon as it occurs, it has been selected an urban area in Bogotá, the Carimagua neighbourhood. This quartier was founded in 1967 and was an example of social housing in Bogotá composed of 1108 single-family homes.

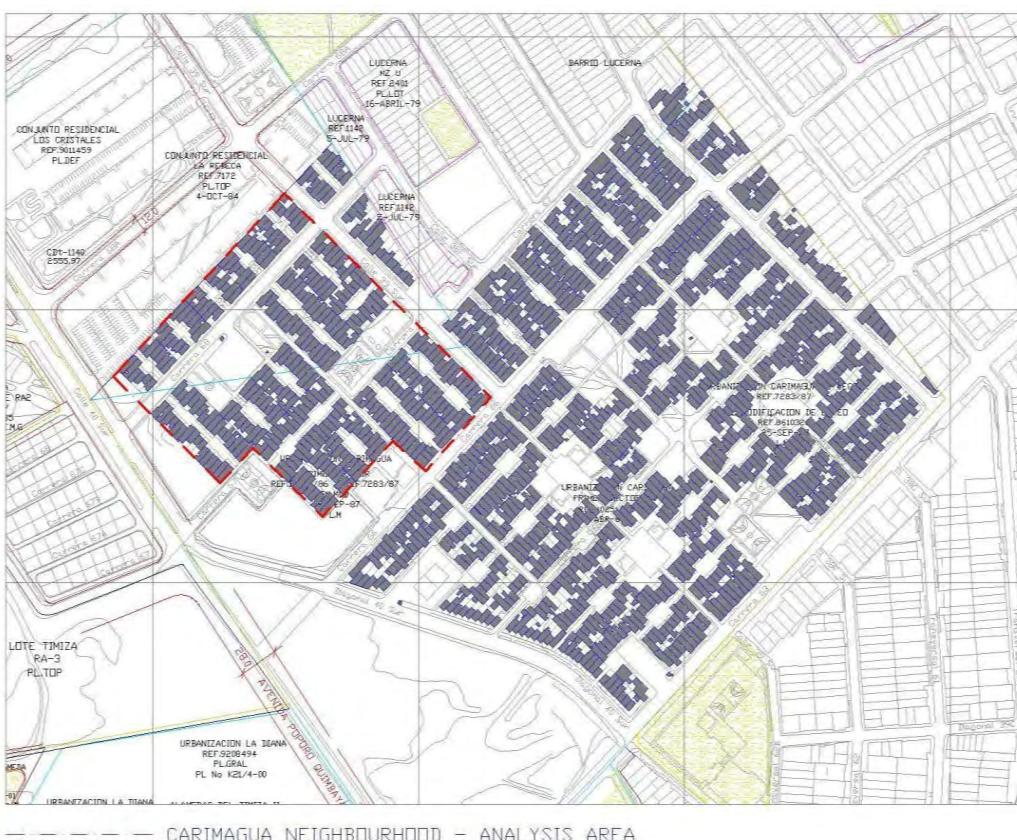

Figure 2. Carimagua neighbourhood: analysed portion evidenced.

Currently, the houses are transformed according to the needs of the inhabitants; however, the urban structure is maintained (figures 3 and 4). On the other hand, Carimagua neighbourhood is in a middle-high flooding risk area, and this paper intends to respond to the following question: is the urban barrio of Carimagua able to mitigate the predicted 30% rainfall increase?

Figure 3. Carimagua neighbourhood in 1967 (left) and today (right).

Figure 4. Carimagua neighbourhood, examples of adaptive initiatives.

To respond to such question, a critical analysis of flooding mitigation strategies to retain rainfall is performed in order to identify which devices are the most suitable ones in terms of costs and benefits (i.e. cost, maintenance, land-take, peak flow reduction and volume reduction) and in terms of extra benefits (i.e. pollution reduction, landscape/wildlife/amenity benefit), as shown in figure 5.

Secondly, an analysis of the case study city block has been carried out. In this context, it is being performed a comparison of the effects of water runoff mitigation of the city block by reducing the degree of impermeability of the surfaces according the use of different finishing surfaces' permeability, as proposed on a recent publication by Ritchie & Thomas (2013), see figure 6, with the value 1.00 being completely impermeable and 0.00 being completely permeable and hence desirable. This city block calculation is aimed at assessing SUDS-based strategies that can be followed to reduce the surface water runoff (i.e. to increase their permeable degree and reduce their impermeable degree).

techniques	investment & benefits						extra benefits	
	surface water runoff reduction							
	capital cost	maintenance	land-take	peak flow reduction	volume reduction	pollution reduction

Figure 5. SUDS analysis of suitability to mitigate surface water runoff in urban areas.

Accordingly, it has been performed an inventory of surfaces materials within a selected area of Barrio Carimagua (figure 2) to then proceed to calculate the overall degree of permeability based on the degree of permeability of each material. This step required to quantify the area of all the surfaces within the city block (such as roofs, pavements, backyards, etc.) and multiply them by the degree of impermeability of the characterising material, as listed in figure 6. This provided a numerical result that is the *overall degree of impermeability*, which for the selected case study is 0.9.

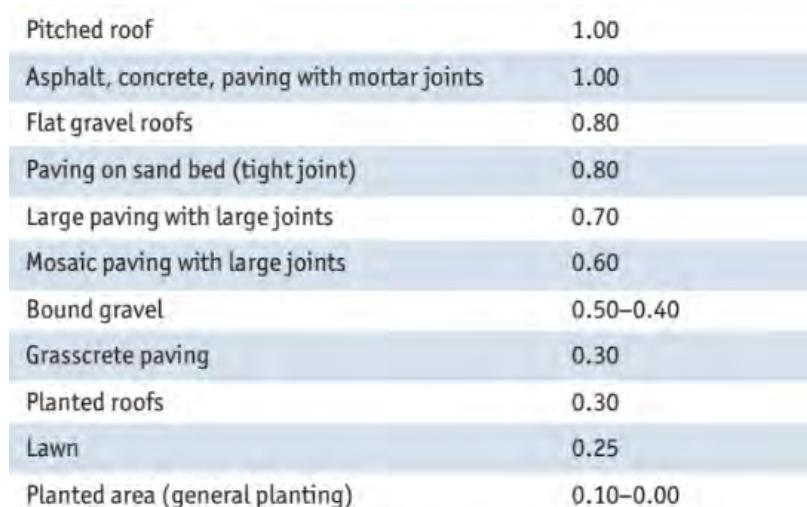

Figure 6. Degree of impermeability of different materials (Ritchie & Thomas, 2013)

Hypothesising the need to cope with 30% increase rainfall, a strategy to reduce such degree of impermeability by the 30%, a new goal of *overall degree of impermeability* to 0.6 for the selected case study is been pursued. This new degree of permeability of the city block will be calculated by changing materials to the surfaces and applying new degrees of permeability as listed in guidance for sustainable urban design (Ritchie & Thomas 2013).

To evaluate the efficiency and feasibility that the proposed devices (green roofs and pervious surfaces) have in reducing the surface water runoff, a selection of strategies were conducted to deliver a new value of impermeability after the surface-materials were substituted by green roofs and pervious surfaces.

Finally, by building on the results achieved in the previous steps, it is presented a critical discussion of the advantages and disadvantages of this adaptation strategy within the city of Bogotá.

## Results

Adaptation of the city block with sustainable urban drainages has been performed, and three possible adaptation scenarios were explored to achieve the aspiring 30% permeability increase to cope with predicted excess rainfall (see Table 1 below).

The first scenario (strategy A) modifies the degree of permeability of the publicly owned areas (streets and parking) by replacement of the (impermeable) cement and asphalt to a permeable parking and permeable asphalt. This strategy achieved the desired *overall degree of impermeability* of 0.6 (see first shaded column in table 1).

The second scenario (strategy B) modifies the degree of permeability of the privately-owned areas (within the plots) by retrofitting roofs to green roofs and by adding planted areas in the front gardens. This strategy also achieved the desired *overall degree of impermeability* of 0.6 (see second shaded column in table 1).

The third scenario (strategy C) combines both the previous strategies, and it has shown that an outstanding 52% increased permeability, equal to an overall degree of impermeability of 0.3 (see last shaded column in table 1).

Table 1. Calculation of improved permeability in Carimagua city block.

Existing situation (Carimagua city block)					need for adaptation (imperviousness reduced by 30%)					
	area (m <sup>2</sup> )	% of total area	degree of imperm.	degree of imperm. (*surface)	strategy A: public	strategy B: private	strategy C: both	degree of imperm.	degree of imperm. (*surface)	degree of imperm. (*surface)
Streets and Parkings (asphalt)	12324	32%	1	12324	0.3	3697	1	12324	0.3	3697
flat roofs (Fibre cement)	9792	26%	1	9792	1	9792	0.3	2938	0.3	2938

front gardens (concrete)	2880	8%	1	2880	1	2880	0.3	864	0.3	864
<b>overall degree of impermeability</b>				<b>0.9</b>	<b>0.6</b>	<b>0.6</b>	<b>0.6</b>	<b>0.3</b>	<b>0.3</b>	<b>0.3</b>
					23%		23%		52%	
						more permeable	more permeable	more permeable	more permeable	more permeable

## Discussion

From the physical realm point of view, the results proposed show that effective adaptation strategies to cope to increase rainfall are feasible, in different ways and in different degrees. However, inhabited built environments are known to present different levels of organisations, so it is recognise that while numerically adaptation is feasible, shortcomings should be expected when implementing these in a real project.

With specific regards to Barrio Carimagua, since its construction, this quartier has embedded continuous modifications and transformative processes, because of the nature of this type of social housing in Colombia (Cubillos, 2006). These processes are expected to facilitate adaptive strategies. In fact, in Barrio Carimagua is has been found feasible some different strategies of flooding adaptation, according to the owners' preferences; i.e. some owners might opt for green roofs and benefit also from the improved thermal comfort with the homes; some might opt for an internal garden). Where no action is preferred, the government can still opt to adapt communal spaces such as parking spaces.

Strategies deployed to increase permeability increase are successful. With the strategies used, the percentage of permeability is increased by 23 percent. It has been possible to increase the total permeable area by 52 percent combined different strategies.

In the parking area it is suggested to change the soil cement by a semipermeable material that improves the permeability percentage but maintains the mechanical properties similar to those of the current cement. And to the extent possible, it is proposed to recover the original garden of the facade to recover the green areas and increase the area of permeability.

## Conclusion

This study identifies the importance of satisfying the need for permeable urban areas today in Bogotá, and consequently, the results propose to implement a model that can respond to such a need, and to implement and optimise life conditions of an urban habitat.

Green roofs constitute an adequate and economical strategy that substantially contributes to increasing the percentage of permeable area in Bogotá and Carimagua neighbourhood is a good example of this adaptability. Also, it could be used as an urban vegetable garden where some vegetables, water retention plants and aromatic plants could be planted.

In Carimagua neighbourhood is evident the demand for habitable soil, because residents tend to occupy all the open spaces available within the plots by physically building on front garden and backyard, with a change use of the plot area, different than the one initially designed. This is a general phenomenon in Bogotá and also other Latin American cities.

It is recognised the limits of this research: while it is used a 30% increase in rainfall is considered over a year, the time factor is not be considered. More research is needed to evaluate the rainfall as it occurs in a short amount of time and test the validity of the present research with the effect of a storm. This could lead to a combined strategy in the outskirts of the urban areas to apply other integrative strategies such as large water reservoirs. However, the ultimate aim of this research is to propose a starting point of adaptive strategies in Latin American urbanised contexts in a moment when heavy urbanisation is occurring and recommendations and guidelines being produced.

Further research is oriented at proposing a factorial model in the study regarding the degree of relationship between variables and factors contributing to increasing resilience to flooding. In this model, variables such as permeability, porosity, percentage of drainage, percentage of runoff and humidity will be interrelated.

## Vertical Farms: Historic Development, Current State and Future Directions

Diana Waldron<sup>1</sup>

<sup>1</sup> Sêr Cymru National Research Network for Low Carbon, Energy and Environment, Welsh School of Architecture, Cardiff University, United Kingdom, waldrond1@cardiff.ac.uk

**Abstract:** Population growth and decreasing levels of land availability is driving our ever-growing society to consider more efficient strategies to produce food. The current state of the depleting natural resources and the straining on the Earth's capacity is putting pressure towards achieving a truly sustainable urban development. Cities will continue to grow hence it is imperative to find solutions to minimise the impact that human development has on the planet. The integration of agricultural and green elements in general, such as vertical farms and green walls/roofs etc., into the built environment has the potential to minimise the damage caused by extensive urbanisation. In particular, Vertical Farming can help towards tackling important issues such as food scarcity, water/flood management and more, offering manageable solutions especially when developed in conjunction with a holistic architectural and urban design approach. This study outlines the current trends and obstacles of vertical farms' development. The following stage of this investigation will be to propose suitable future scenarios for the Vertical Farming concept, based on real case studies, experimental fieldwork and computer simulations. This article is the first step of a larger research project where the potential of vertical farms is explored along their integration within cities.

**Keywords:** Vertical Farming (VF), Urban Agriculture, Biomimicry

### Introduction

Our ever-growing society urgently needs to find better strategies to achieve a sustainable balance between urban development and the protection of the natural environment (Hasse & Lathrop 2003; Johnson 2001). Cities will continue to grow and it is imperative to find solutions to minimise the impact that buildings and cities have on the planet (Al-Chalabi 2015; Johnson 2001). The integration of greenery into the built environment has the potential to minimise the damage caused by extensive urbanisation (Alexandri & Jones, 2008; Safikhani et al, 2014). Nature has inspired humans to find solutions to a number of problems, this is also known as Biomimicry (Lurie-Luke 2014). This concept helps to promote a holistic relationship between plants and architecture. There are a number of examples within architecture where this relationship has been established (Pawlyn 2011; El-Zeiny 2012). This research intends to undertake a deeper exploration in this area, with a particular focus on Vertical Farming, which will be referred to as VF in this paper (Despommier 2009; Despommier 2010; Sarkar & Majumder 2015).

Using nature inspired solutions to tackle modern problems represents a significant source of knowledge-transfer opportunities, as other research have demonstrated through biomimicry (Breuste et al, 2013b; El-Zeiny, 2012; Pawlyn, 2011). However, despite all the advances and research undertaken evaluating the integration of green elements in cities, less sustainable practices are predominant and more research is required (Breuste et al,

2013a). This is particularly true in the area of VF, where regular unsustainable agricultural practices are most common. This research will pay particular attention to the best integration of Vertical Farms (VF) in cities.

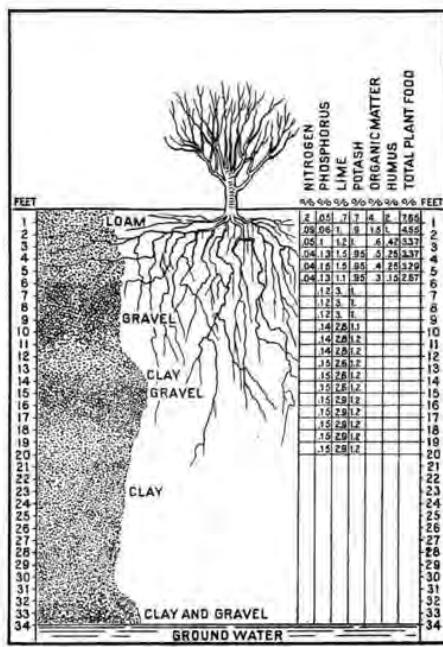

The main aim of this paper is to investigate the current development of VF in order to identify the obstacles faced by their integration with architectural design and urban areas. The purpose is to identify the main characteristics that will help to achieve and maximise an overall sustainability of VF integrated into the built environment, starting with in-depth investigation of the relationship between *vertical farms* and *architecture*. The target is to analyse the feasibility of VF integration and establish the most suitable routes to achieve a cohesive urban integration of these two concepts. Therefore, this study aims to investigate current progress of VF and urban agriculture through literature review, analysis of several real VF case studies at different locations, site-visits, own experimental VF field work and computer simulations. This paper covers mainly the first part of this research project: gathering, analysis and discussion of the information found during the literature review. Further research papers will be published with the progress of this investigation.

### **Historic Development of Vertical Farming**

Research has found that green infrastructure in cities helps to mitigate a number of issues in urban areas, such as Urban Heat Island (UHI) Effect, water/flood management, amongst other (Breuste et al. 2013a). Vertical farms have the potential to add to these benefits, moreover they could also help to solve further problems, such as food scarcity, agricultural land availability and more (Hasse & Lathrop 2003). Nature has inspired humans to find solutions to a number of problems (Lurie-Luke 2014) and there are a number of examples within architecture where the integration of plants provided the best solutions to specific problems (Pawlyn 2011; El-Zeiny 2012). Published literature supports the concept of VF to help solving some of these issues (Despommier, 2010; Garg & Balodi, 2014; Sarkar & Majumder, 2015). In brief, nature inspired solutions in the area of plants and architecture offer a significant source of knowledge-transfer opportunities, as other research has demonstrated (Breuste et al. 2013b; El-Zeiny 2012). Cities should learn to behave as ecosystems rather than parasites, vertical farms can help to achieve this principle (Despommier 2013).

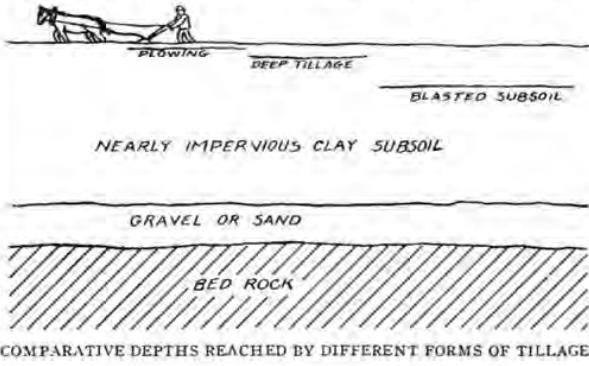

Historically, the term ‘Vertical Farming’ originated back in 1915, it was used in a publication by Prof Gilbert Ellis Bailey, a Professor of Geology at the University of South California (Bailey 1915). The title of his book is *Vertical Farming*, where he used this term mainly to describe a soil-based type of agricultural development. In his book, Professor Bailey explores a number of issues, mainly related to several of the characteristics and properties of agricultural soil, such as soil texture, chemistry, soils moisture, etc. He concluded his book by establishing that with the use of inexpensive explosives, farmers can effectively farm deeper into the soil layers. Thus, increasing the acreage available in their fields and therefore obtaining larger crops (Bailey 1915). Despite of the fact that this book does not use the term of VF as it might be perceived nowadays (Despommier 2010; Sarkar & Majumder 2015), with his concepts, Professor Bailey created a foundation of a concept that will thereafter be shared with the modern understanding of VF:

“Instead of spreading out over more land he [the farmer] concentrates on less land and becomes an intensive rather than extensive agriculturist” (Bailey 1915).

THE DEEPER PLANT FOOD MIGHT JUST AS WELL BE IN EUROPE FOR ALL THE ATTENTION THAT IS USUALLY GIVEN IT

**Benefit of Using Explosives.**—It is admitted that present methods of cultivation do not go deep enough, and it must also be admitted that the use of specially prepared agricultural explosives offers the desired remedy. It is admitted by all

authorities in agriculture that the plow and harrows do not go deep enough and they advise the use of subsoilers. Scores

Figure 1. Diagrams and passages from Prof Bailey's Book, pages 25 & 63 (Bailey, 1915)

In this first book on VF, the author was talking about intensive agriculture in a reduced area of land, in terms of deeper levels into the ground. The modern concept of VF aims to achieve a similar outcome, but instead of using explosives to reach deeper layers of soil, modern vertical farms commonly use the vertical stacking of layers of crops (Despommier 2009; Banerjee & Adenaeuer 2014), by using a number of different techniques, such as hydroponics, aeroponics, aquaponics, etc. (Besthorn 2013; Fischetti 2008) without the use of explosives of course! Furthermore, modern vertical farms are not required to be underground, they can also be above ground, as well as indoors or outdoors. Briefly explained, *hydroponics* "is a method of growing whereby the plants roots are directly exposed to water based, nutrient rich, solutions without using, or needing, a soil or coco medium"(Holland Hydroponics & Horticulture, 2016). *Aeroponics* is also a soil-less method of growing plants, which "uses small microjets to spray the plants' roots with a fine, high-pressure mist that contains nutrient rich solutions."(pH Hydro 2014). Finally, *Aquaponics* "is the combination of aquaculture (raising fish) and hydroponics (the soil-less growing of plants) that grows fish and plants together in one integrated system. The fish waste provides an organic food source for the plants, and the plants naturally filter the water for the fish."(The Aquaponic Source 2017 2017).

The current concept of vertical farms gained new momentum particularly in 1999, with the theoretical work undertaken by Dr Dickson Despommier. He is a Professor of Environmental Health Sciences and Microbiology at Columbia University, New York. Dr Despommier explains that "the concept of the vertical farm arose in my classroom in 1999 as a theoretical construct as to how to deal with a wide variety of environmental issues." (Plan 2B Green 2011). There is evidence of some advances in the area of what is currently known as VF before 1999 (Plan 2B Green 2011) , however major theoretical boost in this area only occurred with Dr Despommier's publications and designs, alongside his professional colleagues (Fischetti 2008). He is considered to be the "Father of the vertical farm concept/movement" (Banerjee & Adenaeuer 2014).

Figure 2. Pictures taken by the author during a site visit to GrowUp urban farms in London

The decade following Dr Despommier's work/publications witnessed a dramatic increase in the number of 'real-life' vertical farms developed, also referred to as vertical agriculture, and occasionally denoted as plant factories (Yang 2014). Furthermore, this number continues to increase exponentially and more vertical farm projects are coming to life (Yang 2014; Association for Vertical Farming 2016). Despite all the existing obstacles to develop vertical farms as Dr Despommier initially envisaged (Despommier 2009), further progress in this area has started. Perhaps not quite as large as the ones suggested by him, but projects of 3- to 5-storey facilities can be found in a number of countries around the world, a few perhaps larger (Association for Vertical Farming 2016). Table 1 shows some of the most notorious developments of vertical farms. There are a number of identified obstacles that class VF as an un-common agricultural practice (these will be discussed here at a later stage) and it is evident that more research and expert skills are needed to make it a real possibility to grow larger quantities. Nevertheless, there is irrefutable evidence that the vertical farm concept is rapidly evolving and the obstacles would perhaps become more manageable.

Table 1: Vertical farms around the world

Country	City	Project Name/Organisation	Size/Type
Korea	Suwon	Rural Development Agency	3-storeys
Japan	Kyoto	Nuvege	Plant Factory
Singapore	Lim Chu Kang	Sky Greens	4-storeys

## **Latest Development on Vertical Farming**

Despite of the significant development on commercial vertical farms (Kozai, et al, 2016; Sarkar & Majumder, 2015; Yang, 2014), there is an evident gap in academic documentation of current advances on VF. Most academic journal papers support common premises stressing the need to encourage further development of vertical farms. Some of the most prominent reasons for these premises are: the lack of land availability, food scarcity and population growth (Sarkar & Majumder 2015; Garg & Balodi 2014; Banerjee & Adenaeuer 2014; Al-Chalabi 2015).

It is frequently stated that the main drivers for the evolution of agricultural research are: 1)Fast growth in science and 2)Technological knowledge (Garg & Balodi 2014; Banerjee & Adenaeuer 2014). The global urbanisation rate is also playing a significant part according to literature, it is predicted that 70% of the population will be living in urban centres by the year 2050 (Al-Chalabi 2015). Furthermore, there is a need to restore the environmental imbalance created by farming chemicals (Garg & Balodi 2014; Despommier 2013). Further issues affecting food demand are the changes in food preferences (Garg & Balodi 2014; Banerjee & Adenaeuer 2014). These changes are arguably the result of the rising per-capita income, particularly in developing countries (Sarkar & Majumder 2015; Garg & Balodi 2014), as well as the increase of purchasing power (Banerjee & Adenaeuer 2014).However, they are also likely to be affected by occupational changes and extended global linkages (Garg & Balodi 2014). It is predicted that by the year 2050 the world will need 60% more food, while figures currently show that 1.3 billion tons of food is lost or wasted every year (Banerjee & Adenaeuer 2014). These later issues are particularly worrying since they show that the main problems affecting food scarcity are not just founded on the depletion of natural resources, but on the lack of efficient management of the available food.

A significant advantage of the vertical farm concept is that they can be located within the urban areas. Therefore, by producing food closer to the end-consumer, the amount of food wasted can be significantly reduced, by decreasing transporting time/distance and also by producing just the right amount for the actual needs of specific locations. This will also help to decrease CO<sub>2</sub> emissions originated from food transport.

The main challenges faced by VF are the high requirements for expert knowledge in plant science and engineering (Sarkar & Majumder 2015). Furthermore, there are a number of practical problems besides the popularly emphasized financial difficulties. Some of the cited challenges are: difficulty to establish an effective and efficient eco-friendly design of vertical farms structures, difficulty to design a well-controlled environment, watering system, monitoring of nutrient solution, selection of ideal crop, etc. (Sarkar & Majumder 2015; Al-Chalabi 2015).

On the other hand, some of the main advantages are: all-year food production, local need-based production(Sarkar & Majumder 2015), reduced transport needs and reduced food waste associated with transportation (Garg & Balodi 2014; Sarkar & Majumder 2015). Furthermore, it has been found that vertical farms have a much higher crop yield, decreased water usage, less disease transmission – less pesticides, pests, deforestation (Garg & Balodi 2014; Sarkar & Majumder 2015). Published research also claims that VF provide a paradigm shift in terms of agricultural behaviour, i.e. it supports the concept of intensified instead of extensified agriculture. For example, 1 indoor acre is equal to 3 outdoor acres of strawberries according to (Banerjee & Adenaeuer 2014). Additionally, VF allows the reuse of buildings (Garg & Balodi 2014; Banerjee & Adenaeuer 2014), encourages coupling of food production (food + fish, i.e. Tilapia) (Banerjee & Adenaeuer 2014). Depending on the type of

VF, most designs do not require heavy agricultural machinery or inorganic fertilisers and it helps to reduce transport pollution (Garg & Balodi 2014). Further benefits are: help to create sustainable urban centres, purifying air and positive psychological effect. Moreover, the vertical farm concept could provide solution for extreme situations such as growing food in space, poles and refugee camps (Banerjee & Adenaeuer 2014). Currently, some of the most profitable and common crops are: green leafy vegetables, cabbage, lettuce, basil, tomatoes, okra, cantaloupe, bell peppers and roses (Sarkar & Majumder 2015).

Latest research analysing various types of cultivation of edible plants on buildings also shed some light in terms of the benefits and limitations of soil-less and soil-based agriculture (Samangooei et al, 2016). Their investigation assessed a number of case studies under a scoring system using these parameters: Environmental, Social and Economic impact. Such study revealed that soil-less systems (such as hydroponic vertical farms) are more productive per square metre. However, soil-based systems are more affordable and are more likely to be more environmentally and socially beneficial overall. Nevertheless, (Samangooei et al. 2016) admit to be only at the beginning of a larger exploration of the two types of cultivation systems (i.e. soil-less and soil-based).

## **Discussion**

Various academic papers stated that the best design for a vertical farm has not yet been found (Sarkar & Majumder 2015; Banerjee & Adenaeuer 2014; Fischetti 2008; Al-Chalabi 2015). Some suggested that one of the best options might be based on the pyramid farm recommended by Eric Ellingsen and Dr. Despommier (Sarkar & Majumder 2015; Ellingsen & Despommier 2008), but this design is still relatively futuristic and it can be perceived as an utopia. The economic and environmental feasibility of a true architectural integration of vertical farms requires further in-depth scientific investigation. Furthermore, the literature also highlights the need to design more efficient systems to handle the energy usage on artificial lighting, heating and cooling (Banerjee & Adenaeuer 2014; Kozai et al. 2016). Some academics also agreed on the need to develop research projects that will quantify and qualify the validity of VF (Al-Chalabi 2015; Banerjee & Adenaeuer 2014). Al-Chalabi, from Oxford University, and various other researchers, stated that there is a strong need for a *real pilot* project to test the true integration of VF, this is supported by other published work (Al-Chalabi 2015; Garg & Balodi 2014).

This preliminary literature review provides strong evidence on a number of problems faced by the development of VF. It can be argued that, despite of the various existing vertical farm developments around the world, this is an area that is still in its infancy. This is particularly noticeable due to the weak finances behind most projects of this nature: "According to a survey in February 2014 by the Ministry of Agriculture, Forestry, and Fishery of Japan, among 165 PFALs [Plant Factories with Artificial (or electrical) Lighting], only 25% made a profit, 50% broke even, and 25% lost money" (Kozai et al. 2016).

Based on the literature review, this research project argues that most of the disadvantages behind VF are due to the lack of true integration between VF and urban architecture. Better planning and a cohesive design response could potentially help towards improving the finances and true viability of these concepts.

## **Conclusion**

As it has been shown above, thorough studies and experiments in the area of urban greening and vertical farms have taken place in a number of research projects around the

world (Alexandri & Jones, 2008; Banerjee & Adenaeuer, 2014; Koyama et al, 2013; Pérez et al, 2014). However, despite all the advances and research undertaken to evaluate the integration of green elements, urban crops and vertical farms in cities, less sustainable practices are predominant. It is evident that more research is required to make their integration a reality (Breuste et al. 2013a). Likewise, there is a significant amount of evidence that highlights the need to develop further research in the area of architectural sustainability with the integration of plants (Breuste et al., 2013a; Centre for Sustainable Energy, 2015; Yang et al, 2015). Especially considering the statistics and research showing that vertical farms (or plant factories) are not particularly strong financially (Kozai et al. 2016), this represents a significant challenge in order to truly achieve the integration of VF within cities.

This paper is the first step of a larger research work. The author aimed to present a brief review on the historic development of vertical farms and the current state of research in this area. This is followed by suggesting and establishing a sensible and informed pathway towards the future direction of the research in the area of urban vertical farms. After identifying the initial gaps that exist in this area, as it was described in the previous sections, the next phase of this research aims to layout a number of VF site visits in various locations. Simultaneously, experimental fieldwork will be undertaken in order to optimise the practises followed by currently active vertical farms, thereafter suggesting improved integration within the built environment. This will be assisted by computer simulation and data analysis in order to provide documented evidence of the followed procedure. The final goal is to provide sound and evidenced academic research in the area of vertical farms integrated into the built environment.

**Abstract:** The effects of urban climate change have drawn attention to monitoring and evaluating outdoor environment in cities worldwide. Especially in China, rapid, large-scale urban development alongside rapid economic growth has resulted in considerable urban climate change since the 1990s, creating urban environmental problems such as haze. Currently, most of the studies on this matter that are being conducted in China focus on the impact of urban development on urban climate change. Few studies have focused on developing solutions for microscale urban climate change. In this study, four micro-scaled districts in Xi'an were selected to represent the typical building styles that developed in different historical periods. These are a traditional residential district (1950s), a low-rise district (1980s), a mixed-rise district (1970s-2000s), and a high-rise district (2010s). The urban climate was here evaluated using the urban environmental simulation system scSTREAM, and the mitigation solutions of urban typology optimizing are proposed in the discussion. The change in the urban micro-climate along with the change in urban typology were indicated, and the proposed solutions indicate in detail the impact of various solutions on different urban conditions. This may which could provide hints for urban climate change mitigation and sustainable urban planning in the future.

**Keywords:** Urban climate change, Environmental simulation, Urban typology, Air pollution

### Introduction

The effects of urban climate change have drawn attention to monitoring and evaluating outdoor thermal comfort in cities worldwide. Especially in China, rapid, large-scale urban development alongside rapid economic growth has resulted in considerable urban climate change since the 1990s, creating urban environmental problems such as haze. The use of primary energy makes up the main constituent of Chinese haze, and the high-density urban typology accelerates the aggregation of air pollution in the urban areas. An “urban air path” is here proposed as a means of optimizing the urban wind pattern and increasing wind speed inside cities from the view of urban planning (Werner, 1979; Ren et al., 2014). Recently, the use of urban wind corridors has become widely discussed (Memon et al., 2013), especially in many Chinese cities such as Beijing (Du et al., 2016), Shanghai (Shi et al., 2016), Guangzhou (Liang et al., 2014), Changsha (Xi et al., 2010), Nanjing (Weng et al., 2015), Wuhan (Li et al., 2014), Zhengzhou (Bai, 2015), and the Pearl River Delta (Ren et al., 2016). Most of the studies on this matter that are being conducted in China focus on the impact of urban development

on urban climate change or on mapping the urban wind corridor on a large scale. Few studies have focused on developing solutions for microscale urban climate change.

Xi'an is located in the middle of China, geographically. With the extremely fast urban development that took place in China after the 1970s, Xi'an had tripled in geographic area by 2010, and the building density increased dramatically. Meanwhile, the annual average air temperature has increased about 3°C in the past 50 years. In 2012, the Xi'an Meteorological Administration reported that 70% of the days in autumn and winter were haze weather days. For this reason, urban climate change mitigation has become an urgent issue in Xi'an.

In this study, four micro-scaled districts in Xi'an were selected to represent the typical building styles that developed in different historical periods. These are a traditional residential district (1950s), a low-rise district (1980s), a mixed-rise district (1970s–2000s), and a high-rise district (2010s). The urban climate was here evaluated using the commercial urban environmental simulation system scSTREAM, and the mitigation solutions of urban typology optimizing are proposed in the discussion. The comparison and discussion among the four selected districts indicated the changes in the urban micro-climate along with the changes in urban typology, and the proposed solutions indicate in detail the impact of various solutions on different urban conditions. This may provide hints for urban climate change mitigation and sustainable urban planning in the future.

## Methodology

### *Field Measurements*

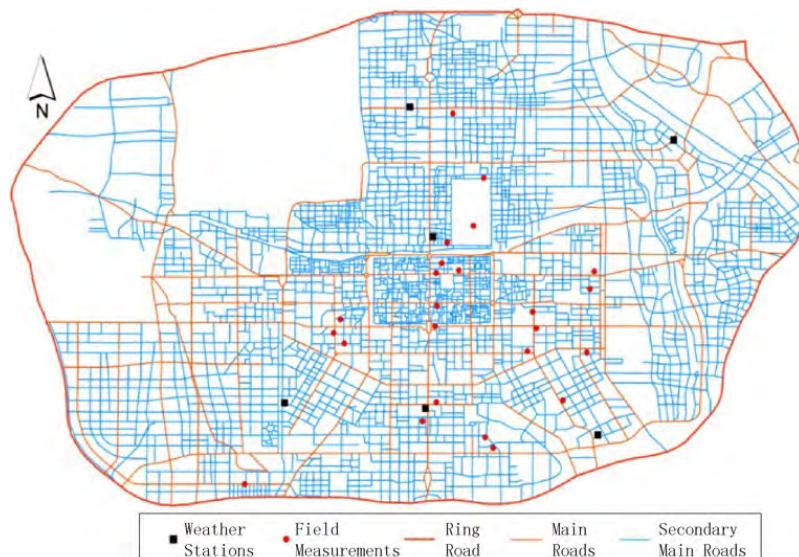

Figure 1. The location distribution of field measurements in Xi'an city

The field measurements were carried out between June 11 and August 27, 2016 in 24 locations in Xi'an City, and 3 days of measurements were taken at each location. The normalization statistical method was used to normalize the weather conditions measured on different days, and Kriging was used for spatial unification (Krige, 1951). The concentration of PM<sub>10</sub> was measured at these points in order to assess the distribution of air pollution in urban area.

## Selected Urban Areas

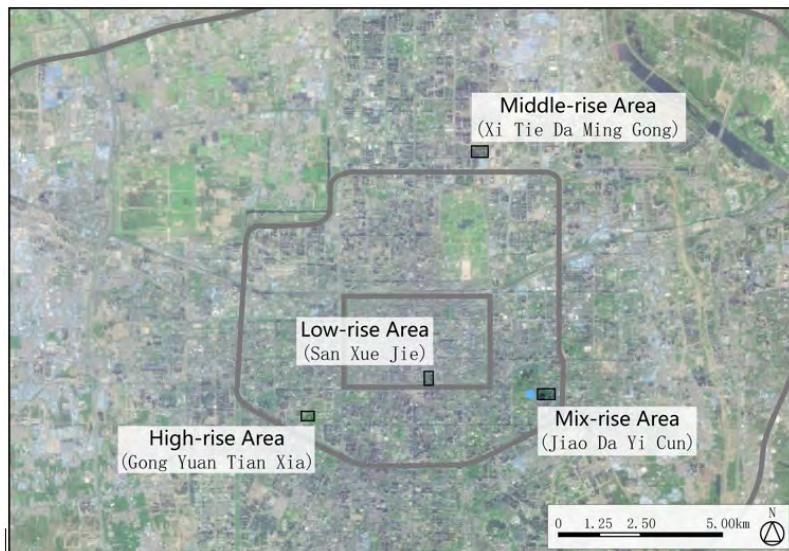

Figure 2. Xi'an satellite photo with the four areas selected for this study, and defined as low-rise area (Sanxuejie), middle-rise area (Xitedaminggong), mix-rise area (Jiaodayicun) and high-rise area (Gongyuantianxia). The area represented in this figure is indicated in Figure 3 and Table 1.

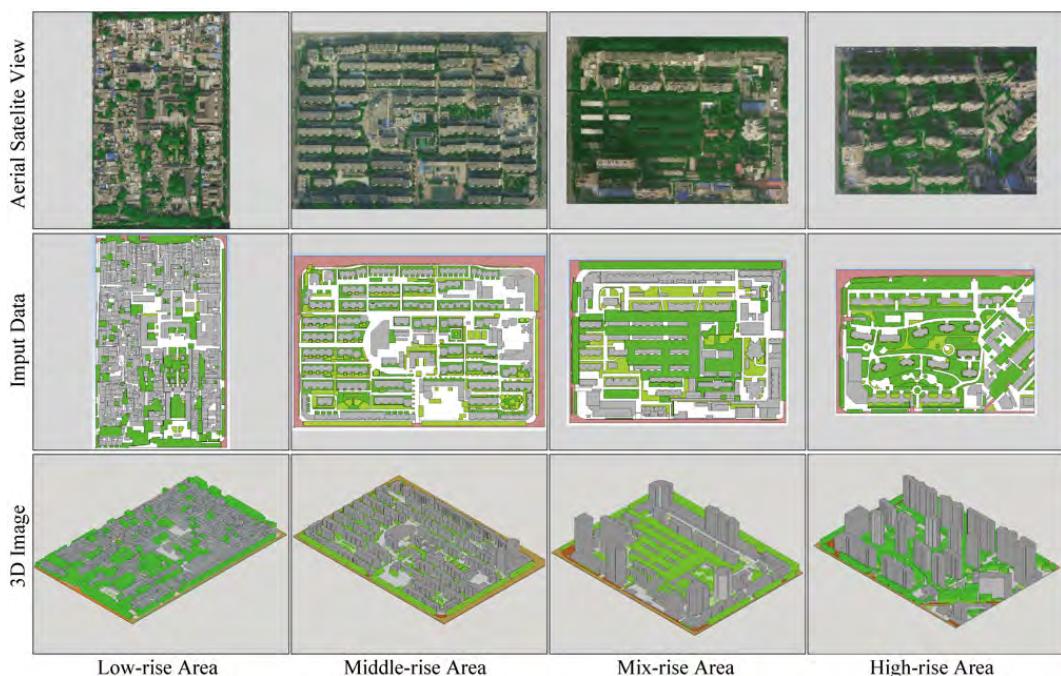

Figure 3. Image selected areas and simulation domain data.

Four typical residential areas were selected for simulation and discussion. The first, Sanxuejie, is a low-rise area, a traditional residential zone rebuilt after the 1950s. It retains the urban form used in China since the Ming and Qing Dynasties (about 600 years ago), with narrow streets between residential buildings, most of which have 2 floors. The second area, Xitedaminggong, is a middle-rise neighborhood developed in the early 1990s. All of the residential buildings are 5 floors in height and perfectly represent the character of the building type constructed in the period between 1979 to the beginning of 1990s. The third neighborhood, Jiaodayicun, is a mix-rise area of low-rise and high-rise buildings, home to a variety of building styles developed around the 1980s and 2000s. The last selected

neighborhood, Gongyuantianxia, is a high-rise residential neighborhood developed in 2009. The average building floor in this area was 17 floors in height, representing the common development style after 2000.

### ***Urban Environmental Simulation***

A commercial CFD code, scSTREAM (Software Cradle Co., 2011), was used to simulate the urban ventilation properties. Detailed distributions of air current and pressure per direction can be visualized. The simulation models were built according to the realities shown in Figure 3, and the detailed input data are presented in Tables 1, 2, and 3.

Table 1. Details of simulation domain size in the four selected areas.

	Low-rise	Middle-rise	Mix-rise	High-rise
Site Size (m)	280*440	520*364	450*340	410*300
Simulation Size (m)	1080*1240	1520*1364	1450*1340	1410*1300
Grid Size (m)	0.6-6.0			

Table 2. Land use and building height properties in the four selected areas.

	Low-rise	Middle-rise	Mix-rise	High-rise
Site Area ( $m^2$ )	123200	189280	153000	95850
Built Area (%)	51	19	14	6
Green Area (%)	22	28	41	49
Floor Area (%)	106	153	242	254
Average Floor	2	5	7	17

Table 3. Details of ground surface material characteristics for simulation.

	Materials	Density [kg/m <sup>3</sup> ]	Specific heat [J/(kg·K)]	Thermal conductivity [W/(m·K)]
Building	Concrete	1600	1000	0.65
Road	Asphalt	2120	920	0.74
Side Walk	Redbrick	1650	840	0.62
Inside surface	Mortar	2000	800	1.3
Green	Soil	1340	1700	0.7

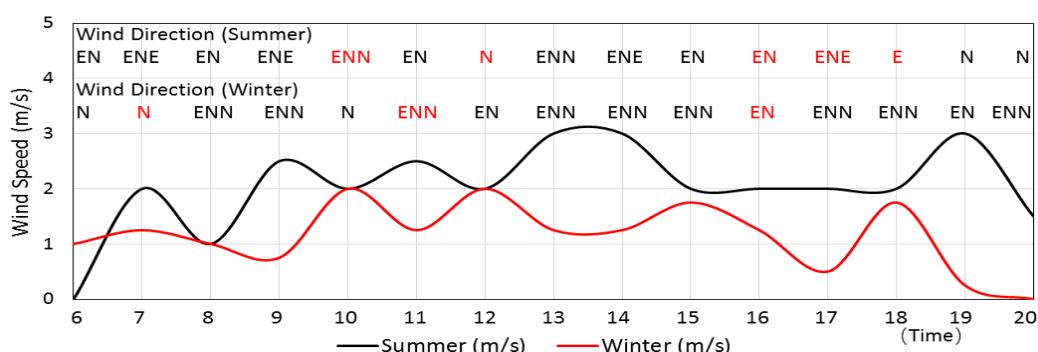

Figure 4. The wind condition in a typical summer day (July 21, 2016) and a typical winter day (December 21, 2015). The main wind directions are shown in red colour.

The wind environment (Xi'an Weather Station, 2016) on a typical summer day (July 21, 2016) and a typical winter day (December 21, 2015) were selected for analysis. The wind direction and wind speed between 6:00 a.m. and 8:00 p.m. are shown in Figure 4. The average wind speed on the summer day was 2 m/s, and the wind directions were N, ENN, EN, ENE, and E, the main being EN; the average wind speed on the winter day was 1.25 m/s, and the wind directions were N, ENN, and EN, the main direction being ENN. The average wind speed and all of the wind directions in different seasons served as the initial condition for the simulations in scSTREAM. The main wind directions were here used for detailed results analysis and discussion.

## Results

### *Air pollution distribution in Xi'an city*

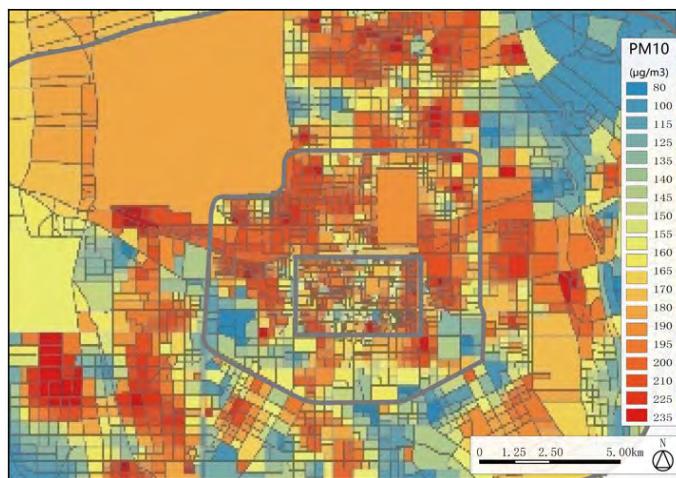

Figure 5. Distribution of PM<sub>10</sub> concentration in the central of Xi'an.

The field measurement results of the PM<sub>10</sub> concentration distribution in the summer of 2016 are shown in Figure 5. The air pollution was found not to be uniformly distributed all over the city. Comparison of Figure 5 and the satellite photo in Figure 2 showed the distribution of air pollution to be partially but directly related to urban density. This is because the urban typology affects urban ventilation and accelerates aggregation, and the air pollution in high density urban districts is subsequently high.

In order to clarify the mechanism of the air pollution concentration in high density areas, the low-rise and middle-rise areas that located in highly polluted areas are selected for simulation. This phenomenon will be discussed with the simulation results.

### *Wind Environment Simulation*

On a summer day, 5 wind directions (N, ENN, EN, ENE, E) were simulated at a wind speed of 2 m/s. On a winter day, 3 wind directions (N, ENN, EN) were simulated at a wind speed of 1.25 m/s are simulated. Figure 6 and 7 present the simulation results in the selected 4 urban areas.

In summer (Figure 6), with the effects from trees, the median wind speed in the low-rise area was slower than in the other areas, and the wind speed in the mix-rise area was fastest. With a wind direction of EN, the median wind speed in mix-rise area was 0.35 m/s, which was 0.15 m/s higher than in the low-rise and middle-rise areas, respectively. The median wind speed in high-rise area was slightly slower (0.03–0.06 m/s) than in the low-rise and middle-rise areas, but there were small areas of higher wind speed in the high-rise area,

and these reached 2.13 m/s (2–3 times of the max wind speed in the low-rise and middle-rise areas). This could explain the results of high PM<sub>10</sub> concentration measured in low-rise and middle-rise areas shown in Figure 5.

In winter (Figure 7), without the effects from trees, the median wind speed in the mixed-rise area was higher than in the other areas. With a wind direction of ENN, the median wind speed in mixed-rise area was 0.24m/s higher than in the low-rise area, and 0.19m/s higher than in the middle-rise area. The median wind speed in the high-rise area is 0.09 and 0.28m/s lower than in the middle-rise and mixed-rise areas. This is to say, the low-rise area (high built density) and the high-rise area (high urban roughness) are reducing the urban wind speed.

In most of the cases, wind direction of EN provides the highest wind speed in all over the area. But the results of high-rise area in summer is lower than the other directions. This is because of the effects from trees.

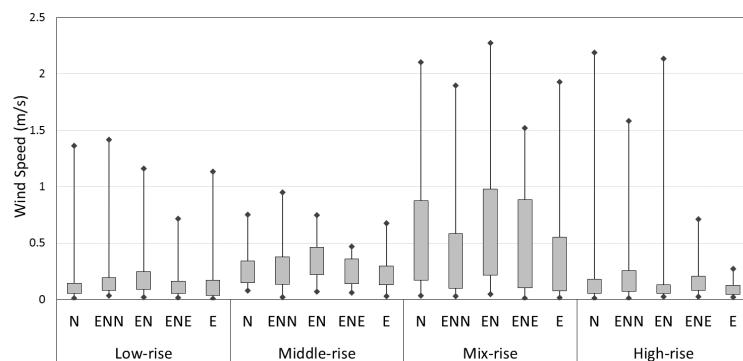

Figure 6. Wind speed in four selected areas in a typical summer day (July 21, 2016).

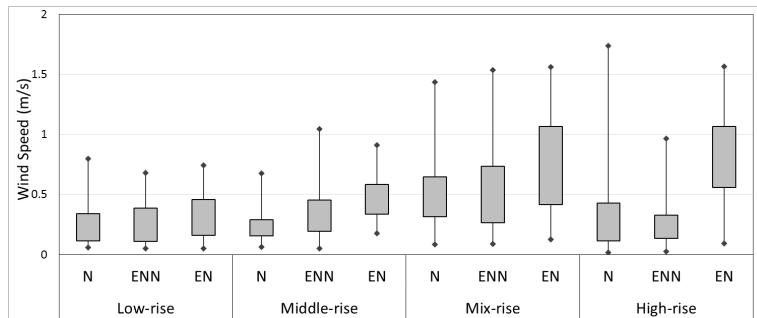

Figure 7. Wind speed in four selected areas in a typical winter day (December 21, 2015).

### **Wind Speed Distribution**

Figures 8 and 9 show the details of wind speed distribution inside these four areas in the summer and winter. In the low-rise area, because of the high building density and narrow corridors between buildings, the overall wind speed was low, and it also had a pronounced effect on downwind areas. In the high-rise area, some areas of high wind speed were observed in between the high-rise buildings, but the wind speed in the leeside of the big volume buildings was extremely low. The mix-rise area showed the best ventilation properties of the four areas. Therefore, the traditional urban typology with low density and high built coverage creates the low urban ventilation at the human level. Meanwhile, high-rise districts with large open space inside of the district also reduces the overall wind speed.

In winter, without the effects from the trees, higher ventilation could be observed inside of the four districts. Especially in the high-rise district, the wind property inside of the community is promoted in the winter.

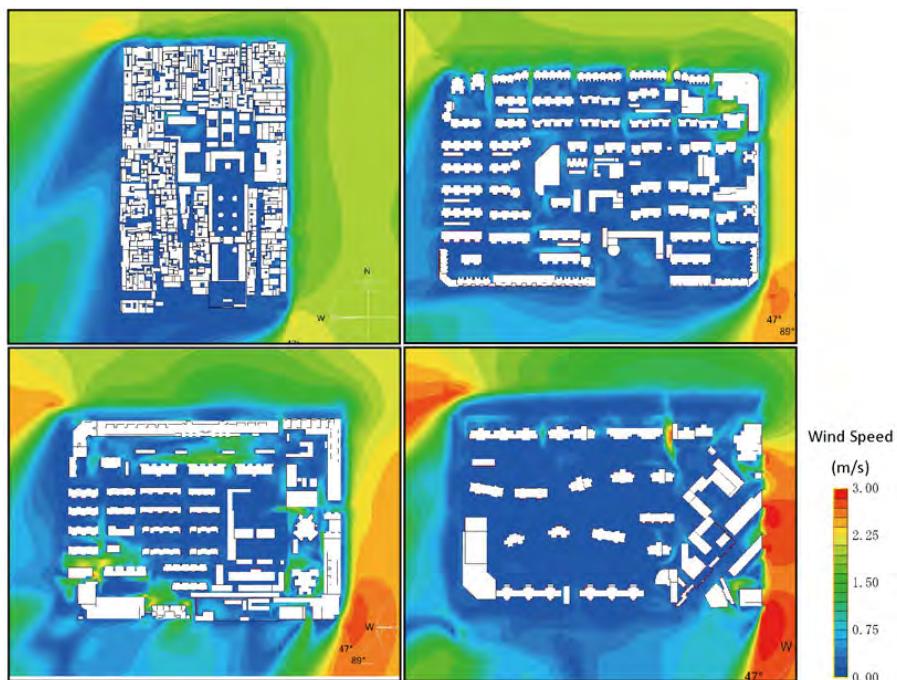

Figure 8. Wind speed distribution in four selected areas at 1.5m height from the ground in summer (wind speed: 2m/s; wind direction: EN).

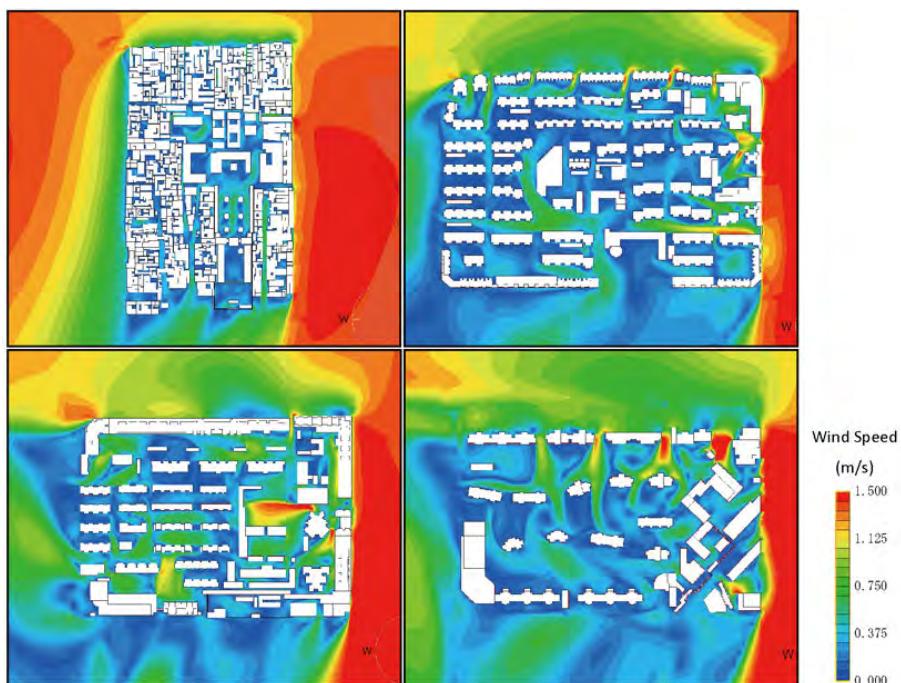

Figure 9. Wind speed distribution in four selected areas at 1.5m height from the ground in winter (wind speed: 1.25m/s; wind direction: ENN).

## Discussion

Urban ventilation plays an important role in the urban environment. In summer, urban ventilation contributes to urban heat dissipation and urban heat island mitigation. In winter, high wind speed accelerates the aggregation of air pollution. Results demonstrated that the urban typology affects urban ventilation and urban air quality. However, it is usually difficult to change the urban form over a short period in areas that have already been developed.

Most of China's cities have undergone fast economic growth, urban expansion, and urban redevelopment. This unique situation is the reason of the rapid environmental degradation in Chinese cities, which could also be useful to the other countries. In the meantime, the fast change in form in China's urban areas has provided an opportunity to optimize urban environments in short periods. This requires an urgent establishment of related policies to regularize environmental urban development and redevelopment.

## Conclusion

This work demonstrated that the wind environment in the low-rise area and the high-rise area are characterized by high building density and the pronounced urban roughness. Wind speed was 0.04 to 0.09 m/s lower in the high-rise area than in the middle-rise area and 0.04 to 0.14 m/s lower in the low-rise area than in the middle-rise area. Wind speed is 0.19 to 0.27 m/s lower in the high-rise area than in the mixed-rise area and 0.21 to 0.28 m/s lower in the low-rise area than in the mixed-rise area. Overall, the balance between building height and building ratio should be considered in future urban development projects. The information from this work provides information useful to the cultivation of environmental urban policy.

<sup>2</sup> Department of industry technology Education, National Kaohsiung Normal University , Kaohsiung , Taiwan

**Abstract:** Annual building energy consumption is dominated by cooling energy in subtropical Taiwan. While cooling energy is closely influenced by outdoor meteorological condition, the global warming effect would affect the change of cooling energy in the future Taiwan. To constrain excessive cooling energy consumption in the future, the cooling energy rise due to climate change should be neutralized and the building regulation criteria should be progressively modified over years in accordance with the future climate. This study tried to investigate building energy performance based on building regulation criteria in Taiwan to understand the cooling energy variation in the future climate. A design of experiments using structured orthogonal array method is adopted for case generation and for studying the synthesis effect of several envelope design strategies. Each generated case was simulated by EnergyPlus against the prepared hourly future climate data encompasses RCP45 and RCP85 scenarios. The results revealed that the cooling energy varying with envelope configuration is hard to remain at current level after 2050s and will increase at least 40% in 2080s. Therefore, we further proposed easily understandable progressive criteria modification schemes that are changed for every 30 years in neutralizing the climate change impact on building cooling energy rise.

**Keywords:** building energy regulation, climate change, criteria adaptation

### Introduction

With the increasing urbanization and relying on electrical power, the research about future climate and energy efficiency are both important in the warming trend especially in hot and humid Taiwan. There are three elements of urban development: infrastructure, building operations, and transportation. A research in the U.S. indicated that the most targeted measures to reduce urban energy usage should focus on building operation (Christopher et al., 2006). In Taiwan, it consumes more than 30% electrical power in essential functions of residential and commercial buildings. Furthermore, there is 40% electricity using in air condition system (Yang and Hwang, 1993, 1995). While the building energy usage is dominated by outdoor climate and building envelope configurations, this study focuses on the energy performance of varying building factors under future climate scenarios.

To understand the climate change impact on building energy, a reach based on the warming scenario predicted by IPCC revealed that a 4.4 °C rise in mean annual air temperature relative to the 1961-1990 period would make the annual cooling energy demand for office buildings increase by 223-1050% in Switzerland (Frank, 2005). In Slovenia, four combinations of temperature and solar radiation change were concerned to predict the future climate and the influences to office buildings (Vidrih and Medved, 2008). The results

showed that the overheat time of office buildings would rise to about 1270 hours per year and that the heating load and cooling load in the future would grow by 12% and 28% respectively compared to those average in 1992 to 2003.

In the UK, Chow *et al.* (Chow and Levermore, 2010) used the UKCIP02 model to predict the climate condition in the future time slices (2020s, 2050s, and 2080s) in UK. They checked the office buildings based on UK Building Regulation and found that the increase of cooling load would be the same as the decrease of the heating load. Additionally, the new office buildings complying with 2002 Building Regulations could just maintain the energy consumption constantly with climate change. Another research in UK (Pan and Garmston, 2012) also found that there are almost one-third of 404 new buildings built in 2006 to 2009 dissatisfied with building regulations. Other research meant to confine the building energy usage by enhancing the building regulations (Kang and Rhee, 2014a, Hamza and Greenwood, 2009) indicated that there are always non-compliance buildings no matter how stringency of building energy efficiency regulations has increased. Generally, the incomprehensible criteria would result in the incompetent regulations. Thus, this study not only means to promote the criteria of building regulations but also means to identify the factors' contribution to building energy consumption over future climate change. The aim of this study is to construct easily understandable regulation criteria for local government or industries in Taiwan.

## Methodology

To investigate the climate change impact on energy consumption of office buildings in Taiwan, this study adopts EnergyPlus simulator with hourly weather data and virtual building cases to simulate the building performance under the future meteorological conditions. Because of the various factors of building envelope configurations, the Taguchi method is adopted to construct virtual building cases and to implement the mathematical analysis. In addition, the factors setting for virtual building cases refer to building energy regulations in Taiwan.

### ***Building energy regulation in Taiwan***

This study introduced the latest version of Taiwan energy conservation regulations for building envelope design which released in 2015 (Taiwan National Architecture Association, 2015) which demands that the U-value of exterior wall ( $U_w$ ) should be lower than  $2.0 \text{ W/m}^2$  and that the U-value of fenestration ( $U_f$ ) and the average shading factor (SF) of window should both vary with the window-to-wall ratios (WWR). These values should be calculated on each aspect of building façades and should comply with the criteria tabulated in Table 1. The calculation of the SF value in regulation is:

$$SF = \frac{\sum f \times SHGC \times A_{win}}{\sum A_{win}} \quad (1)$$

Where SHGC indicates the solar heat gain coefficient of fenestration;  $f$  means the factor of shading overhang;  $A_{win}$  is the window area on each façade.

Table 1 Building regulation criteria in Taiwan

Window-Wall Ratio	>0.5	0.5-0.4	0.4-0.3	0.3-0.2	0.2-0.1	<0.1
<b>Uf</b>	2.70	3.00	3.50	4.70	5.20	6.50
<b>SF</b>	0.10	0.15	0.25	0.35	0.45	0.55
<b>Uw</b>				2.0		

### **Virtual Building Cases and Taguchi method**

According to the regulation mention above, this study considers ten building factors including:

- (a) window-to-wall ratio (WWR),
- (b) U-value of fenestration ( $U_f$ ),
- (c) solar heat gain coefficient of window (SHGC),
- (d) shading overhang,
- (e) U-value of external wall ( $U_w$ ),
- (f) material of external wall, (g) orientation of building,
- (h) shape factor of building plane,
- (i) occupancy, and
- (j) indoor heat dissipation of equipment.

In addition, shading overhang is defined as the depth of shading device over the height of window.

There are ten factors and three levels of each factor in order to understand the building energy consumption that may vary with different insulation level. Since it is too complicated and time-consuming to discuss each combination with all factors, Taguchi method (Kang and Rhee, 2014b) is adopted to solve such a multivariable simulation. Taguchi method is an experimental design technique providing a simple way to reduce the numbers of experiments by setting multilevel factors into a given orthogonal array. The orthogonal array Table L<sub>81</sub> is chosen to fit all factor levels. All levels are put into the array to construct 81 different office building configurations. The factor level settings are listed in Table 2 while the test cases and control cases are established simultaneously. The factor (a) to (f) of control cases are based on ASHRAE 90.1 standard while factor (h) to (j) are set as same as those in corresponding test buildings.

Table 2 Factor levels of virtual building cases

Factor	Parameters	Test case			Control case Level
		Level 1	Level 2	Level 3	
a	WWR	0.1	0.4	0.7	0.4
b	$U_f$ (W/m <sup>2</sup> K)	5	3	1	3.2
c	SHGC	0.8	0.5	0.2	0.2
d	Shading overhang	0	1	2	0
e	$U_w$ (W/m <sup>2</sup> K)	3.5	2	0.5	0.857
f	Material	Metal	Light RC	Heavy RC	Light RC
g	Orientation (degree)	-60	0	60	Average in four direction
h	Shape	1	2	3	
i	Occupancy (person/m <sup>2</sup> )	0.05	0.1	0.15	Same as the corresponding test cases
j	Equipment (W/m <sup>2</sup> )	10	25	40	

### **Future Weather data**

The weather data put into EnergyPlus simulator is required as hourly data, so downscaling the prediction of global circulation model (GCM) is necessary. The hourly future weather data is constructed by morphing method (Belcher et al., 2005, Huang and Chuang, 2014) with the local weather data and GCM data considering two future climate scenarios which are RCP45 and RCP85 defined by IPCC AR5(Stocker et al., 2013). The local weather data is provided by Central Weather Bureau (CWB) in Taiwan. The local site is Taipei and the base period is 1995-2010. The future weather data is obtained from CanESM2.

The morphing method adopts shifting, stretching, and combination of both parts which are shown as Eq. (2) to (4). By this method, we can use the changes predicted by CanESM2 to construct future hourly data that is suitable for Taipei.

$$x = x_0 + \Delta x_m \quad (2)$$

$$x = \alpha_m x_0 \quad (3)$$

$$x = x_0 + \Delta x_m + \alpha_m (x_0 - x_{0,m}) \quad (4)$$

Where  $x$  is the future value of a certain weather variable;  $x_0$  is the local weather variable;  $\Delta x_m$  and  $\alpha_m$  are the monthly linear change and the monthly proportional change between local data and GCM data.

### **Results and discussion**

The building cooling energy consumption is simulated in base period and two future scenarios. The future scenarios are divided into three time slices: 2020s (2011-2040), 2050s (2041-2070), and 2080s (2071-2100). To understand which building factor influences the cooling energy most, ANOVA is introduced to evaluate the significance of all factors.

#### **Factors contribution**

The specific energy ratio is calculated to simplify the energy consumption evaluation. The specific energy ratio ( $r$ ) is defined as the cooling energy consumption of test cases in the future over that of control cases in base period. The calculation is shown as Eq. (5):

$$r = \frac{\text{Cooling energy use under future weather condition}}{\text{Cooling energy use in base period}} \quad (5)$$

The higher  $r$  value indicates the more cooling energy demand under the future condition comparing to the current level. Also, the specific energy ratios are used to implement ANOVA that help us to understand the factors' contribution to cooling energy varying with changing factor levels. Once we define the contribution of each level, we would be able to evaluate and predict cooling energy consumption of more randomly designed office buildings.

ANOVA is carried out by the average specific ratios ( $\bar{r}$ ) in RCP45 and RCP85 separately. The results reveals that there are four influential factors in cooling energy, and the F-test indicates these four factors, which are WWR,  $U_f$ , SHGC, and shading overhang, containing more than 70% contribution of variance in both RCP45 and RCP85. Though, these factors are marked as principal factors which influence the cooling energy usage most. Then, the factor

contribution could be provided as  $\Delta r$ , calculated as Eq. (6), that indicates the effect of certain factor level on the cooling energy use.

$$\Delta r = r_k - \bar{r} \quad (6)$$

Where  $r_k$  means the specific energy ratio of certain factor level. The  $\Delta r$  of principal factors in different time slices of RCP45 and RCP85 are tabulated in the Table 3 and Table 4.

Table 3 Factor contribution results in RCP45

Factors	properties	Factor effect

	0.5	-0.0076	-0.0076	-0.0078
	0.2	-0.1283	-0.1291	-0.1332
Shading overhang	0	0.0813	0.0798	0.0795
	1	-0.0152	-0.0153	-0.0158
	2	-0.0660	-0.0645	-0.0637

### New criteria for Taiwan building conservation regulation

This study further summed up the  $\Delta r$  of the principal factors as the energy consumption ratio ( $R_E$ ) in different time slices compared to the base period:

$$R_E = \bar{r} + \Delta r_{WWR} + \Delta r_{U_f} + \Delta r_{SHGC} + \Delta r_{Shading} + error \quad (7)$$

Typically,  $R_E=1$  indicates the cooling energy consumption of certain combination in the future is equal to nowadays level;  $R_E>1$  indicates the higher cooling energy consumption, and  $R_E<1$  indicates the lower one. That is, we should focus on the envelope combinations which  $R_E=1$  if we mean to construct a criteria recommendation that can confine the cooling energy usage.

The  $R_E$  values of RCP45 and RCP85 are plotted in Fig. 1 and Fig. 2 and are divided into three time slices. The  $R_E$  values increase with the higher WWR and SHGC level and decrease with the higher shading level. In both two scenarios, the  $R_E$  values will be higher than one in WWR=0.7 and will drastically increase in SHGC=0.8. The steady increase of the  $R_E$  values over time will make it difficultly to maintain the cooling energy use after 2050s, especially in RCP85. Additionally, the optimal  $U_f$  is not the lowest one because the over insulated building envelope will store too much indoor dissipation heat.

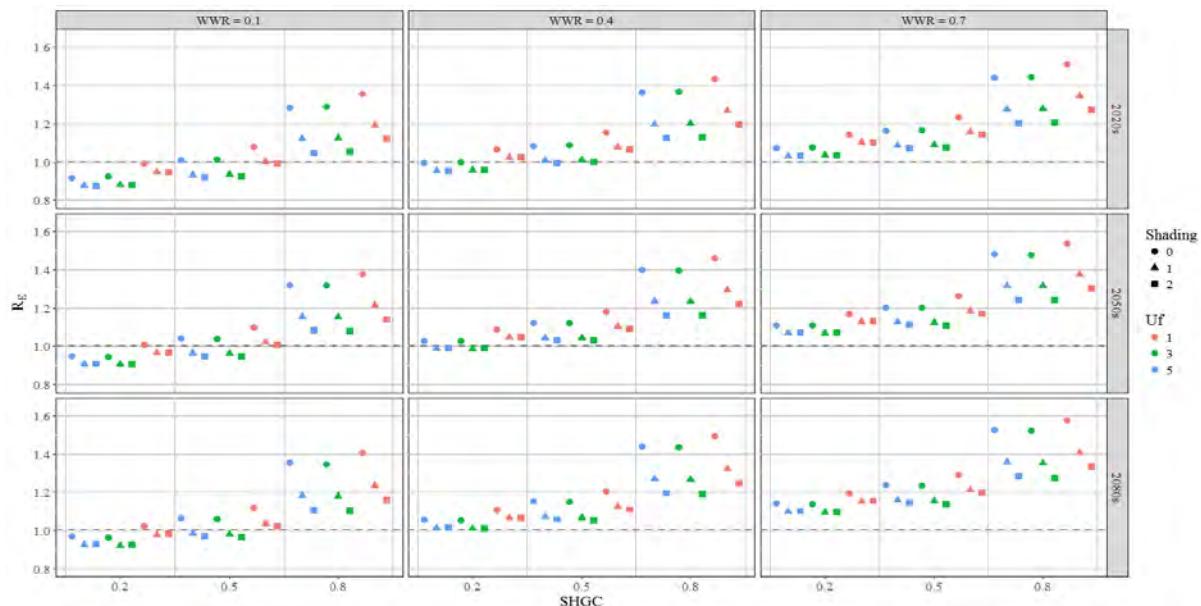

Fig. 1 The  $R_E$  values of top four factors combinations in RCP45

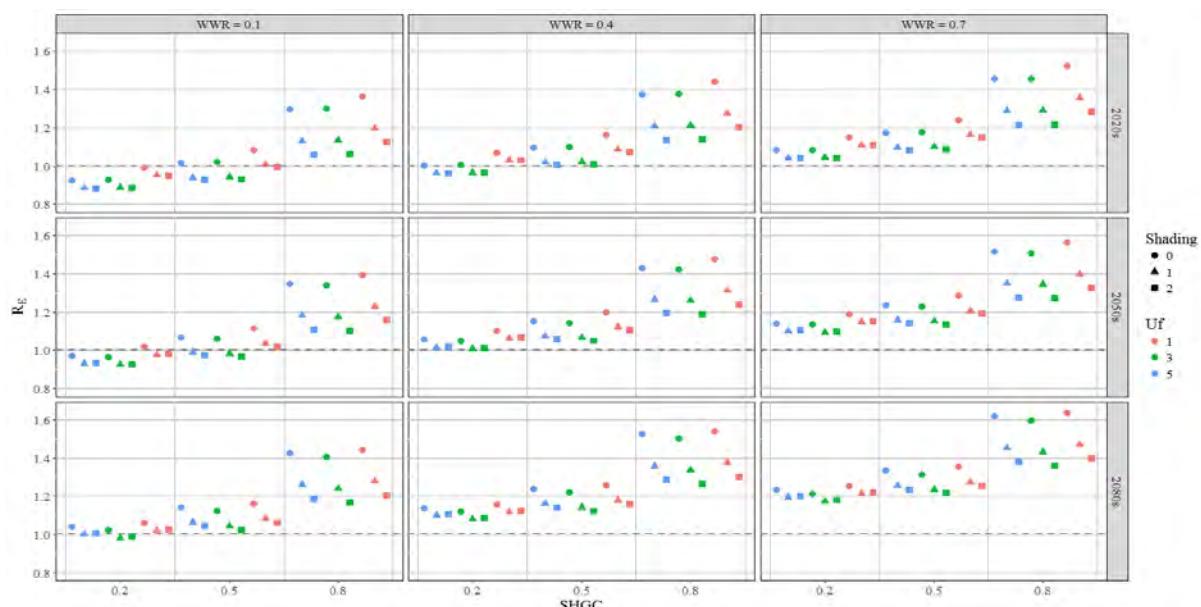

Fig. 2 The  $R_E$  values of top four factors combinations in RCP85

## Conclusion

The office building energy usage in Taiwan is obviously influenced by future climate change. The simulation results match the current building regulation in Taiwan whose major factors are window to wall ratio, shading devices, and the U values of building envelope. The results reveal that cooling energy demand is mainly dominated by the principal factors which are WWR, SHGC,  $U_f$ , and shading overhang. According to the factor contributions, we are able to predict the building energy performance during three future time slices in both RCP45 and RCP85. The increasing cooling energy consumption range varies with different envelope combinations. The worst case in RCP45 and RCP85 would increase 40-60% cooling energy usage in 2080s. On the other hand, the  $R_E$  value would rise when SHGC=0.8 or lack of shading. Moreover, there is no case could maintain the  $R_E$  value in current level when WWR is 0.7 either in RCP45 or in RCP85. That indicates the progress of the building regulation is necessary.

In the meanwhile, this study propose Fig. 1 and Fig. 2 as the criteria recommendation. Through these schemes, it is easily to understand the change of cooling energy use in different building configurations. To maintain the cooling energy usage of office building in Taiwan, we could focus on the cases of which the  $R_E$  values are under or equal to 1 and should make the regulation criteria much stricter over years. The criteria scheme based on the  $R_E$  results is more flexible for Taiwan government and could also provide the measurement over future climate change.

## Towards Advanced Active Façades: Analysis of façade requirements and development of an innovative construction system

Angela Clua Longas<sup>1</sup>, Sophie Lufkin<sup>1</sup> and Emmanuel Rey<sup>1</sup>

<sup>1</sup> Laboratory of Architecture and Sustainable Technologies (LAST), Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland. angela.clualongas@epfl.ch

**Abstract:** In Switzerland, as in many European countries, new energy directives focus on decreasing the carbon footprint of buildings by promoting passive and active energy strategies. Among the latter, Building Integrated Photovoltaics (BIPV), which function both as envelope materials and electricity producers, are rapidly becoming more performant. However, their potential remains largely unrealised due to diverse barriers. Architects, in particular, tend to avoid integrating BIPV in their designs because of their limited expressive qualities. In reaction, this on-going research aims at developing design strategies for low-carbon façades while addressing BIPV expressive issues, with the goal of bridging the gap between technology and designers. Within this overall framework, the paper presents the Advanced Active Façade (AAF) concept, which results from analysing the evolution of façade requirements and solutions over time. The AAF simultaneously aims at achieving low embodied energy by benefiting from passive low-carbon design strategies, and generating energy by integrating BIPV technology. The paper introduces the core phase of the research, which consists in the development of the AAF Construction System and AAF Design Strategies. The output of the research will provide architects with a construction system and assessed design strategies to optimize the design process of BIPV façades.

**Keywords:** Building Integrated Photovoltaics (BIPV), Active Façades, Renewable Energy, Construction System, Design Strategies

### Introduction

The European Union is committed to drastically reduce greenhouse gas emissions by 2050: levels should be 80-95% lower when compared to 1990 (Energy Roadmap 2050, 2012). This is why European energy directives are becoming more demanding with regards to performance standards. Switzerland follows the same evolution. Since it decided to gradually withdraw from nuclear power in 2011 (SFOE, 2014), the country undergoes a profound restructuring of its energy system. Its new energy policy establishes that energy consumption from photovoltaic (PV) will represent 20% of the total electricity consumption of the country. Thanks to this energy focus, such technology is becoming more efficient and affordable.

The most innovative offer of PV technology consists in the constructive and architectural integration of PV elements. Building Integrated Photovoltaics (BIPV) have both an architectural function and energy generation capacity.

BIPV permits to reduce material use and initial investment costs when compared to a traditional construction where PV systems are independent and added to the building (Centre Suisse de compétence BIPV, 2015). However, despite this favourable context, BIPV technology is not exploited to the best of its potential. Architects often justify the lack of PV

use in their designs with the limited aesthetics of existing BIPV solutions. As a result, a real gap between technology and architecture exists.

### **Research objectives and methodology**

The on-going doctoral research presented in this paper aims at filling this gap by developing new strategic approaches for the design of active façades. Its ambition is to propose a new prospective basis for façade composition and construction strategies, by fostering the collaboration of product developers, architects and scientists in order to tackle simultaneously architectural, constructive and technological issues.

The work developed in this research focuses on collective residential buildings in the Swiss context. Its long-term objective is to provide pathways for a wide-scale use of BIPV façade solutions in residential buildings and to develop design strategies to improve BIPV's expressive issues. The research methodology (Fig. 1) involves 5 main steps.

Phase 1 consists in an initial analysis of the state of the art of three different fields: 1A) existing façade design strategies in the Swiss context, 1B) constructive evolution of façade's requirements and 1C) BIPV technologies according to their architectural features and requisites.

Phase 2 consists in meeting all trends, requirements and features identified in Phase 1 by designing the Advanced Active Façade (AAF). AAF combines AAF Construction Systems (AAF CS), developed in 2A, and AAF Design Strategies (AAF DS), developed in 2B. The AAF CS meets the most demanding insulating targets and is compatible with a wide range of existing BIPV formats and emerging BIPV technologies. AAF DS are created based on the existing façade strategies (1A), future façade requirements (1B) and BIPV technologies (1C). This guarantees easiness and coherence in the application of the AAF concept to collective residential buildings.

Phase 3 is dedicated to the multi-criteria assessment of the AAF CS and AAF DS in terms of environmental impact, cost, architectural quality and social acceptance. In parallel, to support the technology transfer towards practitioners in the built environment.

Phase 4 is for the construction of a prototype of the AAF CS, which will demonstrate its feasibility.

Phase 5 consists in organising an international student competition around the use of BIPV to validate the approach's applicability for architects in the practice.

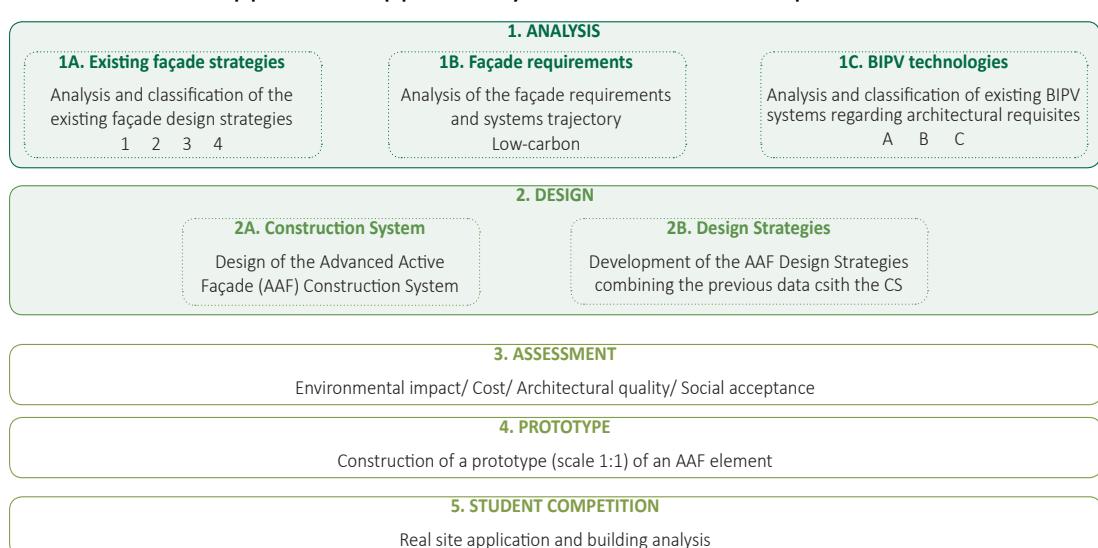

Figure 1. Research Methodology

This paper develops the preliminary results of Phases 1 and 2, i.e. the analysis and the design work packages.

## Preliminary Results

### Phase 1: Analysis

#### *Phase 1A: Analysis and classification of the existing façade design strategies*

While designing a façade, we need to consider the different elements composing it: windows, balconies, doors and solar shading systems (Herzog et al., 2004). The size and modulation of these elements can respect, or not, the pre-existing rhythm established by the building structure: horizontal slabs, beams, pillars and walls. This means that the “face” of the building can allow a direct comprehension of the structure. The façade becomes a skin with an independent expression from the building structure.

We propose a classification based on the dimensional composition of façade materials, elements and building’s general structure in the contemporary Swiss context. The preliminary results provided by this research present a façade composition in four groups (Clua Longas et al., 2016), represented in Figure 2:

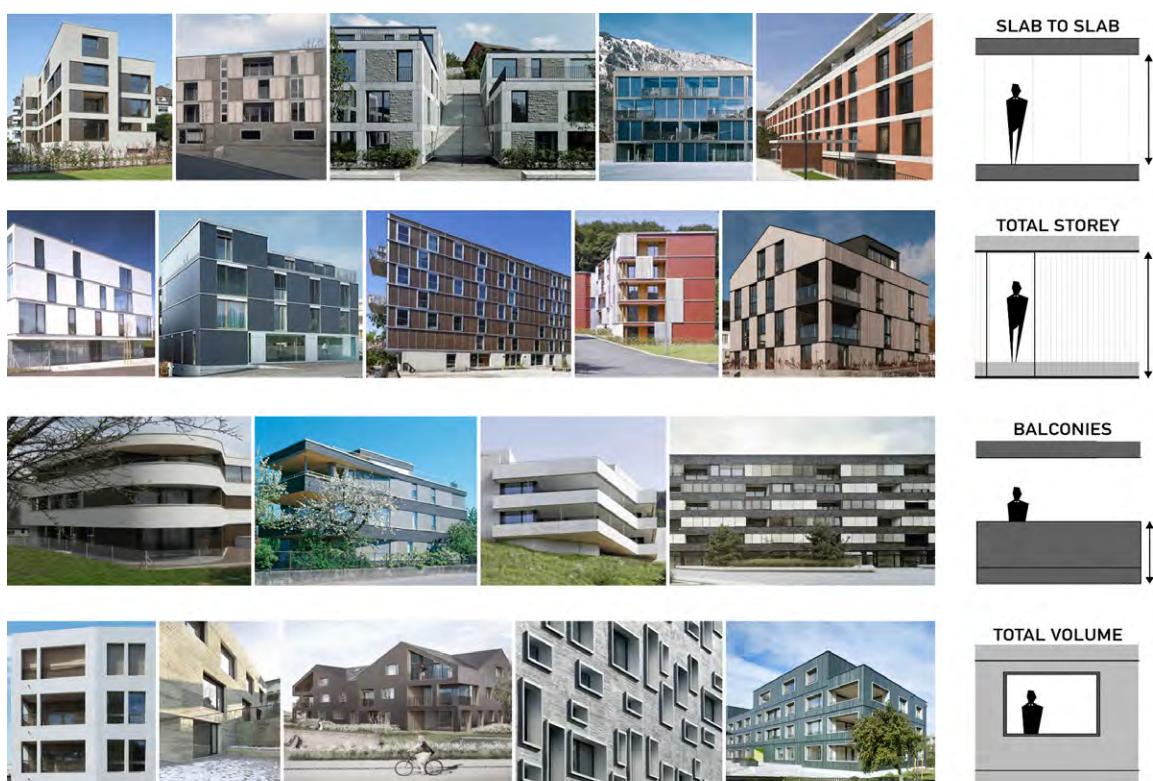

Figure 2. Collective residential buildings’ façade design strategies: classification in four groups

- Strategy 1 ‘Slab to slab’ includes façades where the horizontal slab dimension is apparent and highlighted on the façade.
- Strategy 2 ‘Total storey’ includes façades where the storey structure is also expressed, but the floor slabs are no longer highlighted.
- Strategy 3 ‘Balconies’ refers to facades where balconies are clearly apparent in a large part of the façade.

- Strategy 4 'Total volume' includes façades where the structure rhythm and the interior distribution are not apparent.

Some buildings might present a combination of these four strategies in the same façade or in different ones.

#### *Phase 1B: Analysis of the façade requirements and systems trajectory*

Once the façade composition has been analysed, the façade construction needs to be studied. We have explored the evolution of basic façade systems through history to define the present and near future façade requirements. The goal is to design a façade construction system that meets future needs.

The results of this analysis (Figure 3) indicate that a new objective for façade construction has emerged: achieving a low or zero carbon building. This involves three requirements: i) minimizing the building's energy consumption, ii) lowering its embodied energy and iii) generating energy as part of the envelope solution. Nowadays, there are façades that meet one or two of the mentioned requirements, but very few meet the three of them.

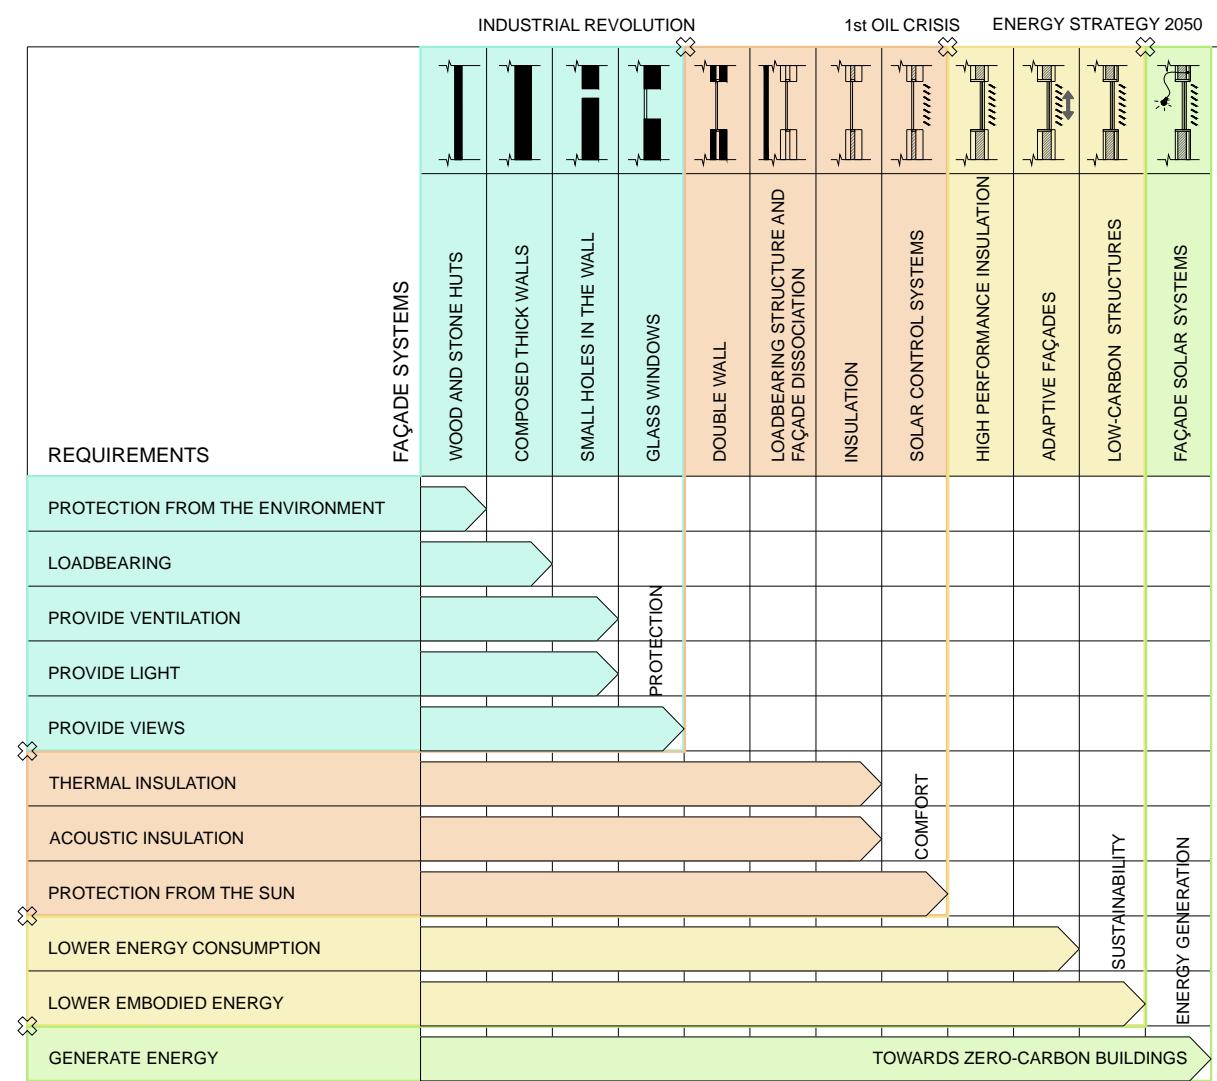

Figure 3. Residential façade requirements and systems trajectory

### *Phase 1C: Analysis and classification of the existing BIPV systems regarding architectural requisites*

There is a growing number of different PV technologies as research is rapidly pushing forward this field (Jelle et al., 2012). PV system's efficiency is greatly improving as science advances. Due to this continuous progress, we will not classify BIPV systems based on PV technology in the framework of this architecture-oriented research. Traditionally, BIPV façade systems have been classified per their technological characteristics. The originality of our approach is that BIPV façade systems are classified per their architectural features given that they play an important role as an integral part of the façade (Roberts and Guariento, 2009).

Therefore, existing systems have been classified, based on their transparency degree, in three groups (Authors, 2016), illustrated in Figure 4: Opaque, Translucent and Transparent. Different technologies such as monocrystalline, polycrystalline or thin-film can fit in one or more of these categories. This classification also welcomes the newest high efficiency modules such as Heterojunction technologies or organic cells, among others.

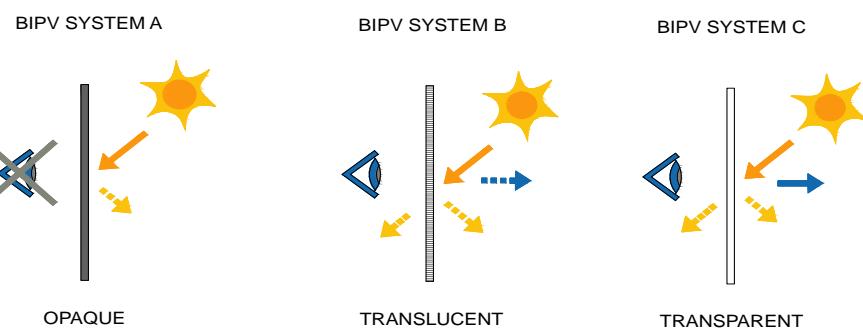

Figure 4. Classification of existing BIPV façade systems, regarding its architectural features

### **Phase 2: Design**

The previous analyses have driven the research to develop the Advanced Active Façade (AAF) concept. Firstly, the AAF design responds to the design trends of today's façade composition. Secondly, it meets the latest façade requirements: it is based on a low-embodied carbon construction, and adapted to the most exigent insulating targets (Minergie P). Thirdly, it is an active element which generates energy thanks to the integration of BIPV systems in its façade composition. The AAF is designed as a non-structural, self-supporting façade, which guarantees more flexibility in its design compared to other loadbearing options. Based on this concept, this research has developed the AAF Construction System (AAF CS) and the AAF Design Strategies (AAF DS).

#### *Phase 2A: Design of the Advanced Active Façade Construction System (AAF CS)*

The AAF CS is a modular construction system that responds to future façade requirements. Its main feature is the combination of passive and active design strategies to lower the building's carbon footprint. The proposed solution consists of a wood-panel based, self-supporting and demountable façade system which meets the most demanding insulating targets and is compatible with a wide range of existing BIPV formats and emerging technologies (Figure 5).

The passive strategy consists of the low-embodied carbon design of the construction system. As seen in the analysis of the façade requirements, energy is one of the most

significant topics in the current debate on façade construction. The embodied carbon of a building accounts for approximately 30% of the total lifetime carbon footprint from the residential building sector (Lane, 2010). More specifically, façades account for 16% of this amount (Cheung and Farnetani, 2015). For this reason, the AAF CS is based on low-carbon construction. This implies the use of local materials (Lupíšek et al., 2015) with low embodied carbon. In the Swiss context, the AAF is designed with a wooden frame (reTHINK WOOD, 2015) filled with cellulose insulation (Gray, 2016). The AAF CS's metallic elements are minimized and, when needed, they are made of recycled aluminium. The use of plywood panels permits the absence of a synthetic vapour barrier as well as a light prefabricated construction. Nothing is adhered, so that components can be easily replaced or disassembled (Kuittinen et al., 2013) for posterior recycling or reuse.

The active strategy consists in integrating a BIPV system in the façade's exterior coating to make it active. This integration implies a previous orientation study of the building to maximize the BIPV performance. An energy-demand simulation is also required to design an active façade which supplies the right percentage of the building's energy needs. The photovoltaic façade's final coating also implies that it has a ventilated construction system, with a 10 cm minimum gap (Brinkworth and Sandberg, 2005, Maturi et al., 2014). Wiring and electrical devices are integrated in the AAF CS façade design to ensure panels' electricity production.

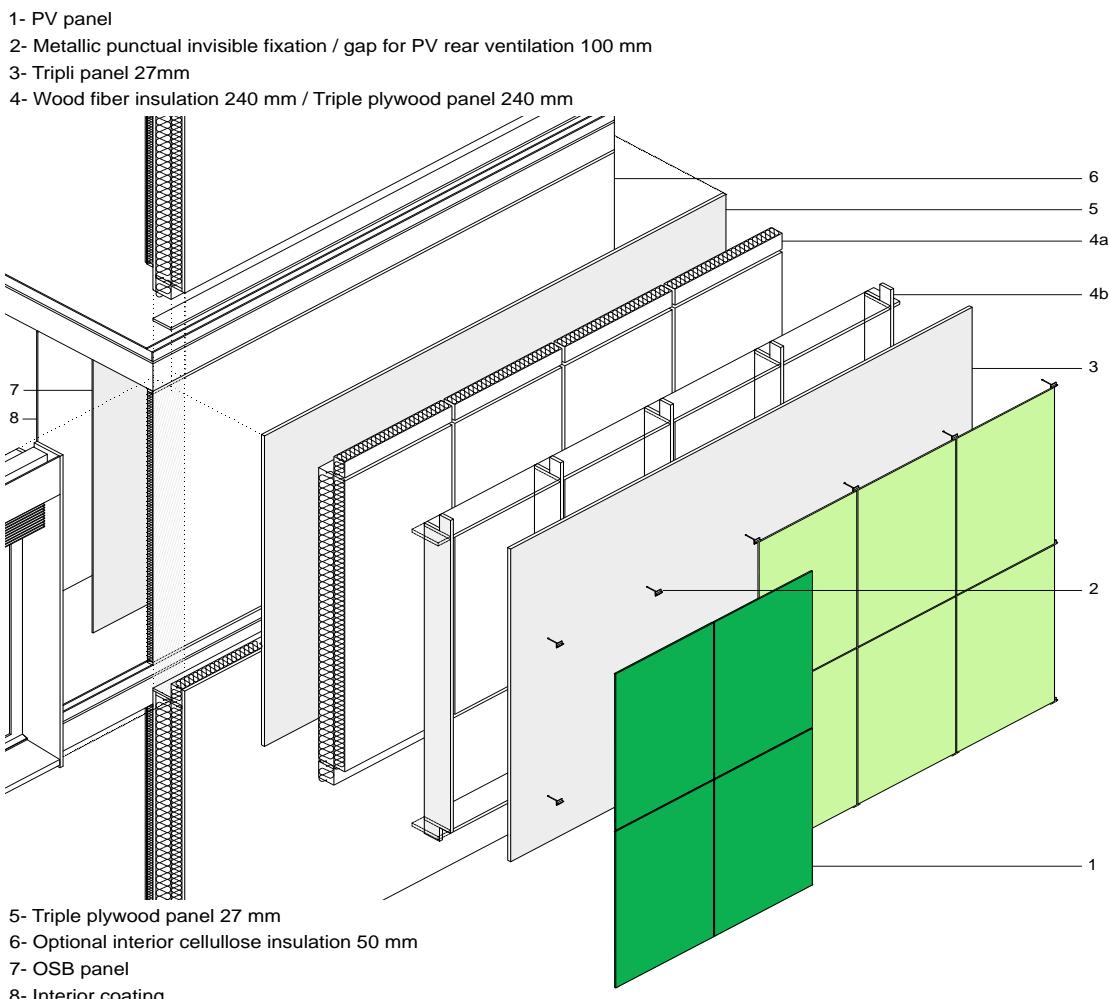

Figure 5. AAF Construction System. Axonometric view of the system composition

The AAF CS, as part of a residential building façade in the Swiss context, also needs to meet other requirements such as comfort and energy regulations, electric directives (LVD 2006/95/EC), security regulations and certification. All these aspects are considered in the AAF CS design.

#### *Phase 2B: Development of the Advanced Active Façade Design Strategies (AAF DS)*

The AAF DS are series of design strategies based on the existing ones (classified in phase 1A) and combined with the three categories of BIPV products (identified in phase 1C). They illustrate different applications of the AAF CS on a real site to validate its capacity to adapt itself to various contexts, architectural requirements and PV technologies. The design process allows the formulation of a series of guidelines for architects to successfully design an Advanced Active Façade. According to recent works (Kylili and Fokaides, 2014), the building orientation which delivers the maximum energy yield for central and southern Europe are the southeast and the southwest façades. This fact will help decide the orientation of a building and the number of AAF to consider to maximize the energy output.

Figure 6 gathers four images which represent the combination of the existing design strategies identified in phase 1A (“Slab to Slab” (1), “Total storey” (2), “Balconies” (3) and “Total Volume” (4)), combined with the three BIPV systems identified in phase 1C (“Opaque”, “Translucent” and “Transparent”). These façade design strategies meet the requirements analysed in phase 1B and can be constructed with the AAF Construction System.

Figure 6. AAF Design Strategies. Combination of different design strategies with different BIPV systems.

## Conclusions

This research aims at filling the gap between technology and architecture in the current practice, demonstrating how BIPV can be considered at the same level as any other construction material. The preliminary conclusions of this on-going research highlight that it is possible to integrate different types of BIPV systems into a prefabricated Advanced Active

Façade Construction System. The latter meets current façade construction requirements and is suitable for residential buildings. The developed work also demonstrates that BIPV can be part of the dimensional composition of a collective residential housing façade. Provided with the Advanced Active Façade Design Strategies, architects are enabled to deal with the expressive and aesthetical aspects of their BIPV designs, producing façades fitting the current composition trends in the Swiss context.

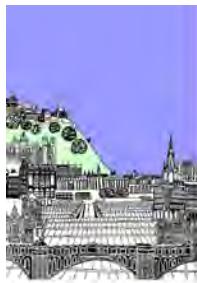

After design issues have been dealt with, the next steps of this on-going research include the detailed multi-criteria assessment of the AAF CS, the construction of a real scale prototype to demonstrate its feasibility and the organization of an international student competition to validate the user-friendliness and convenience of the approach for architects in the practice.

## Acknowledgements

*Design to Thrive*

## Architecture and Landscape, Frank Lloyd Wright's circular house designs

Michael Desmond<sup>1</sup>

**Abstract:** The Jacobs "hemicycle" (1943) is often noted as an early example of the new architectures of the 20<sup>th</sup> century grappling with passive solar design and energy efficiency. It is much more than that. It is a unique moment of creative synthesis wherein the symbolic dimension is brought to the fore as an integral part of unifying perceptions of landscape and architectonics, an example of Wright's concepts of "continuity" and "reintegration." His use of circles and arcs in residential design began with the 1938 unbuilt Jester House project. The also unbuilt designs for John Nesbitt (1941) and Lloyd Burlingham (1942) provide insight into the growing complexity of his use of these forms in relation to specific sites. This effort appears then in the design of the Jacobs hemicycle just as the first designs for the Guggenheim Museum in New York were beginning. Wright extended the layered exploration of perception of self and landscape, form and purpose that the Jacobs design offers into many dozens of others, mostly unbuilt, over the remainder of his career. The most spectacular is the house he proposed in Palm Springs (1950) for Lillian and Edgar Kaufman of Fallingwater.

**Keywords:** Wright, Jacobs, hemicycle, continuity, circle

### Introduction

Frank Lloyd Wright's 1943 design of the "solar hemicycle" for Herbert Jacobs and family is commonly thought of as a landmark moment, as a meeting of the conceptual freedom of the 20th century revolution in architectural form and an early interest in energy conservation. It is much more than this. Conceived as Wright's second career was beginning to flourish, and as he was embarking on the design of the Guggenheim Museum, it represents a milestone in the development of a new concept of architecture in relation to environment. This little building is one of a series of designs created in the aftermath of Fallingwater that can be seen as explorations of his concept of an architecture of continuity, an architecture of reintegration of culture and landscape. The dimensions of this exploration involve impressions of motion, multiplicity, architectonics, and symbolism, all woven together into what he once called an "unbroken wave."

The pivotal design in this sequence is the house designed for the owner of the Johnson Wax Company known as "Wingspread," just as the more famous Administration Building was being constructed. Wright's images of this house generalize an implied rotational motion seen in his rendering of Fallingwater, as the body of that building pivots in space above the waterfall. This occurs again in the aerial renderings for Wingspread, placing the implied movement in the context of the Wisconsin prairies and the horizon. Here the contrast of the rectilinear frame of reference used to control so much of Wright's architecture and a developing symbolism of circles is used to evoke both the processes of nature and our motion through them. This emerging dimension is powerfully expressed in the aerial photograph that replaced the Wingspread rendering in the January 1938 edition of the Architectural Forum that Wright designed. It is perhaps the first aerial photograph he published, saying, "This extended wing plan lies, very much at home, integral with the

prairie landscape which is, through it, made more significant and beautiful.”<sup>2</sup>

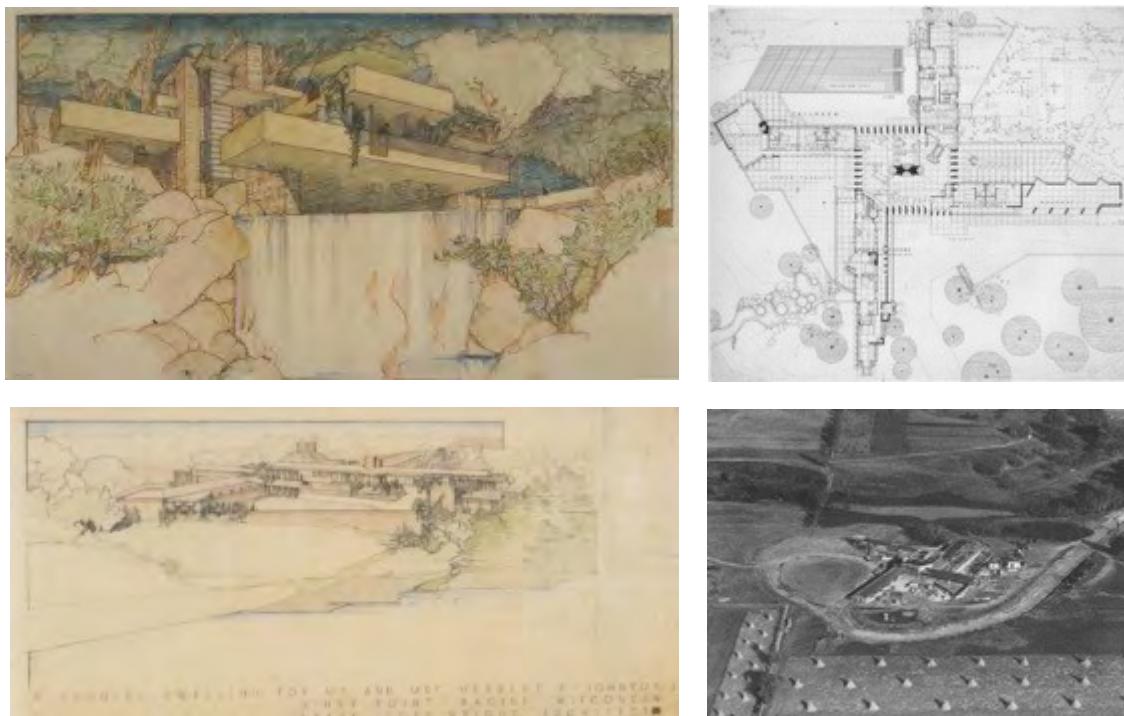

Figure 1. Images of Fallingwater and Wingspread.

#### **Ralph Jester House project, Palos Verdes, CA, 1938**

Wright’s articulation of this dimension began in earnest with the design of a small house on the southern California coast for the Hollywood costume designer Ralph Jester conceived for a site in the Palos Verdes development above Portuguese Bend on the south side of the Greater Los Angeles basin, from 1938 just as Wingspread was being constructed. Especially in the early years before there was much surrounding development, the site provided a unique vantage point that had much to do with the genesis of this groundbreaking design. The location is a small promontory back from the water’s edge, at an elevation of just over 300 feet, repeating the two forms protruding into the bay below. This elevated spot is encircled on the other side by a broad ring of hills rising above 1000 feet that focus the entire valley outward toward the ocean. We can see this in topographical maps just as clearly as the aerial photographs just becoming available in the 1930s.

In the first conceptual elevation of the house a single blue pencil line appears to evoke the ocean horizon so clearly visible from this elevated site. In contrast, the presentation rendering shows the sweeping line of high hills enveloping the other side of the site. A private garden wall to the rear, repeats the arc of these hills, while a pergola on the opposite side reaches toward the sea, projecting outward over the surface of a large pool. One can see this little house engaging perceptions created by the forms of its greater landscape, an abstraction of the structure and qualities defining this place, what one might call its own revealed or governing structure. High to the rear, enclosed and protected by the rounded faces of the encircling hills as the space of the house reaches westward to the setting sun, whose horizontal rays would reach into its center at the end of every day.

The architectonics here can be approached by looking at the graphic vocabulary Wright and the apprentices developed for representing the Usonian house, seen nowhere as elegantly perhaps as in this plan for the first Herbert Jacobs House in Madison. Here, as in

the Wingspread drawings, there is a clear juxtaposition of orthogonal forms used to define and regulate the building, while circular ones portray forms and processes in the landscape. In the Jester design this fundamental distinction is sharpened. Then, in the presentation plan we also begin to see for the first time a careful suppression of the abstract grid that provides measure to the landscape in the way in which it peeks up through the almost random patterning of the stone flooring. The orthogonal becoming a kind of framing device only, receding as our attention is given to forms that interact with and interpret the land.

Wright's renderings and model show the large pool slipping forward through a kind of cleft or ravine also seen in the drawings of Wingspread, although neither of these sites had such a pronounced feature. In the underudies for a Jester aerial drawing the many curving elements of the house and various reflections on the surface of the pool, are transformed as cascading rings of water sliding down this ravine to the sea. The pool, its surface just below the stone floor of the house, would have been seen above the plane of the ocean in the near distance, calling it right up to the lip of the floor. It is a form known today as an "infinity" pool of course – but the point being not only that its surface appears to be continuous with that of the sea below, but more potently the water slipping over its edge hides that boundary as does that of the ocean itself at the horizon – bringing the sky into the heart of the house.

Figure 2. Images of Jester House project and site, with first Jacobs House plan graphics.

#### **Nesbitt House, project 1940-41**

Soon after the Jester project Wright designed a large house for John Nesbitt, intended for a spectacular small cove in Carmel, California, overlooking the majesty of the Pacific Ocean. "*The site is almost solemnly beautiful*" the client wrote, "*a gentle, mildly irregular slope of land that drops down to a . . . rugged, private shore.*" And, "*The cypress and pine much battered by the wind in place, . . . other sections sheltered and tranquil . . . A big surf smashing against granite rocks on the ocean exposure, flamboyant and rich as a Wagnerian last act.*"

The edges of the cove are rocky, ranging from an abrupt cliff at the house site to large patterns of broken rock extending hundreds of feet into the waves. While the site itself was filled with many ancient cypress trees battered by the wind, there was a relatively open and level area on the right side as you entered from the street characterized by a steady slope

dropping along a prominent knoll on the left side. Wright brought the drive into the site there, surrounding almost the entire upper area with an unusual covered walkway to create an enlarged loosely treed forecourt that included the gravel drive area. The body of the house was located directly on the knoll, fitting closely into existing features - identifying a dramatic vantage point, perched above the ocean, standing between the sea and the entry court.

Wright placed a small round pool at the heart of this court to mark the beginning of a ritualized path to the sea. From there a monumental set of piers leads to three sets of double glass doors in a curving wall giving into a multi-story skylit and glass enclosed Interior Garden. Once within this cacophonous space one would have seen the ocean in the distance through the open structure of a steel stair rising diagonally against your motion. The curving line of the enclosing glass wall continues to define an exterior terrace beyond which, cascading down the slope toward the sea, is a further progression of pools fed from the water encountered at the entry, falling from one into the next before being discharged to run over the cliff, back into the sea.

The controlling grid of squares used to organize the house is brought to a pivot where the cascade of pools gives way to views of this cliff, with rocks and ocean beyond. The primary orientation of the house appears to be coordinated with the location of a cluster of exposed rocks out in the cove, visible in the distance, pulling the eye to an intermediate point leading to the horizon. The 30 degree angle of the stair marking the shift of the outer edge of the house is barely noticed on the entry level. The effect of this pivot becomes clear as one moves upstairs to a colonnaded Great Hall and a Sea Lounge that swings out to frame the cove and a broader ocean view. This also frames the dissolving cliff line leading out from the house that defines the cove, bordered on this side by an extensive sequence of broken rock and disintegrating cliff edge, pounded by waves. One would see from here the action of the waves above and beyond the layers of the pools, breaking on the rocks below, dissolving the edge of the continent in full view as a kind of, "... Wagnerian last act."

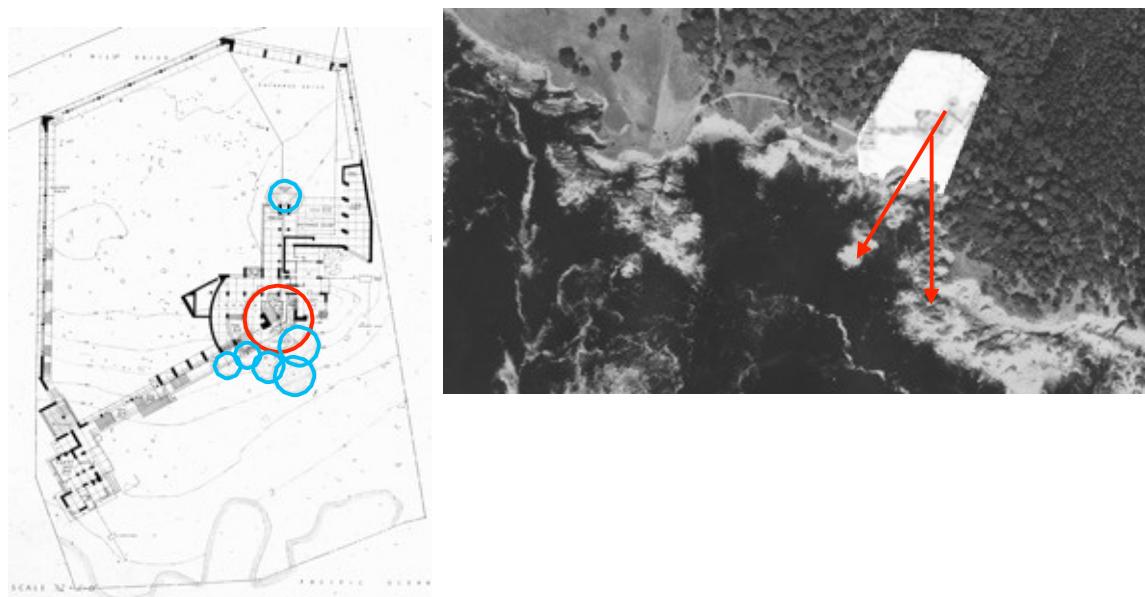

Figure 3. Images of Nesbitt House project plan and site logic.

Engagement with the forces of nature is foregrounded here. As Wright moved from using traditional, hierarchically structured, orthogonal frames of reference as a compositional datum, this design shows him extending the example of Fallingwater, responding to and shaping perceptions of the surrounding environment as a vehicle to order

and conception. This particular project introduces a narrative dimension to the process, using both symbolic readings and motion to ritualize the transition from one state to the next, from the calm of the court and its ancient cypress to the dynamism of the coast. Nesbitt wanted to call it “SeaGarden House,” in recognition of the dualistic nature of his reading of the site. Following the attack on Pearl Harbor and the declaration of war the project did not go ahead.

#### ***Lloyd Burlingham House project, El Paso TX, 1942***

In the next year Wright designed a “ranch cottage” for Lloyd Burlingham overlooking the Rio Grande valley outside of El Paso. This unbuilt project extends the accomplishments of the Nesbitt design by bringing two perceptual events into the formal concept itself rather than lining them up sequentially, a single form that never-the-less is integrally responsive as it engages the surrounding landscape. We see this beautifully here as an arm reaches forward to gather an automobile forecourt close to a small protected yard before leading the eye outward to the sinuous, curving lines of the Rio Grande and trails of smoke floating off into the distance down the valley on the left. In the rendered Jester plan we just saw the underlying control grid was only detected in the nearly random patterns of the stone flooring, clearly present in some areas and wavering in others as the rooms, columns, and furnishings float about with a disengaged unity. In the Nesbit design the grid was interrupted, shifted, washed away by its proximity to the sea. In this Burlingham project Wright utilized the surveyor’s grid in a different way as it anchors the conception of the design to the topography before disappearing entirely. This house was to be composed of arcing lines of enclosure, containment, and circulation organized with respect to two centers selected from grid survey points. One of these, nestled against a rocky outcropping on the high side of the site defines a series of concentric arcs that form the driveway, the enclosed private garden, and the living / bedroom wing of the house. The other located outward toward the vista by means of the 30/60 degree draftsman’s triangle on his drawing board establishes a complementary series of arcs that define the kitchen and service wing about a luna shaped court and pool. Finally a projecting Terrace repeats the figure of the service yard in a kind of moving yin-yang symmetry. The push-pull of the two centers establishes an operational drama for the design which seems suspended between the protective rocky mountainside and the distant river valley, enlivening the prospect and refuge dynamic often referred to in Wright’s domestic designs, allowing the two perceptions to interpenetrate each other.

Figure 4. Images of Burlingham House project and plan.

### ***Herbert Jacobs "hemicycle House, Madison, WS 1943***

The relation of form, symbol, and perception used in that El Paso project appears again in the second home Wright designed for Herbert Jacobs and family in the next year, just as his work on the Guggenheim Museum was beginning. The curving shape of this Jacobs design is governed by a single center divided into two halves. The house's interior and exterior spaces are gathered by the sweeping continuous arc of a single enclosing wall. The obvious redundancy of the circle is reserved for the hearth, a bathroom and utility core, and an inside-outside pool that repeats the dualism of the whole. This pool was initially placed on the central axis of the scheme as seen in this early study before being shifted off center— to create again a kind of disengaged or understated unity. The carefully lowered body of the house looks southward through a sunken garden with a bank of low planting completing the form as it evokes the prairie horizon fully apparent when the house was originally built, capturing the daily path of the sun.

The use of the circle in this design presents a merging of symbolic reference, cognitive process, and cumulative experience as the two sided, narrative dimension of the Burlingham design is folded into a unity, a duality of one where reading the symbol is inextricably woven into the architectonics, it's a stunning accomplishment. Every detail in this apparently simple design serves this purpose. Note especially the horizontal line of the suspended bedroom loft moving continuously just inside the steadily curving wall of the glass French doors, itself comprised only of tall vertical frames uniting the inside and outside with the sky. The intermediate horizontal seen in photos was added by Jacobs during construction and was not part of Wright's original design.

Figure 5. Images of Jacobs "hemicycle" House and plan.

### ***Kenneth Hargrove House project, Orinda CA 1950 / J. J. Vallarino House project, Panama City, Panama, 1953-7***

The tightness of unity in this hemicycle strategy was loosened as Wright encountered various landscapes over the coming years. Designs such as the several each for Kenneth Hargrove and J. J. Vallarino utilized multiple centers for sites in Orinda, CA and Panama. They share with the Jester and Burlingham plans a relationship to sites with distant views backed by rising ground utilized to create a sense of sanctuary. In these designs the steady datum of a constantly curving rear wall is countered by a polyphony of arcs about many centers describing activities of all kinds including living rooms, dining areas, terraces, playrooms, and finally pools held out toward the vista. Moreover, this occurs at different levels as the living rooms rise toward the view, the dining areas slide off toward the kitchen and playrooms, while an upper bedroom wing hovers privately in the middle of it all. Shifting, sliding, moving definitions of enclosure gathered together into one continuous reach outward toward the natural world. In these, and many other unbuilt circular themed designs, Wright

expanded the Usonian geometric framework with the perception of enclosure projected outward to engage features of the landscape as a new architectonic of “continuity”.

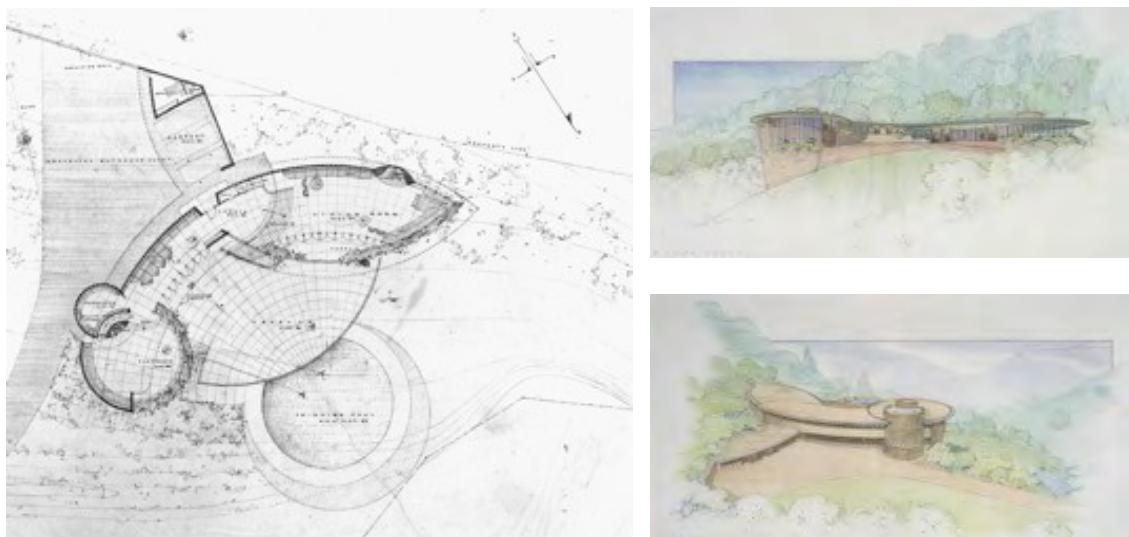

Figure 6. Images of Hargrove House project and plan.

### **Lillian Kaufman "Boulder House" project, Palm Springs, CA, 1950**

In 1950 Wright offered Lillian Kaufman one of the most remarkable designs of his career, as a complement perhaps to Fallingwater, built for her husband almost two decades earlier. This house, meant for a desert site in Palm Springs an hour and a half from Los Angeles, was to be composed of a central element surrounded by a pool and entered by bridges, flanked by outstretched dining and guest pavilions. The simple organizing idea of this "Boulder House" seems almost obvious at first glance, given in the contrast between the three parts making up the body of the house and the expanding circles of court, yard, and boulder strewn landscape. The one seeming contingent, the other totalizing. But the interaction of forms seen in the drawings is of course only part of the story as these are animated by intended relationships to the surrounding landscape. We can see an indication of this in the grouping of trees shown in renderings and plan rising toward the nearest of several ridges that extend into the canyon along its western edge, establishing an affinity with these as they march off into the deep perspective of Palm Canyon and the Santa Rosa Mountains.

One's experience here would have begun with a central forecourt for the automobile, abruptly half lawn and half gravel, framed by the carport wing that encircles the rising stone mass of the hearth which anchors the composition. The entryway pulls toward that distance along the curving side of the dining pavilion, up across a bridge over the pool before being swept into the living room which itself follows a counter motion defining the central luna of the house. It is a process made of fluid changes of direction and orientation, through compressive spaces then expansive vistas as the house curves around you, constantly changing the frame of reference to it and to the ever present visible world outside.

The aerial perspective shows the house's luna shaped masses strewn across the desert floor in dialogue with the mountainous forms pulling one's eye to the distance. The design resembles an orrery, a dynamic moving model of a solar system showing the orbits of planets and other bodies around a central point, yet without ever stating a totalizing order clearly. If you follow your eye as it scans the rendering in a constantly moving dialogue between the lines of the building and the lines of the earth, everything is akilter, off axis, slightly dislocated, creating a spatial experience more like those we find in

the natural world where we establish frames of reference with our own perceptions constantly as we go along. It is a new architecture, the epitome of the dozens of such designs Wright proffered over the last decades of his life, few of which he was able to build, and none at this scale of richness.

In each of these cases Wright identified an experiential aspect of the natural environment as the basis for the placement and orientation of the design, and as the genesis of its formal language, its specific architectonics, and indeed its aesthetics. Each emerges out of something he found in each place, leading our perceptions to a sense of continuity with the natural landscape. He spoke about this in his London lectures, "We are talking about the countryside itself developing into a type of building in which will lie naturally building becoming part of the countryside, building belonging there naturally with grace. . . . The more of such buildings we have in the country the more beautiful community life will become and the less you will be aware of the fact that buildings are there at all as an intrusion."<sup>3</sup>

## An Evolution of Sustainable Aesthetics

Elizabeth Donovan<sup>1</sup>

<sup>1</sup> Emerging Architecture Lab, Aarhus School of Architecture, Aarhus, Denmark, ed@aarch.dk

**Abstract:** This paper will reflect on an exploration of the aesthetical influence of the sustainable architecture discourse from a historical and contemporary perspective. It aims to understand the link between different sustainable architecture movements, their labels, implications and subsequent aesthetics. This paper is framed within the understanding that while sustainable architecture has showcased ethical technology, it lacks the holistic aesthetic language needed for the discipline to progress. A discussion of literature concerning sustainability, architecture, and aesthetics, articulating the particularly overlapping relationships between these three discourses initiates this paper. This analysis is then compared with a study of the sustainable architecture discourse after the 1960s. This analysis is conducted to outline the progression of not only theoretical advances and philosophical grounding but also their aesthetical influence both on alternative architecture and the everyday. In continuation, a visual analysis of selected case studies, both historical and contemporary analyses visually what different theoretical concepts are implemented into different design aesthetics. Initial findings emphasise the importance of understanding the origins and implications of sustainable design choices. By understanding sustainable theoretical groundings and their associated aesthetics, there is an opportunity for a new ethical and aesthetical dimension to emerge.

**Keywords:** Sustainable architecture, aesthetics, history, eco, green

### Introduction

“The ugly truth about sustainable design is that much of it is ugly” wrote Lance Hosey (2012) in the opening pages of his book ‘The Shape of Green: aesthetics, ecology and design.’ Hosey (2012) continues with this quote from the 2009 American Prospect “Is ‘well-designed green architecture’ an oxymoron?” Sustainable architecture has the stigma of being all ethics and no aesthetics, but what does this mean for the progression of the field? Contemporary architecture has been overwhelmed with the effects of ‘greenwashing’ and this has resulted in a built environment flooded with conventional buildings smothered in green-technology add-ons. This not only influences the public’s perceptions of what is considered sustainable but creates a sustainable aesthetic which does not represent a truly sustainable approach to design.

Understanding how sustainable architecture has evolved from eco and green architecture helps to illustrate how the current lack of a sustainable aesthetic language has emerged. With growing environmental, climate and global concerns it is even more pressing that our built environment does its part in lessening its negative effects on these issues, however, sustainable architecture will remain fragmented from mainstream architecture if the connection between ethics and aesthetics are not reflected within each other. To elaborate on this, different literature is explored concerning sustainability, architecture and aesthetics, articulating the current discontent with the field, followed by a historical overview

from the 1960s outlining the progressions of the terms eco, green and sustainable. This highlights the societal groundings, technological and aesthetic advances which influence both alternative architecture and the everyday. These periods are then explored through a content analysis of the sustainable visual features of five different architectural examples to understand how and when different theoretical concepts and strategies are implemented into different design aesthetics and what are the resulting visual implications. The historical background is considered as the context in which the buildings developed. Each of the examples are analysed by highlighting, coding and cataloguing distinguishing manifest and latent sustainable visual features. Comparisons and correlations between their historical context and resulting aesthetics are illustrated to understand their development. All of the examples are compared to understand the visual genealogy of contemporary sustainable architecture. Expected results are a description of the visual language of the contemporary history of sustainable architecture and will showcase the plurality of sustainable architecture and indicate the origins of the technological ornamentation which is prevalent today.

### **Discussions of a sustainable aesthetics**

Aesthetics is a complex notion which has been the topic of many debates, it is often considered subjective and a matter of opinion, as is the subject of sustainable aesthetics. Discourse on the topic of sustainable aesthetics appears in few books but is frequently the discussion of magazine articles and opinion pieces from online blogs. The following discussion is outlined not as hard fact, but rather to explore the different concerns which are currently under discussion within the field of architecture. Lloyd Alter (2009) in his article “Why is so much green architecture so ugly?” for the online blog TreeHugger suggests that the field of architecture is experiencing a design crisis and many developments look as though the design was simply forgotten.

Unlike previous architecture movements such as Modernism, sustainable architecture does not have a rigid stylistic dogma or design rules. This means that each sustainable designer is at the mercy of a cumbersome and often contradictory approach to designing. While ethical intentions are often easier to grasp the aesthetical language is somewhat more elusive. Di Carlo (2000) supports and elaborates that existing sustainable architecture only contains ethical action but has no innovative aesthetic language. Hosey (2012) postulates that “technology has hijacked sustainability” and that the art of architecture has been neglected in favour of focusing on the science of building (Hosey, 2007). The focus on technology within sustainable architecture has developed from the need to solve external problems such as the oil crisis in the 1970s, however, the good intention of solving ethical problems has recently resulted in a shallow and fragmented aesthetic approach which often does not communicate the essence of the fundamental sustainable concepts. Geoff Manaugh (2007) in his blog post “Architectural Sustainability” argues that contemporary architects have become masters at the “art of ornamentalizing sustainability” and Mehaffy and Salingaros (2013) also support this notion that sustainable architecture is being adorned with shallow-technical-add-ons and they elaborate that these components are often ‘bolted-on’ without any consideration for their long-term contributions to the ongoing sustainability of the building. All of this is exacerbated by ‘greenwashing’ within the field and often what is discussed as sustainable architecture is merely a shallow attempt at gaining certifications or marketing endeavours rather than a design which at its core is sustainable, eco or green.

## **Historic overview from the 1960s**

The definition of words like sustainable, eco or green are often overlapping and ambiguous, especially with the field of architecture. These architectural approaches have however developed very differently, responding to different societal contexts to produce different forms and aesthetics to represent their underlying environmental fundaments. Before the 20<sup>th</sup> century, buildings were not significant energy users, with electric lighting, heating and elevators relatively new endeavours. Without these technologies, buildings were at the mercy of nature and were consequently designed to defend against the outside elements. At the beginning of the 20th century the technological innovation of using mechanical cooling within buildings had a considerable influence on the form and subsequent aesthetics of the architecture that was to follow. With the introduction of mechanical cooling, buildings now had easy control of their comfort. Raman (2007), explains that it was thought that technology could solve all problem and take care of the consequences of designs which no longer needed to consider environmental issues as energy was considered plentiful. One of the first examples of this technology transitioning into buildings was the New York Stock Exchange building, built in 1903. Following this in the 1930s, the Empire State and Chrysler buildings in New York City were designed with mechanical cooling but still maintained the traditional defensive attitude towards nature and the subsequent art deco forms entailed protective facades with punched openings. The dramatic shift in aesthetics, which was made possible by mechanical cooling is best illustrated by the United Nations Secretariat Building constructed in New York in the early 1950s. There was no concern for the environment or the buildings impact, with the 39 storey single-glazed facades facing east and west, encouraging overheating. In addition, the pitted-stone material chosen for the north-south walls were at risk of freeze-thaw-action and rather than changing material, 39 floors of steam coils were implemented to react to the outside temperature to prevent this (Ramen, 2007). The link between the architect's relationship with nature, technology and energy prices has had a significant effect on the approach and aesthetics of architecture and this can also be traced through modern sustainable movements.

The birth of the modern environmental movement began in the 1960s with the influential writings of E.F. Schumacher, Howard T. Odum and particularly Rachel Carson and her book 'Silent Spring.' For the first time, it was evident that humans had an impact on the environment. During this time grassroots and counterculture movements formed. Homes had become more than simple shelters, accommodating new technologies and equipment (Tabb, 2014). This period developed two different forms of eco-architecture. One being the radical, experimental and socially sustainable architecture formed with the counterculture movement and influenced greatly by Buckminster Fuller and a 'do-it-yourself' attitude. Within the USA this included Drop City an off-grid, bricolage-geodesic-dome artist commune in Colorado built in 1965 and at a similar time Prickly Mountain an array of anti-establishment architecture inventions. Gordon (2008) mentions young architects were in search of new inspirations for aesthetics and form and looked to cocoons, honeycomb, seashell, space ships and seedpods. Buildings were constructed out of earth, recycled or scavenged and off-the-shelf materials. These ventures did not succeed in the long term, Michael Sorkin (1972) in the Architectural Review stated "totem happy dome dwellers, staked out under their geodesic icons in backwoods utopias" were not going to solve the social problem of this period. More conventionally, the other forms of eco-architecture responded to the climate and environment. Three key figures were, Victor Olgyay who wrote 'Design with Climate' in 1963, Ian McHarg who followed with 'Design with Nature' in 1969 and Paolo Soleri who created the

term ‘arcology’ (architecture + ecology) and designed Arcosanti, Arizona in 1970 (Sadler, 2010). Key design concerns and subsequent form for these three approaches included; building siting, orientation, natural ventilation, plan aspect ratios, on-site resources, reduced waste, access to nature, density and typological layering systems. These significant projects, both radical utopias and bio-climatic, may not measure by current sustainable standard. However, responded to the social and political context of their time before energy usage became a pressing concern.

The 1970s brought with it the oil crisis and with it two drastic spikes in oil prices in the early and late 70s. Previous to this energy and emission in general or specifically from the built environment were not a common concern. After the price of oil dropped back to within the pre-crisis range, so did the publics concern. However, building policy, codes and requirements set during the oil crisis remained, which fostered green technology and architecture (Raman, 2007). The romantic intentions of the previous decades started to be shadowed by more measureable approaches to reducing energy. Green architecture emerged in response to this in three main forms; passive solar, off-grid or autonomous and regional design. Passive solar design aimed to use technological advances to create buildings with reduced energy consumption. David Wright, Phillip Tabb and William Lumpkins were three key architects in the ‘70s which used orientation, passive solar systems, thermal mass (often adobe) walls, clerestories, solar shading devices and hot water collectors to generate their form. Off-grid or autonomous architecture developed from the previous experiment buildings of the 1960s. Michael Reynolds’ Earthships’ followed Drop City’s recycled aesthetic with tyres, cans and glass bottles all built within rammed-earth U-shaped structures. Alternatively, Steve Baer tried to integrate these more radical ideas into conventional buildings, utilising polyhedral structures with passive and active solar energy techniques to create what he coined ‘Zomes.’ After the 1970s there was a reduced concern for energy use, this coupled with the development of the postmodern movement created a lull in the development of technologies and instead an interest in comprehensive design (Tabb, 2014). From this, a curiosity towards culture, vernacular and regionalism emerged. Key theorist and architect, Kenneth Frampton and Glenn Murcutt developed parallel concepts; Critical Regionalism and the contemporary vernacular. These concepts considered topography, orientation, light, passive and natural heating and cooling systems when designing for the geographical and climatic context of their site. During this period the price of oil impacted greatly on the architectural typologies. Creating a mixture of environmental technology development, low-tech experimental and hybrid nostalgic regional buildings.

After the UN report, Our Common Futures published the key definition of sustainable development in 1987, the term sustainable architecture grew in popularity. Parallel to this, new and improved environmental technologies emerged along with the insertion of CAD programmes which aided in the creation of new complex and unprecedented structures. Sustainable architecture had moved from the eco and green isolated buildings on the peripheries to monumental, lightweight, highly glazed, high tech buildings in an urban setting. Philip Tabb (2014) explains unlike the previous styles, sustainable architecture “did not look back to the future, but rather projected the future.” Two scales of building emerged; ‘low-tech’ residential models such as Passive and NetZero houses and complex, large-scale buildings, such as the work of the prevalent architects of this period Calatrava, Foster, Grimshaw, Herzog and De Mauron, Piano and Rogers who integrated environmental systems into their building designs. However, this architecture of ‘good intentions’ as Inaki Abalo (2007) words it became an image of sustainability which concentrates on the development of

technical solutions applied to badly conceived buildings (Abalo, 2007). The introduction of accreditations such as LEED and BREEAM did not help this, with a focus on energy savings and the measurable growing exponentially on what were already high-tech buildings designed in isolation to their wider context. Pohl (2011) sees these as a subcategory of green high-performance buildings which are goal-based with measurable parameters for resources and energy conservation. Dean (2009) discusses this as a devolution of architecture due to the implications of applied technology from the 1980s which had led to a techno-science of building. Abalo (2007) during his presentation went on to say "Through the eyes of professional and especially students, this parade of high-tech-drag-queens hardly stimulates creativity." With the turn of the millennium, approaches to sustainable architecture changed slightly. Buildings were no longer considered in isolated and there was a growing interesting in understanding a building in relation to the wider ecological and urban context. A growing interest in biometrics also emerged and with the help of 3D modelling unique biologically inspired forms generated a new aesthetics. Currently, a pluralism of sustainable architecture is developing. Architecture has responded to a variety of different environmental and societal concerns over the years and this has had an effect on the form and aesthetics in which architects use. Understanding how these have transformed in modern architecture is important to the aesthetics of the field.

### **Examples of an eco, green and sustainable aesthetic**

A visual content analysis of five selected examples to represent a cross-section of the development of sustainable architecture is presented below to explore and compare how theoretical concepts were implemented into different design aesthetics and forms. This is supported by outlining the societal and philosophical context to understand how this impacted the visual design decisions.

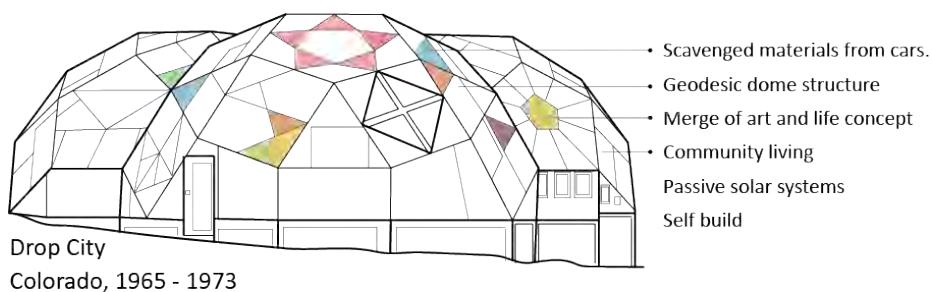

Figure 1. Illustration of one example of an eco architecture aesthetic.

A mentioned earlier, Drop City (figure 1) was an artist commune developed between 1965 and 1973 in Colorado. It emerged as part of the counterculture movements as a form of design activism (Sadler, 2010). Drop City was influenced by Buckminster Fuller's principles and created the first civilian use of the geodesic dome. The societal context of this period greatly informed the utopian ideas which formed this community. The desire to merge art and life and live independently resulted in the use of unconventional shapes, colours and forms. The 'do-it-yourself' mentality which came with this freedom resulted in a somewhat chaotic appearance and use of recycled and scavenged materials, particular metal from cars. The radical aesthetics of these buildings grew out of a social and political sustainability rather than environmental. While this community eventually failed their alternative and radical approach can be seen in later examples.

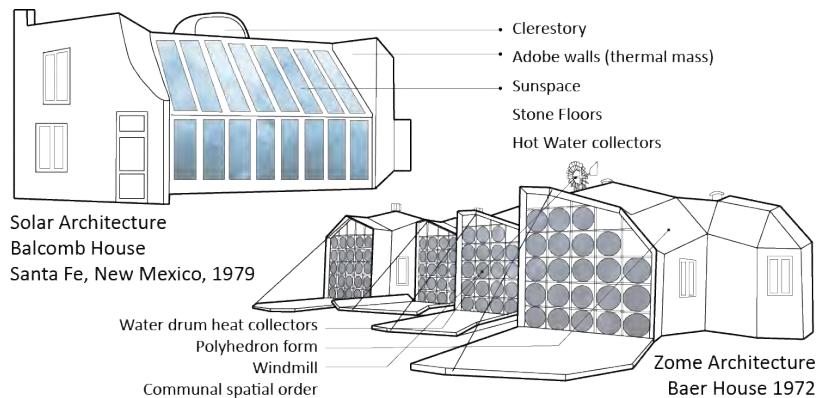

Figure 2. Illustration of two examples of green architecture aesthetic.

The context in which green architecture developed was drastically different to Drop City. Previous insignificant environmental issues were now pressing especially in regards to energy and technology was sought for solutions. The Baer House by Steven Baer illustrated at the bottom of Figure 2, developed from Drop City and Buckminster Fuller's ideas. In addition to the structural efficiency of the polyhedral form, new technology for passive and active energy generation was explored, and this included water drums for thermal mass and windmills. Baer's unconventional typology created communal spatial order and Tabb (2014) described it as "the most recognisable form of rebellion." The Balcomb House by William Lumpkins in 1979 is a well-known example of solar architecture. Solar architecture as mention earlier was designed using passive solar systems to reduce the amount of energy needed. This examples form and aesthetics were designed completely as the subsequent results of the technology needed to achieve the desired energy goals. The material choice of adobe walls was required for thermal mass, the large sunspace which ran along the facade was a necessity for the passive design approach and clerestory delivered the desired natural light and supported hot water collectors. These buildings were designed to explore alternative and unprecedented technology and their aesthetics reflected these unconventional and alternative approaches.

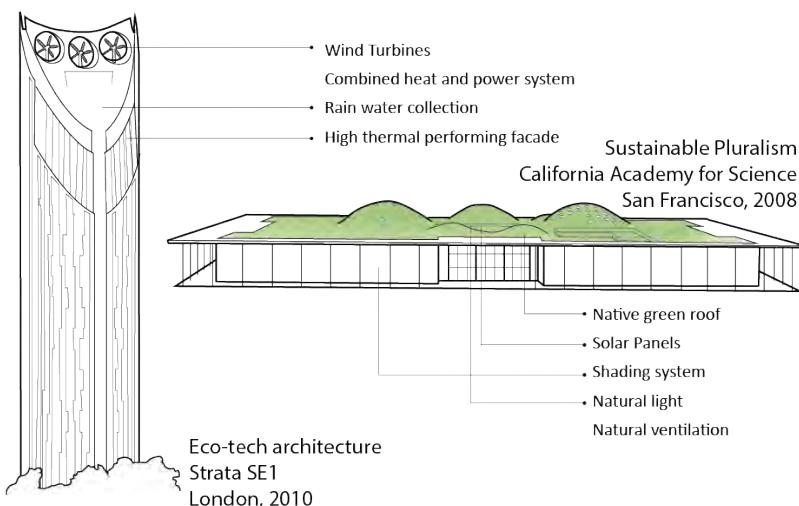

Figure 3. Illustration of two example of a sustainable architecture aesthetic.

These two examples of sustainable architecture in Figure 3 represent two approaches. Firstly, the more integrated approach of the California Academy for Science in San Francisco completed in 2008 by Renzo Piano and secondly, the Strata SE1 building in London from 2010 which highlights an aesthetic of technical-add-ons. Strata SE1 is a 43 storey apartment

building in London which boast three nine-metre wind turbines at the top along with a ‘bespoke’ high thermal performing façade. This building is an example of an afterthought aesthetic which displays sustainable technology with no real consideration of its actual effect as mentioned by Mehaffy and Salingaros (2013) earlier. This building is a prime example of good intentions which failed. To support those three wind turbines, the entire structure needed to be strengthened which required more materials and resources. Unfortunately, while a brave idea, the wind turbines no longer spin which makes the entire building more unsustainable than if they were not there to start with. The lack of holistic thinking with this example led to a shallow, technical aesthetics which unfortunately strengthens the previous discussion that sustainable buildings are ugly and coincidentally this building was voted ‘Britain’s ugliest new building’ by readers of Building Design Magazine (Booth, 2010). The California Academy for Science building is an example of a holistic design which incorporated both natural and environment technical solutions within a cohesive design aesthetic for an incredibly large horizontal building. Solar panels, radiant floors and ventilation systems are incorporated with the large native green roof, natural ventilation and natural light to create both an interesting form and energy efficient structure. This building has a biometric influence in the form of the green roof which is juxtaposed with a relatively convention building below however, this adds to the aesthetic quality. These examples of eco, green and sustainable aesthetics represent only a small section of history but illustrate a narrative of the development of sustainable aesthetics.

## **Discussion**

Current theoretical developments have shifted recently, moving from individual building as experiments to understanding buildings within their wider systems such as in the California Academy for Science (figure 3) which approaches sustainable architecture in a holistic manner resulting in a visually interesting building which merges nature and technology. In contrast, theoretical developments which lean heavily on the notion that technology can solve all, results in building such as Strata SE1 (figure 3) which is a failed attempt of a good intention and without working technology it is actually more resource intensive than is required. The development of each of these example buildings highlights a social constructive perspective in which words, images and artefacts have no inherent meaning and instead meaning can only be understood in relation to the context in which it is ‘consumed’ and analysed. Each building can not be visually understood without understanding the social, cultural and political environment in which it was constructed. These three aspects have had a large influence on the visual latent content of each example and it is obvious that there is direct relationship between the aesthetics and context. A visual transition from the social activism or defiance of the 1960s to a more recent commonplace understanding has occurred in this short history. As the impact buildings have on nature is becoming more evident so is the development of ways in which to solve this. Each decade visually indicates a transition of mans approach to nature, from it being an endless resource to trying to sustain nature for future generations. The form and material use has transitioned from the alternative to more conventional. Domes and polyhedrons transitioned to organic shapes and were then surpassed by more conservative forms adorned with sustainable technology. Some key outcomes of the manifest content were the use of technology, materiality and size development through history. There has been a transition from the reductive perspective of the 1960s, creating efficient forms and reducing waste to the reduction of energy in the 1980s in conjunction with the introduction of technology as a solution which is still prevalent today.

## Conclusion

This paper has outlined how eco, green and sustainable architecture has emerged and evolved since the 1960s, with specific reference to the change in form and aesthetic. After discussing current opinions on the state of the sustainable aesthetic different period were outlined and explore. To understand eco architecture, the social and political context was summarized to situate the experimental and somewhat radical concepts of Drop City and bioclimatic architecture. Green architecture was framed by the oil embargo that influenced the search for alternative energy solutions for architecture. Sustainable architecture was largely influenced by growing technologies and CAD programmes which has allowed for complex and monumental sustainable buildings which are now present in urban environments. With each of these periods of design, new aesthetics emerged and very often were the result of the constraints, reactions and influences of the time. These changes in the aesthetics of the building were visually analysed through five examples in an attempt to form a cross-section of this period of fifty years. This visual analysis clearly shows both the similarities and differences between each approach. It also illustrates how social concerns and technology advancement can radically transform not only how buildings function but also how they are perceived visually. It is clear that with the current plurality of sustainable architecture there is no single sustainable aesthetic language and nor should there be, however, there needs to be a language of integrity that goes beyond the 'greenwashing' examples which currently are flooding our built environments.

## Architectural design and aesthetics of Zero Emission Buildings: An analysis of perceived architectural qualities in the ZEB Living Lab in Trondheim

Luca Finocchiaro<sup>1</sup>, and Solvår Irene Wågø<sup>2</sup>

<sup>1</sup> Institute for Architecture and Technology, Faculty of Architecture, NTNU Norwegian University of Science and Technology, luca.finocchiaro@ntnu.no;

<sup>2</sup> SINTEF Building and Infrastructure, Trondheim, solvar.wago@sintef.no

**Abstract:** Technological development of building components for energy efficiency and renewable energy generation has made it possible to conceive buildings able to produce more energy than they actually consume. Zero Emission Buildings – ZEBs - are based on the assumption that the surplus of energy produced by integrated energy systems could compensate their own environmental impact in a life cycle perspective. Beside their simple aesthetics, ZEBs are often the result of complex architectural design processes where morphology and construction are optimized, through the use of advanced simulation tools, towards optimal environmental performance and maximum energy efficiency. Architects assume, in this context, the role of hubs, collecting the complex flow of information provided by the different experts involved throughout the design process, and synthesizing it into a whole. The ZEB Living Lab was designed in order to be representative, for dimension and construction, of a regular Norwegian detached house. Its aesthetic is the result of a complex multidisciplinary design process where students, researchers and industry partners collaborated in the design of an energy positive solar powered house. Its concept was conceived as an internal competition within the MSc program in Sustainable Architecture and later developed at the ZEB research centre at NTNU. The Living Lab has been equipped with a data acquisition system able to monitor environmental performance and energy flow through the building. Today it is used as a laboratory for action research on users' interaction with state of the art technologies for carbon neutrality. In this paper, architectural qualities of the Living Lab, determined on the basis of both numerical analyses and qualitative parameters, will be discussed in relation to both feedbacks provided by different users and collected data.

**Keywords:** Architecture, aesthetics, zero emission, energy efficiency, users.

### Introduction

Nowadays, technological development of building components for energy efficiency and energy harvesting has made it possible to imagine a new generation of buildings able to produce even more energy than they actually consume. According to the Zero Emission Buildings research centre at NTNU, a building can be defined as a ZEB when the energy generated by the integrated renewable energy system is able to compensate emissions: due to the operation of the technical equipment (level 1), due to the operation of technical equipment and appliances (level 2), embodied in building's materials (level 3), released for the construction and demolition of the building (level 4), (Kristjansdottir, T. et al., 2014).

The ZEB Living Lab has been designed in accordance to passive house standards and then optimized in order to reach the ZEB targets (Finocchiaro et al, 2012). Beside their generally simple aesthetics, passive houses represent the result of complex and multidisciplinary design processes. In order to optimize their environmental performance

throughout the year, passive solar heating systems need to be optimized as an integral part of the building's architecture, taking morphology, construction and energy system into account. In this scenario, advanced simulation software assume a fundamental role for optimizing morphology and construction towards optimal environmental performance and maximum energy efficiency. In such a scenario, results provided by simulation tools might determine the building form but also condition the choice of materials, the glass ratio, orientation etc. affecting architecture and housing qualities, such as the relation between indoor and outdoor, or the tight correspondence between form and program.

In such integrated design processes, architects assume the role of hubs collecting a complex workflow of information provided by the different experts involved and translating it into forms based on their experience and visions. In such a process of synthesis, architects should not look for compromises between qualitative and quantitative variables, but rather ensure that those complement each other. Building aesthetics becomes in this context an honest representation of the effort of synthesizing quantitative and qualitative parameters into a whole, reconnecting the way forms look with the way they actually perform.

### **The ZEB LivingLAB.**

The ZEB Living Lab (Figure 1) is a test facility representative of a single-family house, with a gross volume of 500 m<sup>3</sup> circa and a heated surface of approximately 100 m<sup>2</sup>. Its architecture is the result of a complex multidisciplinary design process in which students, researchers and industry partners have collaborated in the architectural design of a solar powered house able to produce more energy than it consumes on a yearly basis (Finocchiaro et al, 2011).

Figure 1. The ZEB Living Lab at the campus.

The Living Lab relies on the integration of three renewable energy systems for covering its annual energy demand: a 12KWp photovoltaic system on the roof, a solar thermal system in the south façade and a geothermal system connected to a heat pump on the north side of the building. Its construction aimed to demonstrate that ZEB targets could be achieved in the climatic context of Trondheim. In addition, the building serve today as a laboratory for investigating users' interaction with state of the art technologies for carbon neutrality. For this reason, it has been equipped with a data acquisition system able to record any kind of information related to environmental performance and energy flow (Goia et al, 2015).

The building concept was chosen as result of a competition run in the first semester of the MSc programme in Sustainable Architecture at NTNU. Throughout the competition students recurred to an extensive use of simulation software of different kind, optimizing the building environmental performance towards indoor comfort while ensuring the production of an amount of energy sufficient to reach the ZEB targets. The winning concept, originally called *FlexBOX*, was based on a versatile construction system making it possible to adjust the building construction in connection with different users and climatic contexts (Haase et al, 2011). This concept was later further developed within the ZEB research centre, resulting in a flexible construction system including three main architectural components: the functional boxes, the transversal partitions and the roof components. The functional boxes were dimensioned in order to contain technical equipment, building skin and furniture in the compact section of 135x420 cm (Figure 2). Transversal partitions, placed in between the boxes, could be adjusted in accordance to different building programs and serve as internal or external partitions. The roof construction, consisting of two large elements disposed between the boxes, integrated photovoltaic system on the outer side and phase changing materials on the inner one.

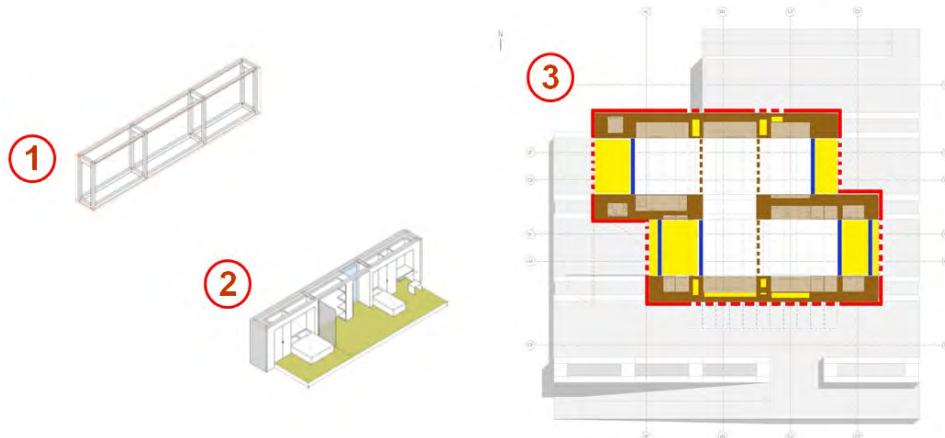

Figure 2. The building concept

The construction of the Living Lab, optimized through different sets of simulations, resulted in a low-transmittance envelope with a glass ratio of 20% circa (Finocchiaro et al, 2012). Walls, floor and roof are all made of a double layer of rock wool insulation with a total thickness of 45 cm. All windows in the house respect the passive house standards with an overall transmittance of  $0,8 \text{ W/m}^2\text{K}$ . The double window towards south, designed as a passive solar heating system, is characterized by a markedly low u-value, varying from 0,65 to 0,69 depending on the ventilation rate within the air cavity (Figure 3). Because of the light construction of the building, solar gains might be responsible, however, for large temperature fluctuations and the risk of overheating in the summer period (Finocchiaro et al, 2016). For this reason, both south and north windows are coupled with an automated control system able to activate, when required, a natural ventilation flow through the building. Skylights towards north can independently be opened to let the exhaust air out through stack ventilation. In the meanwhile, PCM panels integrated in the ceiling construction aim at stabilizing temperature fluctuations within the comfort zone.

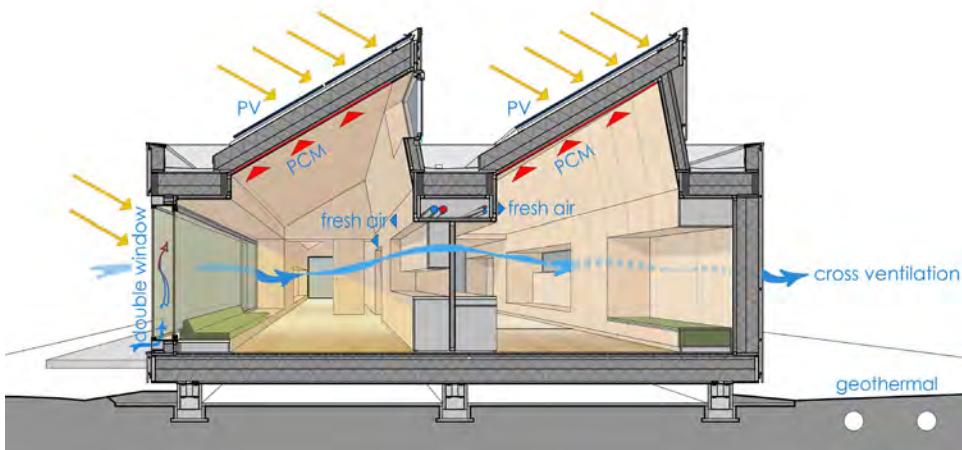

Figure 3. Environmental concept

### **Analysing architectural qualities of ZEB**

Between October 2015 and January 2016, six different groups of users have been living in the Living Lab for three weeks each circa. Users included two young families each with two small children, two senior couples (one of pensioners and one of workers), and two groups of students. Variety among users aimed to unravel if there are any differences in the way users perceive features of zero emission buildings (Korsnes et al, 2016). All of them were invited to take with them any kind of object that could have let them follow their regular living activities and feel home. Users were interviewed before, during and after their stay by an architect and two social scientists from the *Zero Emission Building* research centre (Woods et al, 2016). Questions addressed aimed at understanding how the interaction with integrated technologies could affect their regular living activities. Interviews, transcribed by master students in Interdisciplinary Studies of Culture at NTNU, aimed to give a platform for providing relevant knowledge for future development of green housing.

In this study, we focused on understanding how users experienced those architectural qualities of the Living Lab that were determined by the intention of reducing its environmental impact, and more precisely:

- Space: inner space and floor to ceiling height have been determined optimizing the angle of the integrated solar cells towards maximum energy generation.
- Transparency: was affected by the need of reducing heat losses limiting the glass ratio from 40 to 20% in the latter stage of the design process.
- Materials and components were defined on the basis of simulation results but also with the intention to visually express a prefabricated system based on a clear modularity.

### ***Inner space and functionality***

The disposal of three prefabricated boxes determined the open building plan, organized in two main areas (Figure 4): a living area facing south and a working/sleeping area towards north. Technical room, toilet and kitchen have been aligned along the central axis of the building in order to optimize the distribution of three alternative heating systems, mounted for research purpose (Goia et al, 2015). Supply air terminals have been placed in the living room and in the bedrooms; extract in the bathroom and in the kitchen. The open plan makes

it possible to cross ventilate the building in summer or heat it with only one radiator placed in the middle of the plan; all solutions, those ones, now tested for comfort and efficiency.

The construction of the roof, optimized in order to maximize energy generated by the integrated photovoltaic system, resulted into two slabs tilted of 30 degrees towards south (Finocchiaro, 2012). This represented the opportunity to rise the space between the boxes to an average height of 350 cm circa and catch the daylight coming from north. The high ceilings accommodate a small mezzanine on the top of the bedroom towards west, equipped with a mattress for guests or play area for children.

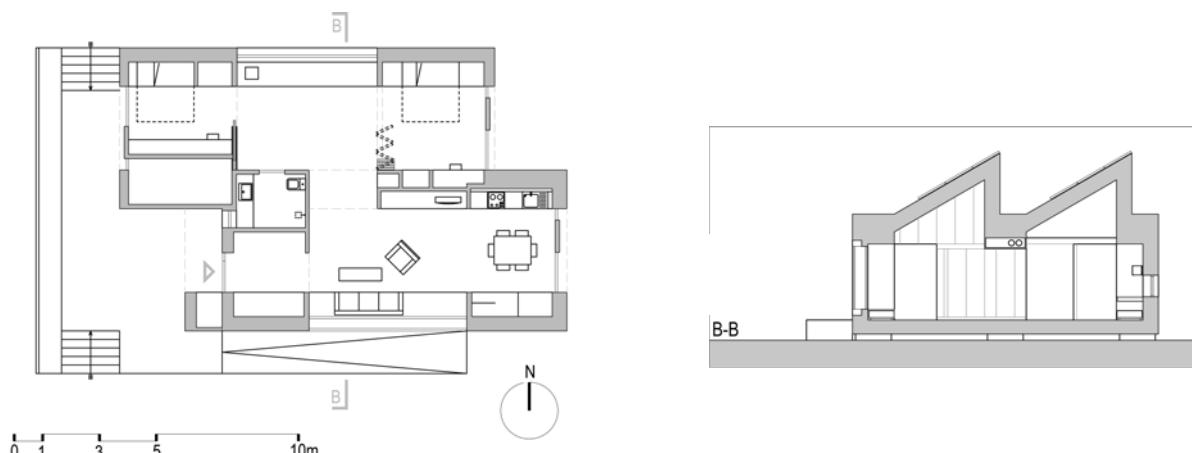

Figure 4. Plan and section of the Living Lab as built.

People living in the Living Lab generally appreciated the spacious interior: "*I think the extra floor to ceiling height provides a nice atmosphere. It makes the room more open and spacious. I want the house to look as nice as possible when I have visitors, so then I use to open all the doors to make the house as open and spacious as possible*" (young family woman). Even more important, users recognized the extra height as a quality given by the necessity of optimizing the position of the solar cells, recognizing the integration of a solar system as the opportunity for giving a different quality to the inner spaces or allocate new functions. "*It is probably like that because it has to but it also provides a lot of space*" (quoting one of the family males).

The open plan was appreciated by some while others felt that the house lacked in privacy and they would have appreciated a more extensive use of flexible partitioning such as the "*magic!*" one between bedroom and studio (young woman with children). The open plan was considered by many "*a bit unusual according to the Norwegian climate and lifestyle*". A door between entrance and living room would have avoided temperature drop due to cold air from the outside whenever the entrance door is open. Moreover, the open plan made it difficult to differentiate temperature between living and sleeping area, something particularly dear to Norwegians for which a temperature of 16 degrees is generally appreciated during night time. Moreover, the sliding door as the only possibility for getting fresh air in the bedrooms affected indoor comfort as this was perceived as a limit to adjust indoor temperature during the night time.

### **Materials and construction**

The construction of the LivingLAB has been optimized through different sets of simulations resulting in a stringent envelope characterized by low transmittance and a glass ratio of 20%

(Finocchiaro et al, 2012). When possible, materials with minimal embodied emissions were identified. Walls, floor and roof are made of a double layer of rock wool insulation - with a total thickness of 45 cm. A light construction system was chosen also because of the intention of prefabricating the building construction. Lightness would have facilitated transportation of components and construction. According to the concept, furniture, made of ephemeral modular elements, could have been moved according to different users' requirements. It was the architects' intention to express building modularity and the use of the light construction in the inner surfaces. For this reason, the surface wrapping the interior is made of birch plywood panels of a constant width of 60 cm (figure 5).

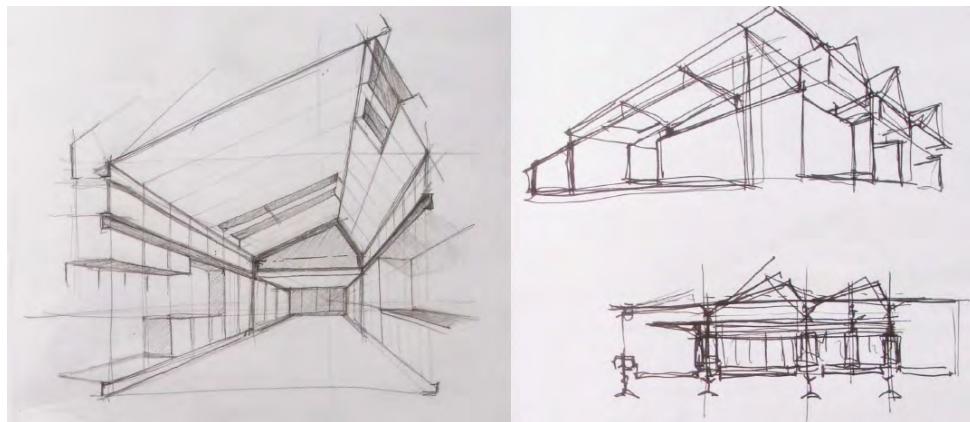

Figure 5. Sketches

Modularity within the LivingLAB was generally perceived as a positive quality, resulting in inner spaces characterized by "*aesthetical calm and comfort*" (*a young female*). Most people felt the wooden surfaces as pleasant, giving "*the feeling of living in the top of a three*"; while others attributed to them the perception of dry air. Inner space geometry, with the two pitched roofs between the boxes, was designed in order to catch daylight from the north, creating variety of colour and changeability throughout the day. However, skylights were reduced to the minimum because of the elevated heat losses due to exposing glass surfaces towards north and the interior turned into a homogeneous surface characterized by a "*white-wooded monotony*". Some interviewees describe the inner spaces as sterile while many expressed the desire to use the high wall-area as the opportunity to make the house more homely with variable surfaces: large paintings, textiles or larger skylights providing an extensive view to the sky.

### **Transparency**

According to the concept, transversal partitions between the boxes should be adjustable in relation to different users and contexts. The construction of external partition in the Living Lab towards east and west was optimized in order to limit heat losses while still let a sufficient amount of daylight indoor (Finocchiaro et al, 2012). Interviewees perceived indoor spaces as with plenty of daylight and with a good visual connection to the outdoor. "*When we come home after being away the whole day, I think it is the flood of daylight that provides the home-feeling. Because we have daylight - lots of daylight from all directions*" (*a female senior*).

The LivingLAB has been placed in the University campus, to ensure visibility and accessibility in connection to public events and research projects. Because of this, openness was soon turned into a privacy issue. Some experienced the connection with the outdoor "*a*

*bit weird*" and uncomfortable, especially in the beginning, when passers were curiously looking into the house. Most people placed the blinders from eye-height and down to be able to have daylight and view to the sky. However, people recognized this as a necessary compromise and simply imagined to live in the same house at their own site "*maybe with a winter garden outside the kitchen, and with the daylight along the floor from floor to ceiling height windows. I think that would be very nice!*" (Male senior).

Figure 6. Interior view

### Summary of main findings

On the basis of the study conducted, interviewees reported the experience of living in the LivingLAB as a positive one. The residents perceived the building as an ordinary house and related their experience to functional or aesthetic qualities more than to the technological content of the building. During their stay, users were occupied with their own well-being and those practical issues that would have let them conduct a regular life and feel home. Throughout the interviews, people referred, more or less critically, to the open plan, inner surfaces, daylight conditions and connection with the exterior. Relatively little attention was devoted to the interaction with integrated technologies, if not few considerations about night temperature and daylight distribution. Variation in the collected feedbacks depended more on individual preferences rather than on the kind of household. People were always referring to their previous house as a term of comparison to the Living Lab experience.

Feedback collected from the different households gave evidence of the importance of balancing quantitative and qualitative parameters in the architectural design of green buildings. "Home cultures and residential practices regarding airing practices and the desire for atmosphere, well-being and sensory experiences" can markedly influence energy use in buildings and "must therefore be taken into account" throughout the whole design process (Wågø and Berker, 2014).

The construction of the Living Lab aimed to demonstrate that Zero Emission Building targets could be achieved in the climatic context of Trondheim. The development of a unique concept, originally based on a prefabricated construction system, also aimed to give evidence that, within the ZEB targets definition, a wide range of architectural solutions can be developed. In this regard, the architectural design and construction of the Living Lab aimed to demonstrate how the effort of minimizing environmental impact of the built environment could become the opportunity to define inedited architectural scenarios.

## Acknowledgments

The Authors would like to acknowledge the ZEB research centre for the opportunity of developing this work and students at NTNU for their valid contribution throughout the development of the LivingLAB project.

## **Contributions to Sustainable Construction Socialisation Project and Construction of Secondary School in Mendoza, Argentina**

**Daniel Gelardi<sup>1</sup> and Alfredo Esteves<sup>1</sup>**

<sup>1</sup> Faculty of architecture urbanism and design, University of Mendoza, Argentine Aristides Villanueva 794 (5500) Mendoza City- Argentine. email daniel.gelardi@um.edu.ar

**Summary:** The main reasons that increase the interest in environmental matters within the field, are connected to technology and material systems. This paper shows that the material- construction stage in an architectural project is a determining factor in the architecture / sustainability equation. With that purpose, a study case is introduced. It describes in detail the project's first construction stage of a secondary school building in the province of Mendoza, Argentina. There is special emphasis on material system criteria, as well as the chosen applied technology, construction technique and materialisation, specifying their compatibility with environmental purposes. Moreover, it will be described how the programme, urban landscaping, the building position in the plot and the resources' economy, together with the constructive system, determine the building's space construction. From this analysis it is deducted that the proximity between the building's materials used and construction techniques, plus the relevance of its space construction, create certain tension regarding sustainability correction criteria.

**Keywords:** sustainability, rationalisation, materialisation, socialisation.

### **Introduction**

There are various causes for our concern regarding the open possibilities that construction techniques and sustainability problems present to architecture from a material point of view. They are diverse, but converge in one point: technology as a problem for architecture.

From a material point of view, buildings' energy self-sufficiency and sustainable construction imply the application of thermodynamic principles as well as the equation resources / energy cost. Different materials thermo-physical properties are brought into play in order to choose and select the elements that are part of it.

Nevertheless, sustainability entails new ways of material and construction systems organisation as well as new building behaviour in relation to the environment. As Ábalos asserts, it represents a technical change regarding a material culture based on mechanical principles towards thermo-dynamic principles (Ábalos, 2015).

This shifting from the traditional tectonic system towards a thermo-dynamic system based on energy, that Javier García, offers alternatives to propose a model to the emerging ecological conscience (García Germán, 2010).

## Description

Architectural products that have been conceived under some sustainability considerations, hold a series of principles which are based on the reasonable use of resources and environmental economy. Certain criteria is imparted in a normative way -without being a prescriptive list- favouring less energy-requiring construction and contexts integrated within their environment. These principles form part of an architectural culture that has never been appeased in spite of the prosperous crystal boxes world that adapted to any place.

Consequently, the environmental issues that are relevant to the field create an ecological conscience model, producing tension between developed construction tendencies that demand an ever increasing use of material and a progressive deterioration of the biosphere.

By this we mean the indiscriminate use of artefacts installed at any price; with air conditioning becoming too important as a mechanical conditioning and immunological isolation system (Sloterdijk, 2010). They break however, with the authentic technical side of architecture that Banham supported, and turn into mere forms of expression (Banham 1975).

However, good quality and consistent low energy-requiring architecture has its roots deeply inserted into architectural culture.

More than just another optimistic technology approach that results in formalistic practices that are generally unfortunate, this is to us an opportunity to investigate the necessity of incorporating instruments to the project's process. We have the chance to think of material organisation in the terms of a dynamic interchange that is both coherent and in agreement with the building form organisation. All this involves providing methods and object conceptualisation forms without losing architectonic identity.

That gives origin to our interest in the contribution to sustainable building socialisation through materialisation.

Architecture being an activity that influences material culture, its link with construction is a determining factor. Nevertheless, having a historic side and consistency in their form, the products of this activity refer to an open system that adapts to different ways of thinking, feeling and acting choosing the most favourable conditions to each case to adapt it to human lifestyles.

Just as the material system's selection stage in the architectonic process is a determining factor in a product's conception, construction techniques are the means by which matter is organised. Furthermore, according to the tendency shown in the past, the direct link that construction techniques have with their physical environment, social context and culture, is essential.

Currently, a building's project that is constructed in a specific space and time, should contemplate the transformations and consequences that it causes in the local and global physical environment. With this purpose, parameter strategies are included in the project's process, to give energetic dimensions to environmental behaviour. Still, the model reveals a parallel between the construction process rationality and structural performance, which is part of a mutual agreement consisting of an instructive historical horizon. That is, architecture's ability to transform and adapt to the physical, social, and cultural environmental conditions.

Furthermore, the interest in restrictive sustainable strategies, focuses again on conceiving from the material point of view, which was typical of the traditional architectural culture tradition until mid-twentieth century.

There are mainly two factors that aim to a rational type which provides guidelines that connect the different interacting parts in a context of conservation and adaptability (Gelardi, et.al. 2014). These factors are the sustainability criteria concerning energy requirements involved in the construction, materialisation and functioning processes; and the consideration of the chosen energy resources.

However, this combination of physical and functional units, acquires internal coherence according to the connection and balance criteria that belong to a specific way of conceiving. As Piñón said, a way of conceiving capable of combining construction systems logic with matter organisation logic or logic of the form (Piñón, 2009). As it's been said further above, from a sustainability point of view, attention is given not only to construction techniques, but also to a systematic conscience that gives order to the construction of the form. This is the approach in our analysis: In the same way we focus on material systems guided by sustainability criteria, we equally focus on the methods operating in the constitutive aspect that characterises architectural products which are successful thanks to their material quality and formal consistency.

### ***Study Case***

The following is the Project and 1st stage construction of a Secondary School building in Mendoza. The building is located in the City of Mendoza, capital city of the province of Mendoza, in the Centre West of Argentina. Situated in the Andes foothills, on the border with Chile, Mendoza is an arid area, with a high risk of earthquakes. The architectural programme consists of 4.644 m<sup>2</sup> of roofed floor area divided into two main buildings. The central building for classrooms and study rooms is 110 meters long on three different levels. The multi-purpose room has a surface area of 942 m<sup>2</sup>. There is a roofed area to practice sports, changing rooms and a gym. The project has five construction stages.

### ***Urban Landscape Settings***

The property is located in the District of Godoy Cruz, within the metropolitan area of Mendoza City. Situated in a two-road junction in a low density residential area, it's bordered by old railway operators' houses in the West, and by Benegas Recreational Park in the South. (Figure 1)

The plot has a surface area of 1ha 1,395.80 m<sup>2</sup>, with an average slope of 2% towards the North East.

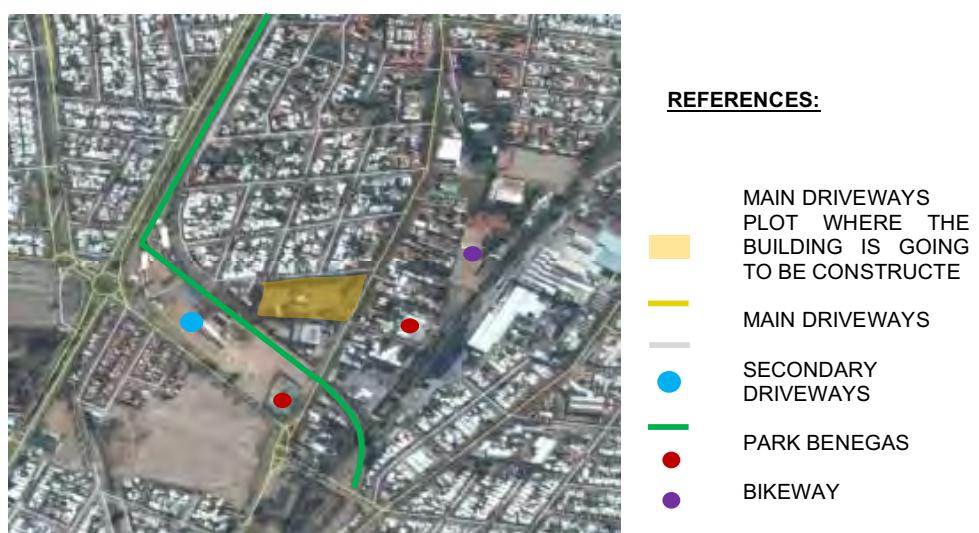

Figure 1. Campus position within the urban local area. Main activities that are not part of the residential area are marked

## Climate

Godoy Cruz is warm or hot in summer and cold in winter. Rain is scarce in winter and common during the summer months. (Figure 2) The wind is relatively calm and it mainly blows from the S-SE-E quadrant in summer (60%) and S in winter (25%). Occasionally, there is risk of Zonda wind, which is a very hot dry strong wind with a considerable amount of dust in suspension. (Figure 3)

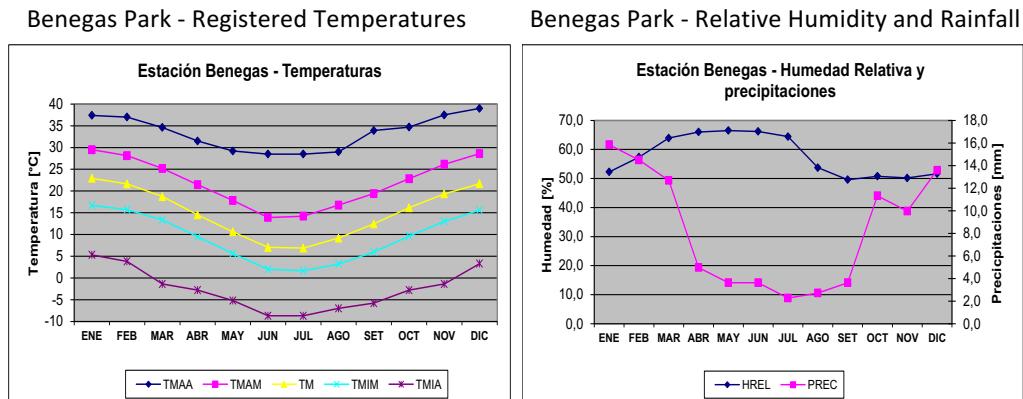

Figure 2: (Left) Absolute Maximum Temperature (TMAA), Maximum Average Temperature (TMAM), Average Temperature (TM), Medium Average Temperature (TMIM). Minimum Absolute Temperature (TMIA)

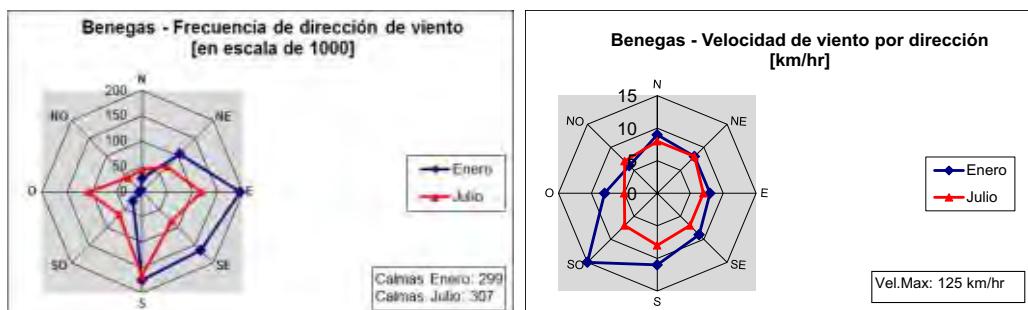

Figure 3. (Left) Wind direction frequency during January (Representative of the summer) and July

## Building's position in the plot

The 110 m long central building, goes from East to West, and the multi-purpose room is in the corner. The campus has a 3000 m<sup>2</sup> garden that integrates the paths and surrounds the space, turning the plot into the area's microclimatic lungs (Figure 4)

Figure 4. Buildings position, Access driveways and paths

### ***Structural System***

The structural system is materialised with precast reinforced concrete panels mounted on site. Transversally, the earthquake resistant structure formed by columns and beams linked by post stressed hybrid joints that support premoulded slabs at different levels. These floors have the sufficient resistance and rigidity to re distribute earthquake actions on their own level (Figure 5).

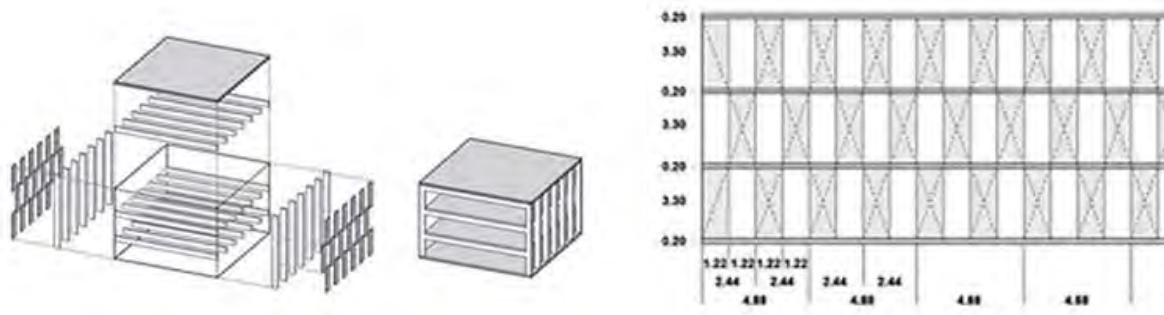

Figure 5. Premoulded and Poststressed Elements Structure System

Longitudinally, the earthquake resistant structure is materialized with crosslinked partition walls, which at the same time, are linked with the second level premoulded partitions. These crosslinked partitions and the resulting windows on the front walls, are necessary to achieve structural rigidity. (Picture 6)

Picture 6. Construction and assembly of the structure and panels

### ***Resources Economy***

The building is strategically sustainable, having been designed using common sense. It faces the North so as to obtain the most solar exposition possible. The screened porch alongside the building, creates a greenhouse effect in winter, conditioning the area. The load bearing structure is at the same time the envelope and enclosure structure, as well as shading for the facade. The materials used for the flooring and envelope structure accumulate energy in their thermal mass. The system is completed with energy conservation depending on the thickness and the concrete's thermal transmittance. In summer, the covered area is opened, allowing the rooms to have shading and generating draughts.

The following figure shows the Ground floor and the two tall plants of the building (Figure 7)

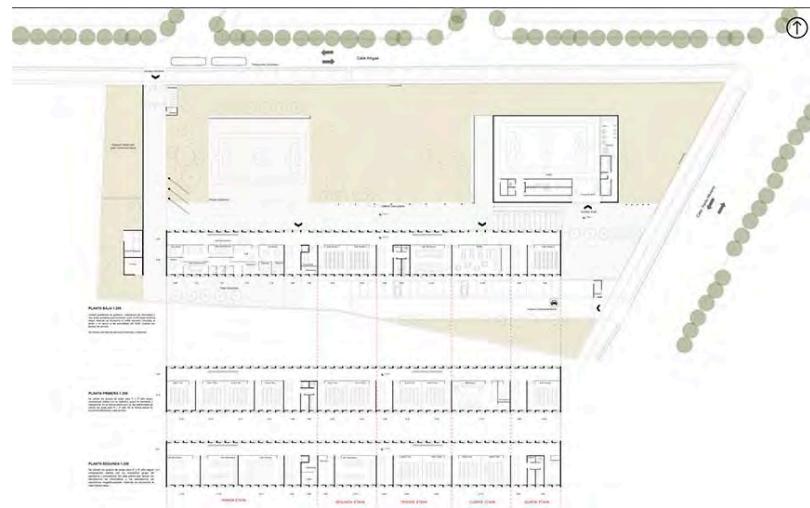

Figure 7. Ground floor, 1st and 2nd floor where screened porches and rooms are shown.

### **Bioclimatic Criteria**

According to the programme's demands and the local climate's characteristics, the proposal has five main sustainability approaches with the purpose of achieving energetic efficiency. They are as listed below.

1. Direct Energy Saving: The North facade and the porch create a greenhouse effect and accumulate energy in the floor's thermal mass. The screened porch's glass panels' surface area is of 43% and allows an energy saving of about 39% compared to the same building conceived without these considerations (Figure 8).

2. Solar Exposure and Natural Ventilation Control: In summer, the facades work as a passive cooler, allowing nocturnal cross-ventilation.

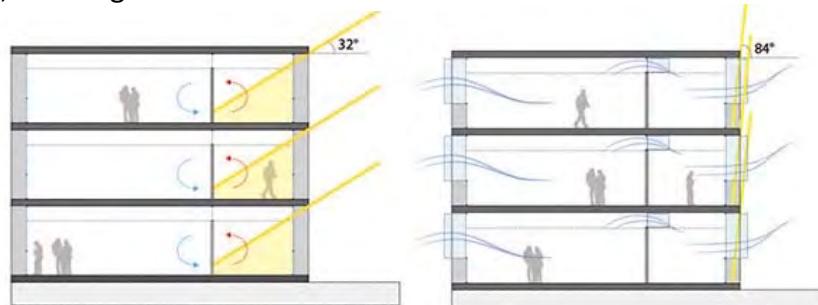

Figure 8. Direct saving system facade – Cross ventilation and facade shading

3. Energy Accumulation: The North facade allows solar exposure, making it possible for heat to accumulate in the materials during autumn and winter. In summer and spring it gets shade during the day allowing nocturnal cross ventilation to cool down the building's thermal mass (Picture 9)

Picture 9. North Facade – Direct saving system. Interior sketch and existing porch photo

4. Energy Keeping: The appropriate thermal insulation is incorporated both in roofs and in aluminum window door frames, using watertight double glazed window panels.

5. The FAEP (Factor Area Surrounding Floor) is the indicator to evaluate the building's exposure to the exterior; it's the ratio of thermal envelope surface area to the floor area (Esteves, et.al.). The lower the HLFF, the lower thermal interchange will be, and also the smaller envelope surface area and floor surface area.

Table 1. Thermal Balance. Bioclimatic Adapted System and compactness of the building's volume

Fracción de Ahorro Solar - Sistemas Pasivos (FAS)		
Sup Exp	FAS	
Ganancia Directa - Galería Invernadero	392 m <sup>2</sup>	42.80%
Solar Saving Fraction – Passive Systems Exposed Surface Area Direct Saving – Screened Porch Greenhouse Effect 392 m <sup>2</sup> 42.80%		
Coeficiente Global de Pérdidas (G)		
	Area (A)	(A). (K)
CNP		7083.195
Vent. norte	391.98	1685.514
Vent. este y oeste	29.64	127.452
CGP		8876.161
Factor "G" - Norma IRAM 11604		0.7

The ground and first floors, have a HLFF of 0.47, while the third floor's HLFF is 1.4. This difference is caused by the roof exposure. Using thermal insulation on the terrace has been considered to reach levels which are even higher than the standards required by the national regulator entity IRAM and with an international point of view (LEED) (Table 1).

6. Energy production by photovoltaic technology: Bearing in mind the actual energetic demand (164Kw), and trying to minimise the network's energy consumption; the plan is to install and distribute photovoltaic panels by polycrystalline or monocrystalline silicon modules, all connected among themselves. The park's rated power will be 50 kW.

There will be 200 polycrystalline solar panels of 250w with 1,65m<sup>2</sup> surface area each. They will cover a surface area of 165m<sup>2</sup> on the building's roof, having an optimum slope of 30° to 45°. The technical aspects to be considered are the following:

Maximum Power=250w; Short-circuit current=8.93 A and Maximum Voltage=29.81 V

## Conclusion

The programme description, urban landscape settings, the building's position in the plot and the resources economy, allow to see the determining criteria for the project's sustainability. The material-construction stage aspects, the chosen technology, the method used and materialisation, stand out as being compatible with the environmentally friendly purposes. This material and formal elements combination's behaviour, have an optimum result regarding its energetic efficiency.

From this analysis we arrive to the conclusion that the juxtaposition between the chosen material systems and the relevance of its construction techniques, create certain tension regarding current sustainability correction criteria.

## RED on RED

### A Framework for the Interaction of Color in the Build Environment

Esther Hagenlocher<sup>1</sup> and Landry Smith<sup>2</sup>

<sup>1</sup> Department of Architecture, University of Oregon, Eugene, OR, USA, ehg@uoregon.edu

<sup>2</sup> Landry Smith Architect, 2336 SW Osage St, Portland, OR 97205, USA, els@landrysmith.com

**Abstract:** This project is based on a proposal for a temporary experimental installation for the International Garden Festival at Les Jardins de Métis in Grand-Métis, Quebec, Canada. Building upon Josef Albers's seminal primer on color theory, *Interaction of Color* (Yale, 1963), the garden project was designed to establish a new framework for experiencing and testing color perception and sensation in a larger field. *Interaction of Color* is valuable architecturally, aesthetically, and in terms of performance. The effect of color can be increased without changing people's perceptions of the color in a space by understanding the interaction of color with the larger built environment in nature or within larger fields. The proposed research project focuses on the connection between design principles and color interaction in order to develop our understanding of how to optimize spatial efficiency, performance, and visual comfort. This research also explores the potential.

**Keywords:** Colorreflectivity, Color Experimental Spaces; Color Perception and Performance

#### Introduction. Initial Garden Project

This research project is based on a proposal for a temporary experimental installation for the International Garden Festival at Les Jardins de Métis in Grand-Métis, Quebec, Canada. Building upon Josef Albers's seminal primer on color theory, *Interaction of Color* [1], the garden project was designed to establish a new framework for experiencing and testing color perception and sensation in a larger field (Figure 1). The proposed garden installation measures 10x20 meters and is surrounded by an open perimeter fence, with entrances located at the east and west ends. Inside are seven walls or fences that organize the plan into eight equal bands, each measuring 2.5x10 meters. Breaks in these interior fences delineate larger spaces and allow for numerous pathways through the enclosed garden (Figure 2). Countering the geometric rigor, the breaks in the fences filter visitors through the garden, loosely defining larger spaces and providing entry points on the east and west sides along the main pathways. Continuous beds of thyme are planted along the organizing bands and are crossed over by visitors (Figure 4).

All the fences are made of painted wood and are characterized by fine slats oriented at 45 degrees and -45 degrees, alternating orientation at each layer. The diagonal slats of the open walls in the garden alternate at each layer, resulting in a series of spaces of intensifying color and opacity at eye level. Recalling the common wooden lattice, these diagonals establish a decidedly supergraphic element in the garden project.

Figure 1: "Red on Red" Garden Entrance Elevation

The artificial tectonic expression serves to abstract the modest methods of construction and articulates a complex set of color effects through minimal means. The perceptual dimensions of color were selected on the basis of contrast and an interest in interaction, participation, and exchange. A range of reds was selected for high contrast with the greens of the surrounding forest and garden plantings, underscoring the contrast between natural forms and the graphic tectonic. The perimeter fence is a pure red. The other fences are painted varying red hues, some of which are tinted (white added), others toned (black added). Since colors of equal brightness but differing hues tend to assume the same spatial plane, the three-dimensional organization of the garden is at times challenged, and an element of spatial ambiguity is introduced. The specifications of the reds used were based on my previously conducted experiments on color reflectivity. These experiments suggest that although our aesthetic valuing of deep colors often conflicts with the high reflectivity that is more effective for daylighting, the average reflectivity of an interior space can be increased without changing people's perceptions of the color in the space. The experiments were conducted using color models of rooms to compare subjects' perceptions of colors and reflectivity to actual measured reflectivity.

### The Colorfulness of Color

Another previous experiment that pertains to this project was conducted to test people's perception of colorfulness. Colorfulness and chroma are described by Mark Fairchild (Wiley, 2005) as comprising one dimension of color (the others being hue and brightness/lightness). In his description, "Colorfulness is to chroma as brightness is to lightness...Colorfulness describes the intensity of the hue in a given color stimulus. Thus, achromatic colors exhibit zero colorfulness and chroma, and as the amount of color content increases (with constant brightness/lightness and hue), colorfulness and chroma increase." Colorfulness is the "attribute of a visual sensation according to which the perceived color of an area appears to be more or less chromatic." Chroma is the "colorfulness of an area judged as a proportion of the brightness of the similarly illuminated area that appears white or highly transmitting."

My experiment on colorfulness looked at techniques that have been used architecturally, such as reflective surfaces. I used a set of experimental measurements to test anecdotal knowledge about the perception of color in space. Seven identical boxes, or models, were built out of black foam board so that no light could go through the edges.

The inside was covered in white for high reflectivity. Each box was 20 x 20 centimeter in plan and 20 x 20 cm in elevation. One side had a central opening: a 5 cm square aperture, called the “window.” On the opposite side was a central viewport of half an inch diameter. The window side, with the 5x5cm opening was colored in a range of 8 different commercial colors, varying in Light Reflectivity Values from 0% to 99%. The colors are listed, along with their LRVs (percentages): Exotic Pink 68,3% Flamingo’s Dream 40,2%, Calypso Orange 37,8%, Red 11,7%, Strawberry Red 14,2%, Red 13,2%, Raspberry Truffle 8,5%, Chestnut 7,2%.

In these experiments 50 participants were tested for their perceptions of colors. The boxes, each with different shades of red on the inside surface on the wall with the window, were observed in varying stages of light. Observations were made at a distance of 5 to 6 feet, monocularly. In a frontal and parallel position, each human subject tested placed the box in front of her/his face, with her/his eye tight against the viewport, looked through the ports of the boxes, and described their perceptions of each color at three different light levels:

a) bright (a light source), b) not so bright (a white wall), and c) the transition between them (a gray wall). The questions asked were: Which is the most colorful wall? Which is the most colorful box? Despite the actual performance of the Light Reflectivity Value in the color range of eight shades of red, the boxes with the “Flamingo’s Dream (LRV 40.2%) and Calypso Orange” (LRV 37.8%)” were perceived by most of the observers to be the most colorful. It proofs that the most colorful colors are not necessarily the darkest ones. This result contradicts the assumption that colors with the lowest reflectivity values are the most colorful.

A follow-up experiment, The Appearance of the Color Red, was conducted. Mark Fairchild (Wiley, 2005) writes in “Color Appearance Terminology”: “While color is typically thought of as three-dimensional and color matches can be specified by just three numbers, it turns out that three dimensions are not enough to completely specify color appearance. In fact, five perceptual dimensions are required for a complete specification of color appearance: Brightness, Lightness, Colorfulness, Chroma, Hue.” In this second experiment on the appearance of red, I built a series of boxes, or models of rooms, to address the question of reflectivity with changing room configurations. Each of the boxes represents a room with a window on one side, as described in the previous experiment. One set of boxes had the color at the window side; another set of boxes had the color on all fives sides except the window side. The project was designed to study the relationship between the amount (size) of color—and its location and reflectivity—and the human perception of it, along two variables: How the daylight factor changes under the same light The boxes provided a limited point of view. Participants could not see the whole space; they could only see the opposite wall with the window and a quarter of the neighboring walls. The experiment showed that the Average Room Reflectivity (ARR) changes very little within the range of colors from an LRV of 7% to 68 % if only one wall is colored. But the ARR changes dramatically when all five sides are colored. The question asked was: Which is the most colorful room? Each version of the boxes tested (1 wall colored or 5 walls colored) showed the same result, which indicates how important the field of view is and that controlling the view is a way to make a space appear colorful. These experiments showed that the eye is capable of making separate judgments about color reflectivity, and therefore the results provide a point of departure for the selection of color for the garden project: That the most colorful colors are not necessarily the darkest ones (Figure 2).

How do these findings translate to an exterior space? The results of this red viewing test based upon 50 participants were discussed and used to determine the selection of the

different reds and their positions in the garden project. This experiment showed that the eye is capable of making separate judgments describing color appearance and perception.

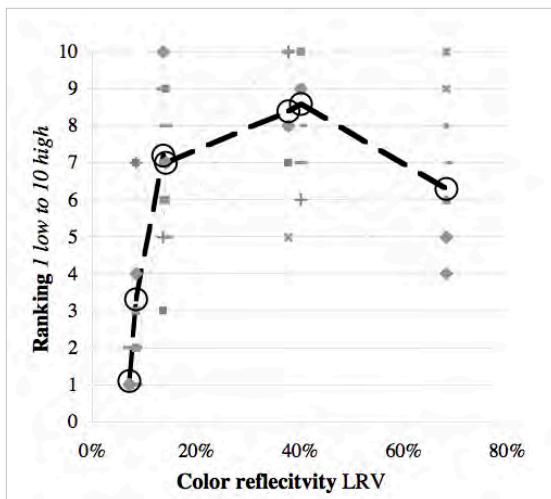

Figure 2: Observers perceived a room to be the most colorful when it was in the reflectivity range of 30-40%.

Therefore the 8 different reds used under the same set of viewing conditions (indoors and outdoors) including reds with significantly different light reflectance values, yet same size, texture, sample type and set-up, have been used for the garden project. It was found that human subjects' results are with little difference or similar to the tested performance of the reds to the empirically location of the colored fences in the garden project. The reds with a LRV 40%-60% have been perceived with the strongest interaction of color in the garden project. With the garden-project we understood that the interaction of the painted slats both with each other and with the colors in nature would remain a dynamic condition. By interspersing small areas of color through the slats, the project highlights the relativity of color and serves as a playful manifestation of the Bezold Effect—that a color may appear different depending on its relation to adjacent colors. The garden is an invitation to see and celebrate that interaction on multiple fronts (Figure 5).

### Garden Project Revisited and Expanded

Using the initial garden proposal as a point of departure, this project delves into the history of color experiments focusing on visual perception and the analysis of color, intensity, flicker and ambience within larger fields of interaction. The objective of this research project is to study, test, and evaluate a series of multiple and complex visual effects as they occur in the built environment and in nature. The project aims to expand upon Albers's color experiments in this larger field and to examine the potency of his discoveries outside of his regulated and abstract color experiments. To what degree do the experiments in *Interaction of Color* translate to architectural spaces— both interior and exterior? What are the limits of these color effects? What is their potential in larger and more complex fields?

Hypothesis: Interaction of Color is invaluable in aesthetic, architectural, and performative terms. Our research project focuses on the connection between design principles and color interaction in order to develop a better understanding of how to optimize spatial efficiency, performance, and visual comfort. This research also explores the potential for using colors to expand, confuse, conceal, and misrepresent built three-dimensional forms.

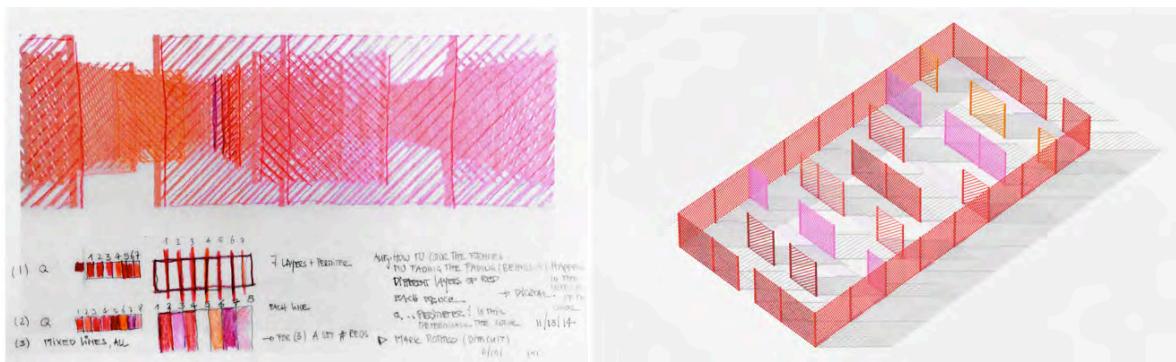

Figure 3 and Figure 5: "Red On Red" Sketch Color Pencil. Concept Axonometric

The effects of color interaction in architecture are neither widely applied nor understood in the field. The color experiments, observations, discoveries and explanations of Joseph Albers represent an untapped potential to further expand our knowledge about color interaction as more variables are introduced. To test the hypothesis, the perception of color interaction will be assessed empirically. The proposed subsequent studies and iterations will largely maintain the existing formal strategy and will focus primarily on the effects of color and reflectivity, understanding the interaction of the painted slats, both with each other and with the colors in nature, which are in a constant state of flux over the course of the day and seasons of the year, as a dynamic condition. This project asks similar questions to those of Albers: What colors recede? What colors advance? What colors appear to share the same spatial plane? The study will seek to amplify the relativity of color: that a color may appear different depending on its relation to adjacent colors. How does color interact outside of Albers's two-dimensional color experiments? What is the dimension of color in space? We anticipate comparable results of color interaction, and will test the interaction of color in space through a battery of empirical tests within a structured exterior construction (Figure 3). The research projects developed a series of scale physical models in order to test the interaction of color within larger spaces and environments. The models explore color interaction by using a range of graphic techniques to maximize the relative appearance of a color in relation to adjacent colors when these fields are interspersed.

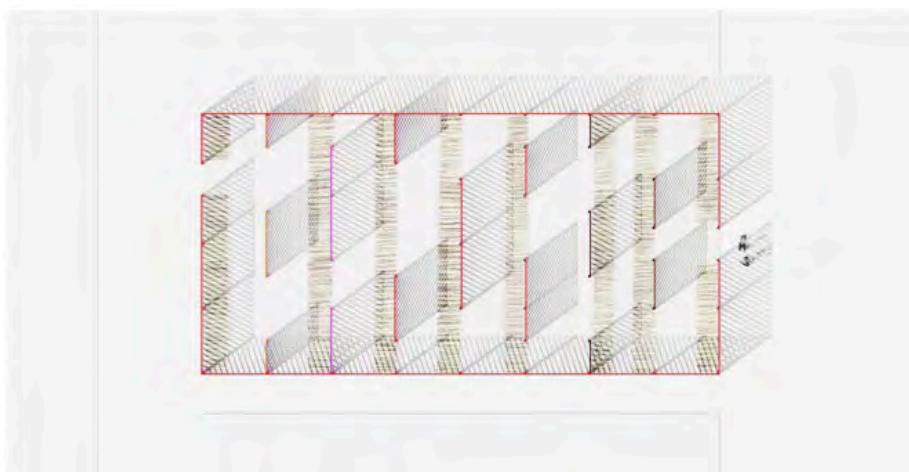

Figure 4: "Red On Red" Garden Plan

#### Guiding Research Questions and Experiments:

- Can we achieve the perception of intense colors while also providing little color?

- How can space be colorful without using too much color? Moreover, what is the minimum required?
- What is a strategy for color interaction in nature—with the plants, the sky, the seasons?
- How do we apply the *Interaction of Color* to conditions that are in a constant state of flux?
- Building on El Lissitzky and Theo van Doesberg, are there other ways to challenge the primacy of spatial form?
- In what ways can the use of color alter or deny three-dimensional space?
- Can spatial composition and color be at once independent and dependent systems?
- How can one minimize and/or maximize the optical destruction of volumes and forms in space? What are the fundamental techniques?
- What are the potentials of the Liebermann effect—where two colors that are of equal brightness but differing in hue assume the same spatial plane?
- What are the ways that built forms can generate the atmospheric effects of a Seurat painting? How can the viewer assimilate colored elements?

### **Evaluation of Reflectivity: The Experimental Garden**

These effects will be investigated in a larger context of variables, including daylight, shadow, background conditions and colors (seasons and plants), and the position of the viewer. The following issues will serve as key points of investigation:

- The outline and definition of space through color.
- The undermining of architectural space through color application.
- Spatial effects of color, including compression, extension and resolution of volumes.
- Connection and disconnection of spatial elements by color.
- Contrast effect of color especially in outdoor and/or daylit spaces.
- Experimental measurements to test anecdotal knowledge about the perception of color in space.

### **The Experiments**

The initial proposal for the “Red on Red” Garden was an experiment designed to observe how color interacts in an outside landscape. Special attention was given to background, horizontal and vertical vantage points, and changing light conditions. Further experiments are based on the planometric geometry of the initial garden proposal—a 10 x 20 meter area surrounded by an open perimeter fence and subdivided by a series of open fences into eight equal bands, each measuring 2.5 x 10 meters. In the experiments, several variables were introduced: color, reflectivity, ordering, height, density of the slats, time of day, time of year, and the relative position of the various viewers.

A set of 8 colors may be assigned to the garden: 1 color for the perimeter condition and 7 colors for the seven interior fences, whereby each plane of the project has a specific color assignment. The colors may be matte or glossy (varying degrees of reflectivity). The assignment of colors and their sequential order could be reorganized. While the regulating plan geometry was fixed, the position and site of the openings that allow people to pass through the garden could be changed. All fences, however, would remain equally spaced at 2.5 m and be parallel with each other and perpendicular to the viewer and direction of

movement. The overall structural support positions would remain, but the height of the garden walls could be increased up to +1m or reduced up to -.5m from the original 2.5m above the ground plane. For each of the experiments the height of the fences is constant in each configuration. Depending on the eye height of the viewer and the height of the fences, the illusion of spatial advancing, or spatial receding, could be reinforced. The parallel fences form a series of vertical and horizontal transparent planes. If the planes of color generated by the fences form a series of concentric rectangular planes of color, the spatial effects are reduced to a minimum. In the case of the initial garden proposal, given an average eye height of approximately 1.57m and a fence height of 2.5m, the color sequence appears to advance counter to its plan metric organization or spatial ordering generated by the colors because of the larger areas of color that appear in perspective on the lower boarders.<sup>1</sup> The dimensions of the individual diagonal slats that comprise the series of parallel fences remain constant. Similar to the original garden proposal, the slats are always oriented at 45 degrees and -45 degrees, alternating orientation at each layer. The spacing of these slats, however, can either be doubled or reduced to half the dimension of the original garden proposal for each wall. The effects produced are known as the von Bezold Spreading Effect (sometimes referred to as spatial color mixing), which is facilitated by the alternating direction of the slats as well as the staggered positioning of the openings in the fences.

Additional variables in the experiments are environmental and perceptual in nature. The time of day was examined for the summer and winter solstice, as well as the autumn and spring equinox—both in direct sunlight and under a cloudy sky. The garden was re-oriented from its original position so that one of the entries faced north. Similarly, the surrounding forest, garden, and sky color reflected typical seasonal and daytime changes. Because these environmental inputs frame the color experiment of the colored fences, the vertical, horizontal, and diagonal boundaries between colors and fields of perceived color may be either strengthened or softened depending on the hardness or level of contrast with the skydome and surrounding vegetation, based on the weather and time of day and year.

Cinematic studies involving a series of stills moving though the various test gardens were developed for each of these conditions (time of day, year). Views were methodically recorded at eye level starting at one entry (moving south to north) and taken at each subsequent fence plane until the other entry was reached. A similar recording was made moving in the opposite direction (from north to south). Records were produced recording these variables, compared and analyzed. Depending on the colors and the order chosen, the garden at times reinforced its own organization, and at other times confounded it. When color and form were in alignment, the garden, or parts of the garden, could be regarded as a functional use of color: color as a means to orient and provide three-dimensional information. However, when the viewer is moving in the opposite direction in the garden, the same colors could have the potential to take on a more de Stijl approach, especially that of Theo Van Doesburg, to confound and disrupt architectural space. In these instances color refuses its typically secondary role in architectural space-making as a decorator or informant.

---

<sup>1</sup> The effect of this, as was discovered by Josef Albers and articulated by his student Lois Swirnoff, was "that the illusion of spatial advancing or receding with perceptually mixed colors can be reinforced or diminished by their placement within the vertical/horizontal frame of reference. When seen as concentric groupings, with all intermediate areas appearing equal in size, the spatial effect is diminished. When aligned with unequal amounts of areas or bands of color visible in the upper and lower fields, the perspectival spatial placement reinforced the illusion. With a large area of colors visible along the upper boarders, the groupings seemed to recede in space." p. 44

Here it is not so much the artist playing a subversive or perverse role in the relationship between color and space, but rather the viewer.

## Conclusion

Although these are preliminary experiments and results, the implications were of sufficient interest to continue the work to explain and demonstrate how color can alter our perception of space. Multiple personal tests are being conducted, and we will increase the number of human subjects. These results will be evaluated to establish rules and guidelines for the interaction of color and for color perception in larger fields.

These guidelines will inform design applications for the use of color in architectural spaces and other environments and will be pursued further in a larger experiment. These initial experiments showed that color is much more than a paint or a coating; it is rather a dynamic and highly subjective element. Contrary to its often ascribed secondary role in architecture, color has powerful dimensional potential on par with form itself. These experiments underscore the ongoing significance of Albers's body of work and the continuing relevance of his color experiments.

Architects and designers underestimate colors and their dimension in the built environment and cannot understand the special quality and characteristics of color and color combinations by looking at colors in isolation or without a larger context and field of color interaction. The implications from the results of these experiments are that designers should not rely on their intuition but need tools to apply color and its interaction in all kinds of spaces: interior architecture, architecture, landscape architecture and urban planning. We see this as it is presented as both an ongoing research competition entry and a broader more general research project on the theme of color and form in architecture.

## Theory and Precedent in the Design of Sustainable Environments: A Case Study of Two Schools of Art – Manchester and Glasgow

Prof Dean Hawkes<sup>1</sup> and Dr Ranald Lawrence<sup>2</sup>

<sup>1</sup> Darwin College, University of Cambridge, duh21@cam.ac.uk

<sup>2</sup> Department of Architecture, University of Sheffield, ranald.lawrence@sheffield.ac.uk

**Abstract:** The design of a modern building, not least a building that seeks to achieve the greatest efficiency in its environmental design, is substantially a matter of quantification and computation. Design objectives for environmental performance are stated numerically and are assessed using tools such as computer models. But the analytical tools of building science do not directly inform the initial design idea for a building. This frequently derives from reference to *precedent*. This paper presents an analysis of two recently completed designs for schools of art, at Manchester by Feilden Clegg Bradley Studios and at Glasgow by Steven Holl and, in which the architects adopt distinctive approaches to environmental precedent. As background the paper illustrates the significant 19<sup>th</sup> century art school designs in each city, by G.T. Redmayne and Charles Rennie Mackintosh respectively.

**Keywords:** Theory, Design, Precedent, Environment

### Introduction

In a previous paper (Hawkes, 1996a) it was argued that precedent, reference to previous examples of a building type, plays a fundamental role in the development of designs in architecture. Using the example of auditorium buildings it was shown that, even following the development of the modern science of architectural acoustics, precedent continued to be the principal influence on the initiation of a design idea. This paper further examines this proposition in the relation to the design of sustainable environments in modern buildings by considering the design of two recent buildings for schools of art at Manchester and Glasgow. In each case reference is made to the influence of major 19<sup>th</sup> century buildings on their respective modern counterparts.

The original building for the School of Art at Manchester, designed by G.T. Redmayne, was completed in 1881. In 1893 a deputation appointed to write the brief for the new School of Art at Glasgow visited the building. That building, designed by Charles Rennie Mackintosh, was completed in 1910 and is acknowledged to be the masterpiece of its architect. Environmental factors were central to the design of both buildings (Lawrence, 2014a).

Common to each was the priority given to the design of painting studios, where the emphasis was on the quantity and quality of natural light. But, of equal importance, was the attention paid to the design of the thermal environment in which advanced mechanical systems were adopted and integrated into the physical fabric of the buildings. In the first years of the 21<sup>st</sup> century these two institutions have built major new additions to their

campuses. At Manchester by British architects Feilden Clegg Bradley Studios (FCBS) and at Glasgow by New York architect Steven Holl, with JM Architects, Glasgow. It is an intriguing and instructive exercise to draw comparisons between these and their respective 19<sup>th</sup> century predecessors. The following description and analysis places particular emphasis on questions of environmental design and sustainability and explores the relationship between the new buildings and their neighbouring, historic precedents.

Figure 1. Four Art Schools. Left to right: Manchester (1881, 2014); Glasgow (1910, 2014).

### Description: 19<sup>th</sup> century buildings

#### *Manchester School of Art*

Redmayne's Manchester School of Art is on the south side of All Saints Gardens. Its austere, north-facing, symmetrical yellow sandstone Venetian façade is a late example of gothic revival. Behind the façade, however, is a remarkably functional response to the 'cold, foggy and dark climate' of the 19<sup>th</sup> century city, 'its disagreeable qualities much heightened by excessive smoke' (Manchester School of Art, 1874).

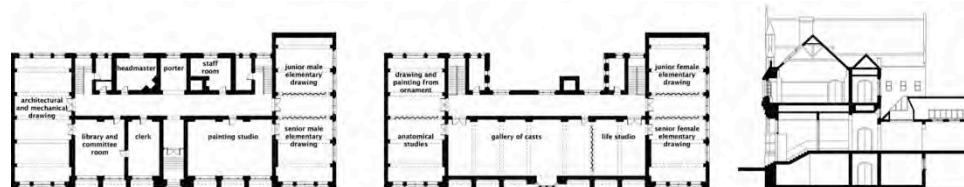

Figure 2. Manchester School of Art. Left to right: Ground Floor Plan, First Floor Plan, Cross Section looking east.

The plan is broadly symmetrical with a centrally located entrance. A corridor runs the length of the building connecting two large studios in east and west wings, with staircases rising up to the main studio floor and down to the workshops lit from lights to the pavement. The main Gallery of Casts on first floor (the principal drawing studio) is lit by a large skylight disguised behind the parapet in the north pitch of the roof. This feature is a development of official guidance, which stated windows should be at 'a height above the floor equal to  $\frac{3}{4}$  the depth of the room, or if the pitch of the roof be steeper than 60°, a skylight should be made in conjunction of the window, so as to gain the same effect in lighting' (Department of Science and Art, 1888).

The quality of the interior environment is controlled by a displacement ventilation system, with inlet grates set in the floor, and outlets through the spine wall to a plenum running the length of the building to a large chimney located to one side of the entrance at the rear of the building.

### **Glasgow School of Art**

The Glasgow School of Art was constructed in two phases, the eastern portion between 1897 and 1899, and the western portion between 1907 and 1910. The orientation of the building takes full advantage of the northern aspect of the site on Renfrew Street.

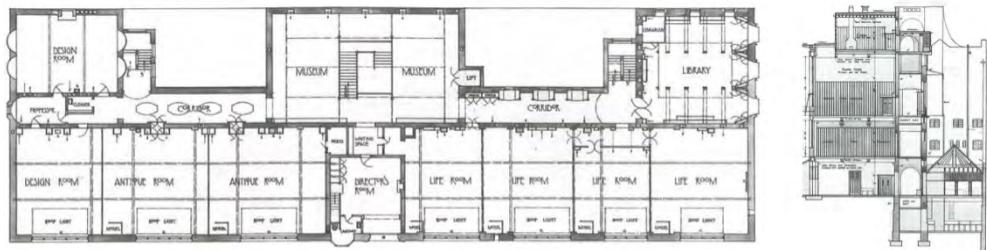

Figure 3. Glasgow School of Art. Left: First Floor Plan; Right: Cross section looking east.

The layout of the environmental systems, an evolution of those installed in Manchester, mirrors the organisation of the plan of the school, with a fan room located directly underneath the main entrance drawing air over heating coils into the main plenum which runs underneath the length of the basement corridor. Ducts rise up vertically from this plenum feeding the studio spaces and corridors to either side of the spine wall, which serves as the thermal ‘hearth’ of the building in section, dividing north-facing studios from the library, museum, workshops and other circulation spaces to the south. Contemporary testing of the school reveals the fine-tuning that was conducted to ensure that this sophisticated system was adequately warming the spaces located furthest away from the fan room. The heating engineers reported that the system exceeded expectations, with internal temperatures in the studios around 60-61°F [16°C], given external temperatures between 41-48°F [5-9°C]. (Lawrence, 2014b).

### **Description: 21<sup>st</sup> century buildings**

#### **Manchester School of Art**

Feilden Clegg Bradley Studios (FCBS) was founded in 1978. From the outset a priority was to develop “an environmental approach to architecture” (Clegg, 2007). Over almost 40 years they have produced a body of work in which the meaning of this term has been extensively explored. In a review of the work of the practice one of the present authors (Hawkes, 2007b) proposed that, “each design exhibits the ‘discipline’ that comes from the application of environmental principle, given expression through clarity of form and directness of detail.” It was suggested that, in this respect, the work represented an environmental development of the ‘Functional Tradition’, proposed by the British critic J.M. Richards (Richards, 1958), in which buildings, by their, “expressive use of materials ... display ... the essential attributes of architecture.”

The new building for Manchester School of Art, by FCBS, the Benzie Building, is located to the south-west of Redmayne’s building. It incorporates a 1960s extension with a 9-storey tower above a 3-storey podium. The new building is a 4-storey, deep-plan rectangle to the west of this. Topographically the plan is clear. The entire north, a glassy vestibule, dubbed the ‘living room’, occupies the entrance front. Behind this lies the working part of the building, ‘the factory’. At the heart of this, a stepped, top-lit atrium is criss-crossed by staircases and surrounded by four floors of studios and workshops. The building has an

insitu concrete frame, an inheritor of Le Corbusier's 'Domino' frame. This is clearly expressed throughout the interior. The exterior is clad in anodised aluminium panels that alternate with vertical strips of glazing.

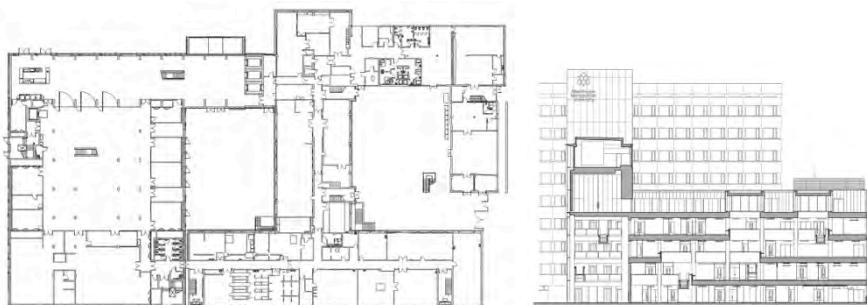

Figure 4. Manchester School of Art. Left: Ground Floor Plan; Right: Cross Section looking east.

Writing about the early work of FCBS, Hawkes (Hawkes, 2007b) identified three consistent principles that informed their environmentalism: *orientation*, *cross-section* and *envelope*. These factors, whilst still identifiable, are here less influential, both formally and environmentally. *Orientation* is acknowledged in the southerly stepping of the atrium of the 'factory' and it is here that the concern with the *cross-section* is most clearly registered. It is with the *envelope* that the design most apparently departs from earlier practice. Here we have a curtain wall, identical on east, west and south façades, with alternating panels of glass and aluminium. The north, entrance façade is a six-storey skin of mirrored glass, differentiated by annodised aluminium fins at high level.

Figure 5. Manchester School of Art. Photographs showing transitional spaces. All 1/30 sec at f/3.5, ISO 200.

A single storey porch entered centrally through automated double doors articulates the entrance to the building. This provides an air-lock before the entrance to the circulation hall itself. This light-filled space is photogenic and has become the social centre of the building, justifying its designation as the 'living room' (figure 5, top left). Beyond the 'factory' is more utilitarian and presents a gradual transition into dimmer spaces that are more and more closed off from the outside world, with daylight replaced by the uniformity of energy efficient lighting calibrated to provide precise lumen levels upon detection of occupancy. This artificial light is provided by cylindrical metal lamp fittings set in the concrete slab and

fluorescent tubes set into the suspended acoustic panels that line the ceiling of all the balconies and studios.

The thermal environment is controlled by a combination of air-handling units with underfloor heating. The system provides different volumes of air according to occupancy levels in different spaces, and recovers heat from the air for use in cold weather. It can also supply recirculated air in conditions of low occupancy. A 2015 post-occupancy survey (Pendergast, 2015) indicates that temperatures are considered too hot in both winter and summer (mean scores of 5.00 and 5.63 on a scale from 1: too cold – 7: too hot, which translates into an average score of +1.32 on the ASHRAE Thermal Sensation Scale). 59% of respondents reported no control over ventilation, and 37% reported that the temperature has a negative impact on their work. This suggests that the internal temperature as controlled by the Building Management System may not reflect seasonal variation in external conditions, leading to discomfort, as users are more conscious of their adaptation to the internal environment. The survey records that annual energy use (including both the new building and the refurbished tower) is around 191kWh/m<sup>2</sup>.

### **Glasgow School of Art**

In 2009 Steven Holl won the competition to build a new building for the Glasgow School of Art. The Reid Building, executed in collaboration with JM Architects Glasgow, was completed in 2014. The site is directly opposite Mackintosh's original building and it is appropriate to discuss Holl's design in relation to that. The ground plans of the two buildings show their broad similarity. Each is a clear-cut rectangle with relatively simple spatial organisation. It is the cross-section that is the key. In both designs the dominant factor is the priority given to the north orientation of the main teaching spaces. For Mackintosh the windows of the north-lit painting studios are the dominant element of the main façade, but for Holl the faceted glass of the studio elevation fronts a lane to the rear. Mackintosh's plan is divided by a masonry spine wall that directs the main horizontal circulation of the building. To the south of this lie a variety spaces, small and large, whose uses positively enjoy direct sunlight from the south. Holl follows a similar principle, although now the spine wall is replaced by a complex void that divides the building into north and south zones and through which runs a sinuous circulation route.

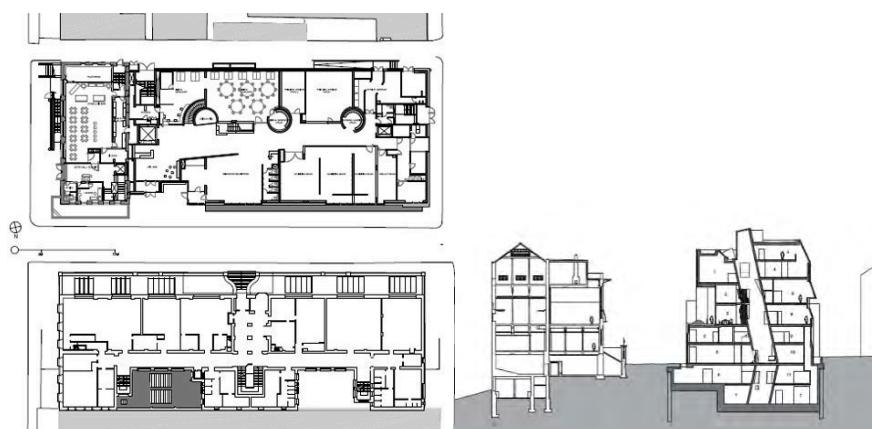

Figure 6. Glasgow School of Art. Mackintosh and Holl Buildings. Left: Ground Floor Plans; Right: Cross Sections looking west.

The structure of the building consists of in-situ concrete load-bearing cross-walls that support the floor slabs. The external envelope is also of in-situ concrete, but clad in a taugh

glass skin, translucent over solid walls with an over-cladding of thermal insulation and transparent at openings. Prominent elements of the building are the three 'driven voids' that cut through and animate the central circulation space from basement to top, maximising the penetration of natural light deep into the building.

Figure 7. Glasgow School of Art. Photographs showing circulation space. All 1/30 sec at f/3.5, ISO 200.

The environmental strategy of the building is summarised in Fig. 8. This illustrates the adoption of a series of principles that contribute to both the environmental quality of the interior and to economy in its operation. These include the use of exposed thermal mass in the ceilings, high performance glazing and building lighting controls. The 'driven voids' are used to facilitate stack ventilation throughout the building. A new biomass boiler jointly serves this and the Mackintosh building. Other features are storm water harvesting and accessible areas of green landscape.

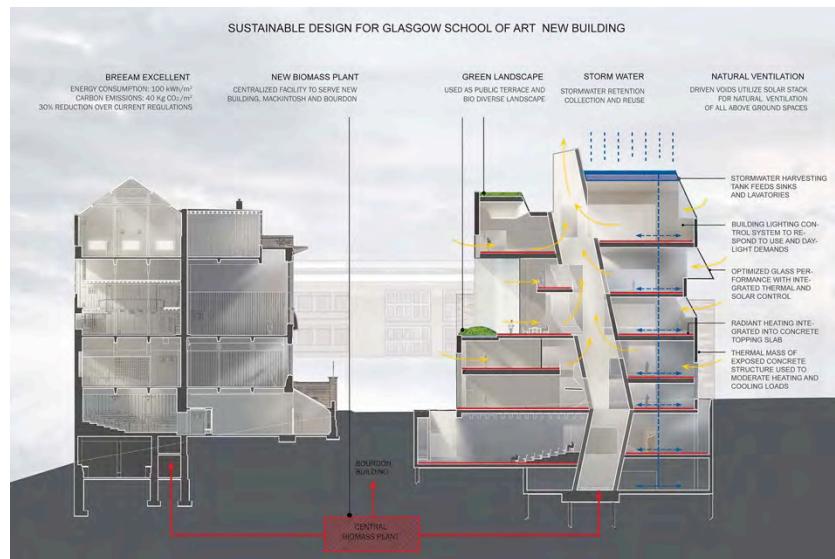

Figure 8. Glasgow Sustainable Design.

A survey of 72 students conducted by one of the authors in the new building indicated that students found the building to be on average slightly warm (+0.76 on the ASHRAE Thermal Sensation Scale), but when questioned about their thermal preference they desired little or no change to the temperature (+0.25). This shows that mechanical servicing does

not necessarily equate to improved occupant comfort, and, furthermore, that the capacity for users to control and to fine-tune environmental conditions in different spaces afforded by a more passive strategy (such as in the Reid building) can provide more opportunities for occupants to adapt to their internal environment in different seasons. Annual energy use in the Reid building is around 182kWh/m<sup>2</sup>. (Stewart, 2017)

Figure 9. Lighting conditions in new studio spaces in Manchester and Glasgow. Both 1/30 sec at f/3.5, ISO 200.

## Discussion

In the 19<sup>th</sup> century the ‘purpose-built’ art school was a new building type. But, as we have shown, the designs at Manchester and Glasgow rested upon well-established conventions of architectural composition, of symmetry and style that informed the new urban building types of the time. Environmentally, whilst both buildings incorporated ‘advanced’ systems of warming and ventilation, their form and detail followed from the historic need to design with natural light. In other words, the design of these ‘new’ buildings was informed by precedent. We have also shown how the Manchester building became, within ten years of its completion, a direct reference – a *precedent* – for the Glasgow building. A century later much has changed. Architecture has experienced the paradigm shift of the Modern Movement and, within this and, perhaps, as a consequence, the basis of environmental design has been transformed in its priorities, method and technology. In addition to providing good physical environments in buildings we now have the obligation to minimise the impact of buildings on the local and global climate. Environmental requirements are now defined quantitatively and design proposals are assessed using sophisticated computer models. Building materials and environmental technologies have changed out of recognition.

The two new art school buildings studied here are quite different in conception. At Manchester the building by FCBS is, in form, material and technology, demonstrably of its time. It may be placed in the lineage of the practice’s earlier work, with its environmental emphasis and acknowledgement of the influence of the ‘Functional Tradition’ and its legacy in the Modern Movement. Its relationship to its 19<sup>th</sup> century predecessor is, perhaps, quite remote. Steven Holl’s Glasgow building is also of its time, as is declared by its initially startling appearance, behind which we find advanced constructional methods and services systems. But the influence of Mackintosh’s building across the street is powerfully present, not least in environmental matters. This is shown in the cross sections, where both buildings adopt the same principles of orientation in determining the disposition of spaces and in providing daylight throughout the building. Our comparative studies show that both new buildings achieve a high standard of energy efficiency. In their environmental intentions, however, they are quite different. The Manchester building, with its clear differentiation of zones, adopts a utilitarian perspective. The social territory, the ‘living room’, is flooded with

daylight from the north-facing floor to ceiling glazing. In contrast, the studio is designated a ‘factory’ in which the environment is a matter of mechanical management and predominantly artificial lighting. At Glasgow the internal environment is more diverse, with a variety of room sizes and types, almost all daylit. A quantitative and qualitative comparison between the buildings may be seen in the images at Figs. 5 & 7.

## Conclusion

Where then does precedent now stand in environmental design practice in architecture? The argument for reference to precedent is that pre-existing designs provide a degree of security in the production of new buildings. They embody principles from which development and innovation may proceed. We suggest that the Reid Building at Glasgow School of Art reveals a deep influence from Mackintosh’s original building. This is not a superficial procedure, but derives from analysis and reinterpretation of the lessons of the earlier building. This is precedent at work. In apparent contrast the Benzie Building at Manchester exhibits no direct reference to such antecedents. Nonetheless it is not free of influence. The ‘Modernist’ frame construction is a convention in contemporary design. More important is the accumulated experience and expertise of FCBS in its 40 years of environmental design practice. This constitutes a body of knowledge that itself acquires the status of precedent.

*Design to Thrive*

## Towards a Tropical Architecture: Modernism in Northeast of Brazil

Daniele Abreu e Lima

School of Architecture, Victoria University of Wellington, New Zealand

**Abstract:** The participation of Pernambuco State in the development of the Brazilian Modern Architecture begins from the first stages of the Modernism in the country. In the city of Recife, the debate related to the new architecture falls on a basic theme; the tropical climate. The identity of the architecture should not have only national features but most of all, a regional one. The climate was the principal excuse to support the creation of a new architecture that not only was able to respond to the necessities of a new era, a new time, but also bring climate comfort, which is essential to the life on the tropics. After a heroic beginning, Modern Architecture came to a period where few buildings were constructed, but from the 1950s this all changed. In the following decades there was a clear option for the Modern language for the architecture of Pernambuco State in the hot and humid north of Brazil. The dominating characteristics of Modern Architecture in that state was the experimentation in the creation of formal elements for climate adaptation. Although with distinct formal manifestations, the proximity of the projects methods and the ideology of the architects at work in Pernambuco at the time, indicate similar references. But, to which point these created elements really worked? Were the architects interested in the creation of a tropical modernism? To answer those questions I collected data on 140 buildings constructed between 1950 to the end of 1970s in the city of Recife. I analyzed their formal, thermal and lighting aspects to see if those building conform to the clear views expressed in the Modern tropical speech of the architects of the time.

**Keywords:** Tropical Architecture, Brazil, Recife, Modernism. Final paper upload

### Introduction

The Modern Movement arrived in Brazil at a very significant moment in the country's history, when the discussion around a national identity in architecture was topical. It is quite ironic that at the time the formal modern prototype was received not as a tradition breaking tool, but in fact, as a *tabula rasa* where the fusion of the colonial past with visions of a progressive future could happen (Costa, 1962). Therefore, modern architecture offered a new and acceptably genuine Brazilian tradition divorced from negative imperial symbolism and with a clear vision of having a modern country. The work of Brazilian pioneers such as Lucio Costa and Oscar Niemeyer and the tacit adoption of modern architecture by the Brazilian government finally guaranteed the triumph of modernism as the symbol of a national architecture (Segawa, 1997).

However, the discussions concerning the new architecture in Brazil were more nuanced than one might imagine, and indeed had many different aspects. It was clear that Brazilian architecture at the time did not partake of a single unifying national attribute that was not copied from Europe; being a country of continental dimension there were quite a few identifiable regional features (Berquo, 1998). The modern discussion tended to emphasize the creation of an architecture adapted to the country's climate conditions and, therefore, a real identity-related solution for Brazilian architecture (Bruand, 1981). The problem then

became the identification of this national climate. The reality is that the climate throughout the year in the various regions of Brazil differs greatly (Frota & Schiffer, 1998). If an architectural pattern seems appropriate for the cities of Rio de Janeiro or São Paulo, could it be right for a region such as the Amazon, or for Brazil's Northeast coast, where humidity and heat are so much higher?

The intention of this paper is to discuss a type of architecture created in and for the city of Recife, which represents the model built in the northeast of Brazil from the 1950s to the late 1970s. With reference to this subject and relevant to this paper, the main, and most intriguing aspect is whether the architects were justified in creating a School of Architecture with a distinguished style based on responding to the climate (Abreu e Lima, 2000).

### **The Climate in the Northeast of Brazil**

In order to understand the issue at hand it becomes necessary to first discuss the climate of the northeast region of Brazil. Most of the major cities of this region are situated in the bay areas where the climate can easily be defined as Tropical-humid of low latitude (Frota & Schiffer, 1998). Among its many specific characteristics this climate is defined by its high temperature (IDEM).

In this type of climate the temperature does not vary much between night and day nor even between different seasons (Hertz, 1998). This is due to the constant relative humidity found in the air that does not allow for the sun's rays to elevate the temperature in the day time and will not let the elements cool down too rapidly at night. The lack of great fluctuation in temperature over the whole year round is explained by the low latitude and the constant and stable ventilation of the region (IDEM).

Although high temperatures determine the heat sensation in this sort of climate, it is actually the relative humidity of the air that plays the most important role in human perception (Frota & Schiffer, 1998). With high humidity, human sweat cannot evaporate and without a certain amount of evaporation, an uneasy sensation of heat is perceived (IDEM). But if the body is subject to some air movement (ventilation), even with the temperature and the high relative humidity levels, the sweat produced by our bodies is evaporated refreshingly (Hertz, 1998).

Unfortunately, such simple but quite illuminating technical definitions were not known to the architects of Pernambuco in the beginning of the nineteenth century. Still it was common knowledge that European architecture built unchanged, simply did not work in countries with hot and humid climates and that a good architecture was one which made possible effective ventilation of internal spaces (Serra, 1999). With this knowledge, the question became what would the external appearance of this tropical architecture be like?

### **The Brief but Decisive influence of Luis Nunes**

In the 1930s the State government invited a group of young modern architects to run the department of construction of Pernambuco (Vaz, 1989). This was the first public initiative in Brazil related to adopting modernism as a style in architecture for the construction of public buildings and the only one before the federal government of President Getulio Vargas (Baltar, 1951). Luis Nunes was to run the department of construction and his contribution to Brazilian architecture is quite unknown due to his short career; he died rather prematurely (Baltar, 1963). But among his staff were some young professionals whose work became very well known, such as Roberto Burle Marx, who is renowned all over the world for his landscape design, and Joaquim Cardozo, who after the experience he garnered in Recife, became the

chief engineer on key works of Oscar Niemeyer, mainly in projects such as the Pampulha and the Brasilia National Capital (Barros, 1976).

There was no explicit intention of creating an aesthetic language within the buildings they constructed, but rather a cheap and quick-to-build structures with well-ventilated internal ambience (Marinho, 1989). For this purpose, Nunes and his staff trained the laborers in the production of concrete modular structural elements that were to be made at the construction site itself, and were designed in such a way that they could be repeated in many projects so such elements might be reused (Nunes, 1935). The solutions they came up with for ventilating the buildings ended up offering great inspiration to a whole new generation of architects to come. Their impetus and practice of incentivizing the creation of new ways of adapting a building to a tropical climate were particularly influential.

### The Making of a School of Tropical Architecture

After the Luis Nunes experiments, in the 1940s few modernist buildings were raised in Recife, but modernism was very much a palpable presence in Pernambuco.

With the coming of the 1950s modernism became pervasive in Pernambuco architecture. The question of why this became so must be explained by the academic upbringing of the architects who graduated in Recife (Amorim, 2002). The Faculty of Architecture of Pernambuco had four lecturers by the end of the 1940s, three architects and one philosophy teacher, and these academics had a critical influence on a whole generation of professionals. The three architects were the Italian Mario Russo, the Portuguese Delfim Amorim, and Acacio Gil Borsoi, who was from Rio de Janeiro. The three came from a strong modernist background with lengthy careers both as lecturers and architects.

The skyline of the city of Recife was virtually transformed during the 1950s, and this modernist building bonanza was fueled by an economic boom that occurred during that period. At that time, Russo, Amorim and Borsoi were responsible for planning many apartment buildings as well as important government constructions. As lecturers, they taught the basic principles of modern design, and as architects, they would employ a great number of their students as trainees in their offices and later on, as architects (Amorim, 2002). So, the construction site would invariably become a classroom where their teachings were to be put into practice.

Nonetheless, in spite of these three architects having similar modernist backgrounds, each used different methods and had distinct aesthetic influences. The one element that united the three, and that later on would be recognized as the one characteristics of the School of Architecture, was their inventiveness in creating climate adaptation elements. Following the experience of Nunes, the teachers strongly encouraged the continuous creation or re-interpretation of constructive elements which could offer any betterment in the adaptation of buildings to the tropical climate (Borsoi, 1994).

Fig. 1. Wall tiles patterns designed and used by Delfim Amorim, photos by the author

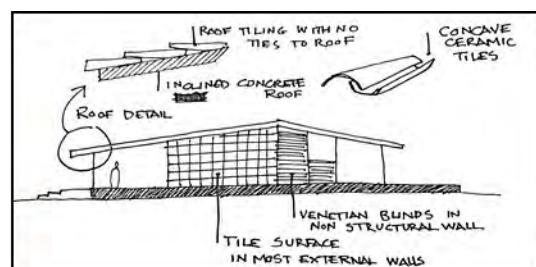

Fig. 2. *Casa tipo* (Type House) by Delfim Amorim, drawing by the author.

Towards that goal, virtually anything was valid, from the use of a different modern architectural vocabulary, via adaptation to the tropical climate, to the reinterpretation of effective solutions from previous architectural styles. An example of this is clear in their use of tiles; their re-interpretation of the use of tiling as an external coating was not something that was in vogue before the 1950s. The Pernambuco architects brought back wall tiling as modern geometric motifs following the Old Portuguese tradition where the same pattern is repeated over and over in the building's façade (Fig.1).

They also re-interpreted the Portuguese-Brazilian traditional colonial roofs. Such a return to traditional roofing was first tried by Delfim Amorim in some housing projects he designed (Amorim, 2002). He came up with a simple solution of a concrete roof just a little tilted, over which the roofing tiles are fixed without any type of wood to hold them in place (Fig.2). This roofing tile design permits the air to travel between the concrete and the tile. Air is not trapped as the tiles are not completely sealed, and in this way there is a constant renewal of air between the concrete and the tile. Although this air movement is not strong enough to move the tiles themselves, it is enough to cool down the roof. With time, this type of roof became so popular and was used on such a scale that it has become one of the major characteristics of the houses in Pernambuco (Amorim, 1999).

Delfim Amorim arrived from Portugal with a strong background in European modernism in which the aesthetics of a building had to follow a clear geometric rigor. It did not take long for Amorim to alter his design method to accommodate the social and economic conditions he found in Brazil, as well as to the climatic conditions of Pernambuco (Amorim, 1988).

With a different approach, the Italian architect Mario Russo understood that the climate condition was just one of the many aspects to be tackled by architecture. Russo was a modernist, not just aesthetically and design-wise, but also ideologically (Cabral, 2001). His buildings followed rational modern principles, searching for answers to the problems faced by the building's design with a detailed study of its functions and necessities (IDEM). His method of design left no space for aesthetic tastes regarding fashion or any type of regionalism. That being said, it is a fact that Russo never departed from the modern flat roof even when a more traditional roof might have been more suitable (Fig.3).

On a curious note, to this day most of the buildings designed by Russo, more than 50 years later are still used without much alteration, such as the examples of the School of Medicine and the University Hospital and it must be said that they still present remarkable thermal and natural lighting conditions.

Fig. 3. Milton Medeiros House, 1956, by Mario Russo, photo by the author

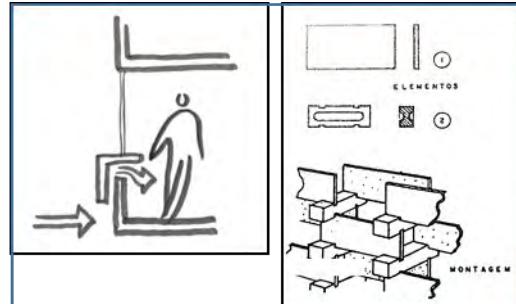

Fig. 4 . 1<sup>st</sup>. drawing: *ventilated sill* created by Augusto Reynaldo and 2<sup>nd</sup> drawing: Acacio Gil Borsoi re-interpretation.

Acácio Gil Borsoi came to Pernambuco from Rio de Janeiro, which at the time was still the national capital of Brazil. His greatest contribution can be found in the development of an architectural design methodology which later would be widely adopted by the majority of architects from Pernambuco (Segawa, 1997). This methodology, though he never called it such, concerned itself with a detailed knowledge of all the components of a given building: its materials and the construction technique to be used, the function of the spaces, of the windows, the doors, even of the hinges (Borsoi, 1961). It is true that his methodology more closely resembled ideological principles found in the *Arts and Crafts* movement than that of the modernists, but as a Brazilian, Borsoi felt that he was free to make his own interpretation of the modernist European movement which he believed, was open to additions and reinterpretations as long as this represented a positive gain to the building (IDEM).

Making use of his detail-specific methodology he systemized the thing that is considered the main characteristic of the architecture of Pernambuco, which is the creativity involved in finding elements for climate adaptation. He was himself responsible for designing various alterations to the *ventilated sill* created by a colleague, Augusto Reynaldo, and to the *cobogos* – a perforated ceramic or concrete block (Fig 4).

In 1963, Borsoi designed one of the most important projects of his career. It was an urban and architectural design for a housing estate made for the Social Organization of the shanty-town of *Cajueiro Seco*, at the time, one of the poorest *favelas* (shanty-towns) in Recife. He proposed a project that was to use local workmanship and a system of construction that was well known to the poorer community, a system called *taipa de pau-a-pique* – lath-and-plaster wall (Borsoi, 1984). This system consisted of the binding of a trellis made of very thin wood that is coated on both sides with clay. Using modern methods of organization and industrialization he modernized the old way of building this type of house turning it into a healthy, quick and cheap construction system. As it was still the same system, the community knew how to use it, so they could build their houses themselves without the need of specialized training (IDEM), (fig. 5). Though aesthetically the houses had no attachment to what is perceived as Modern Architecture, the system in what they were built, the method of assemblage and the possible enlargement of the building were nonetheless based purely in modernistic ideas.

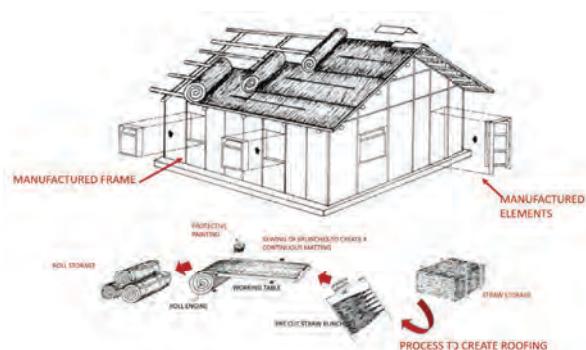

Fig. 5. Cajueiro Seco construction system, by Acaio

Cajueiro Seco became one of the icon examples in Brazil of a cheap alternative to extremely poor conditions that was abandoned by the Government for political reasons. The project, and the architect himself, were considered too left wing for the military dictatorship of the time. The community was abandoned to its original extremely poverty level and some of the land it occupied were sold to private initiative to build hotels.

Nonetheless the ideas Acacio Borsoi, Delfim Amorim and Mario Russo were vital for the creation and the perception of an architecture for Pernambuco by consolidating the ideals of the modern movement with the region's climatic needs (Borsoi, 1994). The aesthetic result of resulting buildings, nevertheless, did not offer much uniformity between them. The one uniform quality that unified them all was their elements of climate adaptation that defined the volumes and the interiority perception. The interior quality of these buildings is acknowledged by the architects of Pernambuco having been directly influenced by another one of the faculty's teachers; he was the Sociologist Evaldo Coutinho.

### The different faces of a single School

Without ever having designed a single building, Evaldo Coutinho had, nonetheless, a most remarkable influence over the architecture of Pernambuco. For him, architecture was the most complex art form and it could not be understood simply as being limited to such physical aspects as walls, sealing, and floors (Coutinho, 1998). A good architectural design had to be related to sensations of wellbeing, where the presence and the idea of beauty was a most fundamental quality (IDEM). This impetus was not related direct to aesthetic taste but to translate itself to fundamental questions, such as the need for and use of natural lighting and human sensual perception of colors and textures, how vegetation played an important part in changing light by diffusing it and generating shadows, and how the proportions of height, width and length impact a person's perception of a given space (IDEM).

Therefore, 'beauty' for Coutinho, was synonymous of a well-adapted building to its climate, where its inhabitants will not feel cold nor heat, but the perfect state of comfort (IDEM). With such principles in mind, the architects went out and would search for the ideal ambience considering the climate of Pernambuco. The use of *brises soleil*, *cobogós* or of any other element of climatic adaptation, does not interfere in the plastic composition, in fact, these elements seem to contribute to the geometrical character of the building.

Other buildings show a greater fusion between the modern form and traditional elements such as venetian blinds, verandas or roof top details. A good example of this type of integration can be found in the "Vila Mariana" Building designed by Wandekolk Tinoco in 1977. The building was designed as a pure white volume following the distinctive language found in the works of Le Corbusier. But here the windows were pushed back 2 metres to give space for gardens on every floor. The intention of the architect was to create internal spaces that were similar to traditional Pernambuco residences, where sight of a vegetation filled garden is the norm. The natural light is naturally diffused by the vegetation and the apartment interiors would feel like the interior of a traditional house (Fig. 6).

Fig. 6. Vila Mariana Build., by W. Tinoco

Another aesthetic tendency of the school of Recife was the design of buildings which deconstructed the pure volume typically found in modern architecture. The nooks and crannies of their volume were justified by the pursuit of greater insolation and ventilation conditions. *Brisas Soleil* were used as elements of adaptation to the climate as well as elements of aesthetic composition, giving a kind of rhythm to the façade of the building.

This pursuit of an adequate architecture for the climate and the specific economic realities of Pernambuco, was to travel many different paths, with degrees of achievement.

## Conclusion

The aesthetic diversity of the modern architecture produced in Pernambuco might lead to the conclusion that there existed many different currents with different attitudes and distinct design justification. However, when research into the generating process of this diversity of forms reveals their unity. This unity is related to the idea of a School of Architecture that shared common characteristics and references and that shepherded a specific type of process of architectural design.

There is no doubt that the union of these characteristics and references in the works of the architects in Pernambuco was the result of a direct influence from their academic upbringing in the Faculty of Architecture of Recife.

The incentive given to aesthetic experiments and the creation of climatic adaptation elements, contributed to a rich stock of solutions. The techniques, building methods and elements created and used by the architects, contributed to the quality and originality of their work. They also had a profound influence on the whole built environment production of the northeast region of Brazil. To this day, anonymous architects and laymen builders make use of these elements of climate adaptation, even though many may do so simply to give some sort of plastic expression to their buildings.

The modern architecture built from the 1950s to the late 1970s produced some remarkable examples of how a modern society can adequately coexist with the heat and humidity of a tropical climate, by reconciling traditional references with modern ones. Although the need to create a Brazilian tropical architecture had been the theme of great debate since the beginning of the twentieth century, it was only with the adoption of modern design that the architects were able to realize their goal. The various aesthetic approaches used by the architects of Pernambuco still permit the recognition of the basic principles that gave unity and quality to the architecture produced in the state's capital. These principles qualify this architecture as the fruit of a school of tropical architecture emanating from the design of the School of Recife.

## Fifty Shades of Green: an empirical analysis of sustainable design approaches in fifty case studies of contemporary architecture

Marianna Nigra<sup>1</sup>

<sup>1</sup> Department of Management and Production Engineering, Faculty of Engineering and Management, Politecnico di Torino, Turin, Italy, marianna.nigra@polito.it

**Abstract:** It is largely recognized that the world is facing fast changes in the environmental conditions, in the economic structure, and in the social dynamics. In this context, the fields of architecture and urban design have been evolving and reacting, by: addressing issues; proposing innovative design and technological solutions; and envisioning potential sustainable scenarios in a structured manner. Yet the debate around the value and the identity of the sustainability aesthetic is still open (Hosey 2012). Despite the complexity of this theoretical debate, the aesthetic of architecture and urban design has, in practice, already started to shift under the influence of economic, environmental and social sustainability principles. With the aim of shedding light on these changing dynamics, this paper proposes an empirical analysis to compare and contrast the aesthetic approaches of fifty case studies of recent buildings, which have been awarded with International sustainability prizes and/or with high score certifications by the major energy rating systems across countries. Specifically, the analysis will offer an interpretation of the relation between economic, social and environmental principles and the design solutions that were triggered by those concepts. The results of this analysis will show a remarkable variety of successful design strategies, as well as a number of design opportunities that yet need to be explored. The importance of this work is: to produce a set of statistic data that can contribute both to practice and to the theoretical debate on the aesthetic of sustainability, by providing examples of cause-effect relations between sustainability concepts and design solutions; as well as to understand and assist the changing dynamics of our built environment.

**Keywords:** Sustainable design, architecture, aesthetic of sustainability, design organization, sustainable architecture

### Introduction

It is since the Brundtland Report (1987), when the concept of sustainable development was formally defined that the practice of architecture has started evolving and searching for new means, methods, and aesthetic approaches. Aesthetic is defined here as a set of principles governing the idea of sustainability, which finds its expression in visible features of architectural form. It was not many years later that Guy and Farmer (2001) had already identified at least six approaches to sustainability in architecture, namely eco-technic, eco-centric, eco-aesthetic, eco-cultural, eco-medical, and eco-social, gauging the complexity of interpretation of the concept of sustainability in architecture. These approaches encompassed different technological solutions, sources of environmental knowledge, and images of space, which contributed to define the overall aesthetic approaches that each of those represented. Yet, ten years later Lee (2011), by editing the book: '*Aesthetic of Sustainable Architecture*', collated the contribution of at least twenty five academics and architects, in which various approaches to the aesthetic of sustainability were defined and

explained, underlining the fact that the debate on the aesthetic of architecture was still open, and more complex than before. Moreover, Hosey (2012) stretched those concepts both, by shedding light on the degree of controversy that exist in the debate around sustainable aesthetic in architecture, and by proposing a 'manifesto' of principles for a new conception of what he defines 'the shape of green'. Recently, the debate seemed to be more open than ever: the aesthetic and management matters related to sustainability are still subjected to enquiry and exploration, both in practice and in the scientific community (Helsen and Nilsson, 2016). Despite controversies and variety of approaches, aesthetic plays a crucial role in communicating the value of sustainability, and therefore maintains its important for the work of many designers and architects. Most of the work carried out in practice focuses on the changing of work organization, as well as on the architectural form. Yet, many examples of so called 'sustainable' buildings recently built, have demonstrated that projects offer far more opportunities in communicating the value of sustainability as well as in their project organizations and delivery process. This would occur by shifting the aesthetic paradigm from the architectural form to a wider range of design opportunities also concerning the building development life cycle as an occasion to communicate the value of sustainability, relying on more inclusive processes.

### **An enquiry on the current state of art: a methodological approach**

By empirically analysing the current state of practice, this work wants to present and analyse fifty sustainable projects by conceiving projects as complex systems, focusing on both architectural form and components, and delivery process. By widening the scope of the analysis in considering the delivery process as an opportunity for aesthetic design decisions, the work will attempt demonstrating that the debate on the approach to sustainability in architecture practice is still a remarkable source of innovation opportunity and development occasions. This approach will allow to shed light on the relation between sustainable design decisions, development process and environmental, economic and social effects generated; rather than attempting to define guidelines for a unified formal aesthetic definition of sustainability. In order to do so, the methodological approach utilized in this work is: 1) to select fifty case studies of contemporary buildings – located in different geographic and socio-technical contexts (i.e. Africa, Europe, USA, Asia)- among the ones that in the last ten years have received either a high score by the major energy rating system in use, or more in general sustainability and/or architectural awards; 2) to carry out an analysis of the relation between specific design decisions, development process, and sustainable effects generated; and 3) to identify tendencies, dynamics, and rationales behind each approach identified. This is an attempt to understand firstly: differences in design approaches to the concept of sustainability according to socio-technical and geographic context, and secondly: the relation between design characteristics and social, environmental, and economic effects, as well as the impact of design decisions and project delivery process.

### **A possible analytical method**

The analytical method utilized relied to analyze the case studies on the conception of building seen both as product and processes (Turin 1980). To do so, the building components analyzed for each case study selected are selected on the basis of the EU building directive 2010/31/EU OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL OF 19 May 2010, which - among other aspects - defines the projects aspects which are sensitive to sustainability. These components are dimensions, shape, floor number, access and circulation, structure,

environmental control systems, water treatment. The process is explored in accordance to the principle of building/project management identified keys aspects of project productions. Specifically, the analytical areas analyzed for each areas are: commissioning, financing methods, building programing, form and shape, technical specifications, contract relations, project production, project erection, work coordination, drawing organization, project use and maintenance.

Each building component and process characteristic of the case studies selected are assessed according to a number of parameters defined to explore environmental, social and economic effects. The type of effects - as highlighted in table 1 - are: *mixité*, social inclusion, wealth, education, safety for the social discipline; market expansion, competitive advantage, comparative advantage, knowledge acquisition, property/land value increase for the economic discipline; and emission reduction, resource generation, waste reduction, environmental sustainable strategy introduction, technological performance increase for the environmental discipline. These effects are assessed on a scale from one to five, in terms both type if impacts/change and results. The impact or change is analysed by relying on a scale of degree of change from the standard practice - irrelevant change - to total novelty - radical change (Henderson and Clark 1990).

Table 1. The table below shows the assessment parameters utilised in the proposed assessment method

EFFECTS	TYPE OF CHANGE	SCALE OF EFFECTS	TYPE OF EFFECTS
Social Effects	Irrelevant, Modular, Incremental, Architectural, Radical	1 to 5	<i>Mixité</i> , social inclusion, health, wealth, education, safety, et cetera
Economic Effects	Irrelevant, Modular, Incremental, Architectural, Radical	1 to 5	Market expansion, competitive advantage, comparative advantage, knowledge acquisition (patents), property/land value increase
Environmental Effects	Irrelevant, Modular, Incremental, Architectural, Radical	1 to 5	Emission reduction, resources generation, waste reduction, sustainability strategy introduction, technological performance increase

The output of the analysis provided a mapped set of information regarding the degree of sustainable innovation, the type of approach of sustainability and the social, environmental and economic effects that the design decisions and the process organization produced. As it is showed in figure 1 and 2, it was possible to produce a graphic output from the analysis which demonstrate firstly, the distribution of sustainability type decisions made on the case study analysed (figure 1); and secondly the relation between building components, process characteristics and sustainability effects achieved (figure 2). This analysis was then conducted on each of the fifty case study selected.

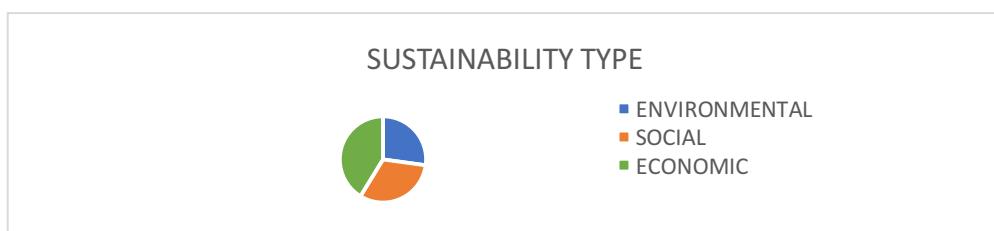

Figure 1. The figure shows and example of the distribution of sustainability type design decisions for one of the case study analysed

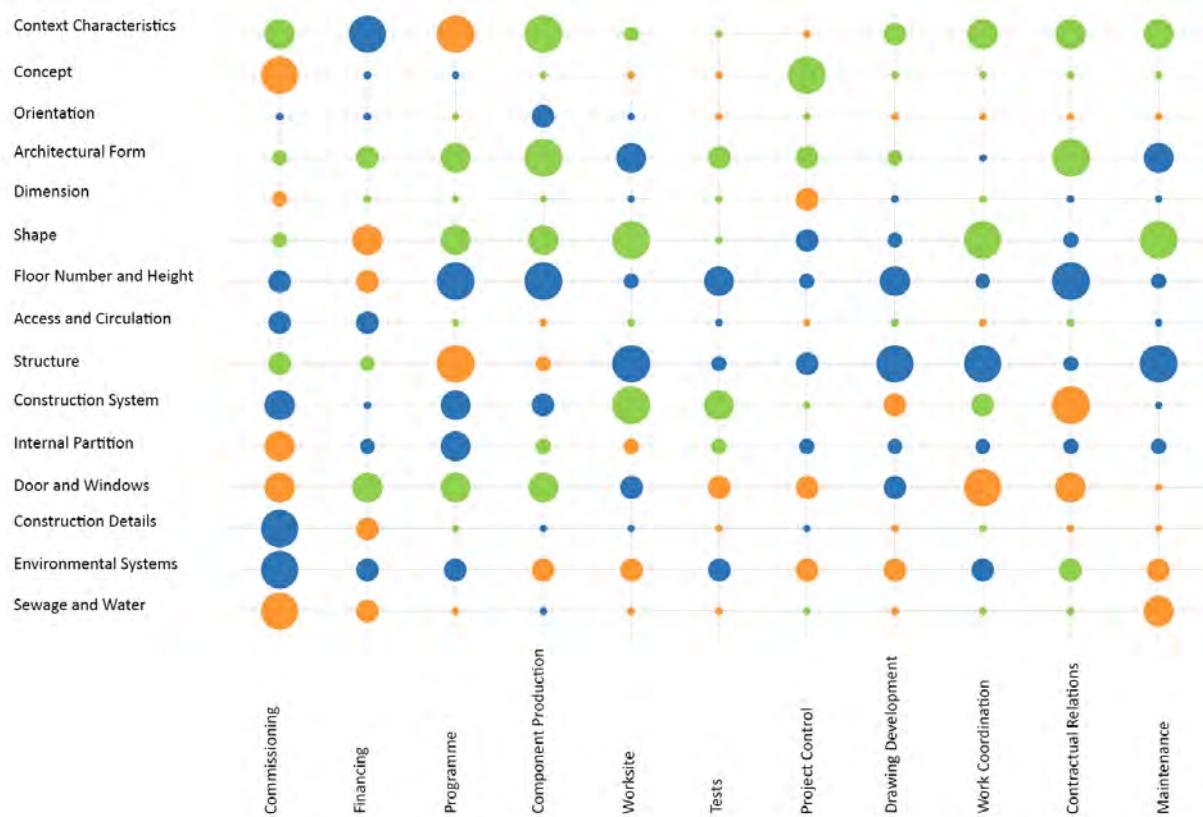

Figure 2. The figure shows the relation between building components, process characteristics and type of sustainability effects and impact produced during the delivery design and delivery process in one of the case study analysed. Each colour identifies the type of sustainability (environmental, social and economic) and the ball dimension identifies the degree of impact that the design decision had on the delivery process

### The results: The aesthetic approach of fifty case studies

The result of the analysis showed great variety of approaches to the sustainability matter among the analysed case studies. The differences are concerned with both the aesthetic – as a set of definitive characteristics – as well as with the effects produced by each project in terms of environmental, economic, and social outcome.

At a first glance, at least three major approaches to the sustainability needs were detected. These approaches followed either the environmental, economic or social declination of the concept of sustainability, showing aesthetic characteristics that were a reflection of one of these approaches. Rarely, an equilibrium was found between the three dimensions of sustainability in the same project. These distinctions largely influenced the aesthetic characteristics in which the value of sustainability was placed. It was possible therefore to identify building elements and/or design decisions which were more relevant in the production of either an environmental, economic, and/or social effect or result.

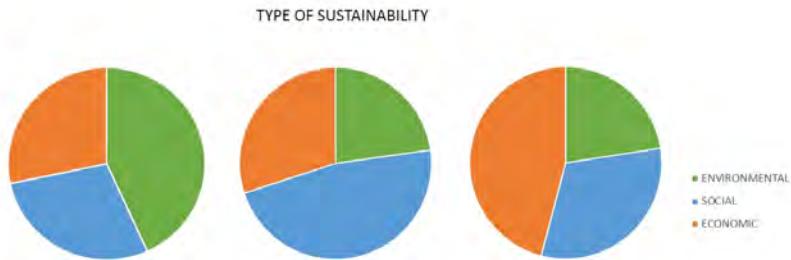

Figure 3. The figure shows the type of sustainability distribution in the case study analysed

Most of the case studies that showed a higher attention to the social sustainability were able to do so because of their scope, location, and process of production. Most of those projects were located in a developing country, with extreme climate conditions, low industry skills and technical development, and strong social contracts. Aesthetic components which characterised the opportunity for sustainability design decisions were: use of local materials, opening design, roof systems type and shape, orientation, access, ease of construction, and building procurement method. Mostly though, the critical factor to achieve social sustainability was the participation and the social inclusion during the production and erection process of the buildings, which served not only to define a common identity, but also to train labour with new skills, and to produce the larger impact socially within the community. The aesthetic of the sustainable choices in these category of projects was the reflection of the participation and the ownership of the building by the community, not only by relying on the physical participation in the construction process, but also in the ability to rely to sets of physical building features that represents well known elements in the local areas and therefore representing a cultural ownership by the local population, i.e. local materials, traditional layouts, use of natural ventilation by utilizing double roof ventilated type as a reflection of the climatic conditions, et cetera.

Figure 4. The images show an example of mapping of social sustainable type of project: The Gando Primary School by Francis Kéré, In Burkina Faso, Africa (Photo: <http://www.kere-architecture.com/projects/primary-school-gando/>)

The case studies that were more environmentally oriented were largely characterized by ownership type, government incentives, capital availability, technological robustness and availability. The attention toward the environmental issue was in those cases actualized by relying, where possible, on the use of both technologies and/or natural solutions, particularly concerning with lighting and ventilation. This latter was though the aspect that was most

relevant in the overall design organization of the projects analysed. Moreover, the presence of green roofs, green walls, complex engineering solutions, as well as the generation of new microclimates, energy consumption reduction or energy production were also the aspects that the environmental approach mostly followed, in accordance with the analytical parameters of the major energy assessment methods currently utilized in practice (i.e. LEED, BREAM, et cetera). Those projects reflected aesthetically the scientific effort of technologically solve the energy consumption issue, and therefore relied on displaying the feature which were aimed at covering this function.

Figure 5. The images show an example of mapping of an environmental sustainable type of project: The Academy of Science by Renzo Piano in San Francisco, California, USA (Photo: <http://www.archdaily.com/6810/california-academy-of-sciences-renzo-piano>)

The case studies that were more oriented toward an economic sustainability type did not necessarily found a geographic match in their location, but rather were strictly related to the capital availability of economic condition of the end-user and/or the client. The economic sustainability in these cases was found in the re-use of materials, use of rough finishes, use of rational geometrical shapes and layouts, use of standard construction systems, ease of construction, participation of the industrial community in supplying products and materials, type of financing (i.e. crowd funding, donations, volunteering, et cetera), and procurement type. The aesthetic of these projects was generally the expression of a set of functional needs, which was the main visible feature of the projects.

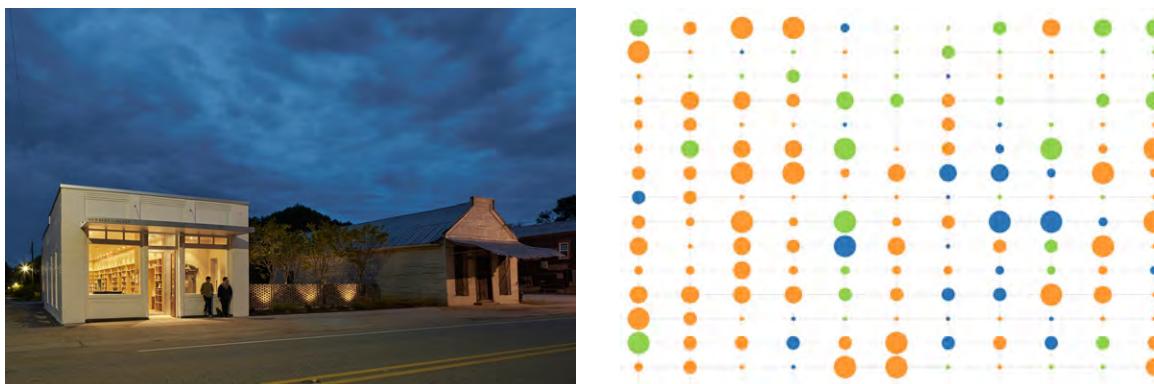

Figure 6. The images show an example of mapping of an economic sustainable type of project: The Newbern Library in Newbern, Alabama, USA by Rural Studio (Photo: <http://newbernlibrary.ruralstudiodblogs.org/>)

Although most of the projects analysed tried to express their sustainability approaches in a set of visible features (aesthetic choices), either in the type of materials, use of construction systems and finishes, or shapes and layouts, some remarkable results were represented through those projects, which did not attempt to use architectural set of elements to represent a sustainable approach, rather they tried to rely on the ‘aesthetic of the effects’ that sustainable design choices produced to communicate their own value.

One example of these externalities was the case study of the office building ‘The Edge’ by PLP Architecture in Amsterdam, which showed a strategy that empowered the users of the building to monitor the environmental effects of the building by highlighting all the building components that were directly dependent upon the interface with the users’ behaviour. To this end, a number of ‘green plugs’ were located all over the building to encourage users to use electricity produced by alternative sources, as well as the company Philips developed an ad-hoc phone application for the building users to take part into the energy management and consumption of the building. In this case, by showing the aesthetic of the ‘sustainability effects’, rather than the architectural components characteristics, the project offered an example of new feature of the building functioning that could be a new design opportunity, such as the interface with the building users.

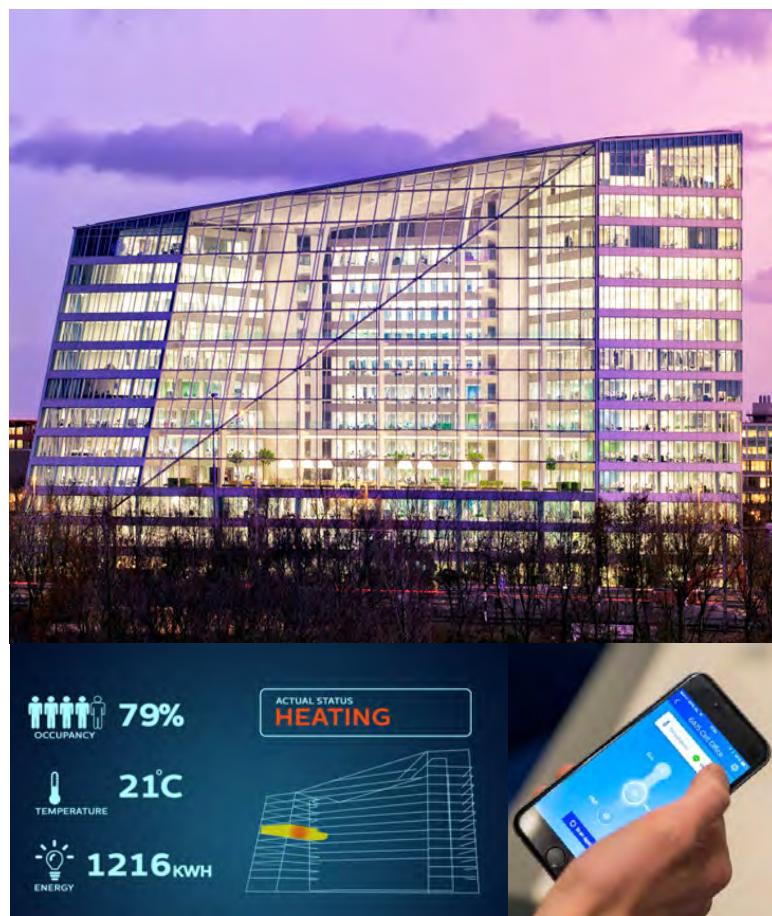

Figure 7. The images show the building ‘The Edge’ in Amsterdam and an example of the app developed by Philips for the interface between users and building management (Photo: <http://www.usa.lighting.philips.com/cases/cases/office/edge>)

## **Discussion: The influence of the social economic and environmental context on the design solutions and the new opportunities detected**

At a first glance, the results produced by the analysis conducted were in line with the six type of sustainability approaches already discussed by Guy and Farmer (2001), and later expanded by Lee (2011). Yet, by widening the scope of the analysis to both the artefacts and the delivery process, this work was able to expand the reflections that Hosey (2012) conducted on the aesthetic role of sustainability. Specifically, this work pointed out the importance to understand the value and the opportunity that the delivery process can offer in communicating the importance of sustainable choices by design. By understanding these opportunity, the aesthetic role that has been generally covered by the architectural form, can also be refined and amplified by new design areas concerned both with architectural features and delivery process (for instance: the interface with the users for example, the construction process, or the industrial participation of the designers in a tight collaboration with the suppliers or manufacturer, et cetera). Being sustainability a complex matter, its aesthetic - conceived it as a set of features governing the idea of sustainability - can be find not only in the architectural form but also in the life of building artefacts from its conception, delivery and life cycle, in order to fully expressing the value and the importance of making sustainable design choices.

## **Conclusions**

In a context of fast changes in the environmental conditions, in the economic structure, and in the social dynamics, a fast response by architects and designers is crucial to address issues; propose innovative design and technological solutions; and envision potential sustainable scenarios in a structured manner (Grosso, et al, 2015). To do so, cultivating and mastering the aesthetic component of the design decisions is an essential practice to ensure the effective communication of value and meanings of sustainability. The importance of doing so relies in the ability of the architectural and design field to take actively part into the societal discourse on sustainable development and to propose solutions that can positively encompass the complexity of sustainability development. It is critical therefore that conceiving aesthetic as a tool for effective communication of sustainability principles becomes a structured practice, which encompasses a wide range of aspects from the architectural form to the artefacts delivery process and life cycle, as a reflection of the changes that our societies are currently facing.

## Formal Representations of Seasonal Adaptation - On a Search for Sustainable Architectural Forms

Agnes Nyilas<sup>1</sup>, Yoshihito Kurazumi<sup>1</sup>

<sup>1</sup> Department of Human Environmental Design, School of Life Studies, Sugiyama Jogakuen University, Nagoya, Japan

**Abstract:** Since sustainability emerged as the most important keyword for the last decade, the question whether it has any formal representation has been at the centre of architectural debates. At the core of debates, the reconsideration of the relation between climate and architectural form is based on the recognition that the main principles of sustainability are rooted in the environmental conditions of the building site, including its climate. In regions with hot-humid summer and cold-dry winter, however, the seasonal differences require different considerations for the same building depending on season. This is the reason why the concept of seasonal adaptation is at the focus of interest in sustainable architectural design. Different examples of seasonally adaptive buildings are analysed here to make clear the relation between their concept and the architectural form. Through the analyses, it is assumed that the concept of seasonal adaptation might not have any concrete form, but it has the abstract image of form as periodically changing entity. Based on this finding, the aesthetics of seasonal adaptation can be referred as the aesthetics of periodical change represented in a 'fluctuating form'.

**Keywords:** sustainability, seasonal adaptation, aesthetic, architectural form, fluctuating form

### Introduction

In our environment-conscious era, energy efficiency emerged as one of the most important requirements toward buildings. However, it often confronts other human needs, like indoor comfort, health or aesthetic needs. In vernacular architecture, indoor comfort and health were maintained through the appropriate orientation, form, proportion, spatial layout or building materials. Beyond merely satisfying aesthetic needs, architectural form has served indoor comfort and health. But with the development of technology, traditional methods were replaced by efficient building equipment, making architectural form free from the environmental circumstances. The freedom of expression encouraged architects' freakish intellectualism, and leaded to the degradation of the aesthetic quality of the built environment. On the other hand, active methods were soon proved to be immensely energy-consuming, necessitating new sustainable design strategies. As such strategies would in turn require the reconsideration of passive methods, they are commonly expected to result in a new aesthetics through re-relating architectural form to indoor comfort and health issues.

Sustainability is already the most important keyword in almost every aspect of Life. In architecture, based on the recognition that the main principles of sustainability are rooted in the environmental conditions of the building site, including its climate, there is a renewed interest for climate responsive design. In regions with dry-cold winter and hot-humid summer, however, seasonal difference requires different considerations for energy efficiency, health and indoor comfort of the same building depending on season. Passive methods encourage

natural ventilation, which provides comfortable condition for summer, but such traditional buildings are cold in winter. To provide comfortable conditions for winter, either immensely energy-consuming equipment is used or buildings are made to be super-insulated and airtight, which often causes health problems for the occupants. To solve the equation with the three variables (energy efficiency, health, comfort), the idea of seasonal adaptation was invented. It is based on the analogy of ‘adaptation’ in Nature. That is to say, seasonally adaptive building can adapt to seasons through an environmental change response mechanism, just like a living organism, thus it has the optimal parameters to maintain healthy and comfortable indoor conditions with low energy consumption throughout the year. On an attempt to getting closer to the understanding of the aesthetics of sustainable architecture, this paper examines the relation between the concept of seasonal adaptation and the architectural form.

## **Architectural Form and Aesthetics**

### ***The evaluation of Architectural Form***

It is widely accepted view that form is the biggest factor to contribute to the aesthetic quality of a building. The evaluation of form is, however, a very complex issue. Without going to details of cognitive psychology, one can assume that people basically evaluate form through a three-stage process of perception-cognition-evaluation. In the stage of perception, the physical stimulation of the sense organ – light falling on the retina – arouses neural impulses. In the stage of cognition, signals sent to the brain by the nervous system are identified and interpreted. Cognitive mechanism is pre-conscious: people understand what they perceived depending on their memory, expectation and attention (Goldstein, 2009). Finally, people judge about what they understood according to their value standard.

There are different theories about how people evaluate visually perceived matters. According to some theories, people tend to positively evaluate something familiar to them, because familiarity with a thing gives them a sense of security. Zajonc asserted that repeated exposure to a thing enhances the observer's positive attitude towards it, by unconsciously making the thing visually familiar to him/her (Zajonc, 1968). The relation between the mere exposure effect and aesthetic preference has been stated also in art theories. According to Cutting, “(a)rtistic canons are promoted and maintained by a diffuse but continual broadcast of images to the public by museums, authors and publishers. (...) Tacitly and incrementally over time, it teaches the public to like the images, to prefer them, (...) and to want to see them again” (Cutting, 2007). It is essentially the same with our built environment. To buildings, which we have been exposed to us for long, we tend to attach positive feelings, while we are often resistant toward new architecture at the first sight (Tange, 2011). By the same logic, as each era has its commonly favoured architectural form reflected in the built environment, it is reasonable to assume that people from the same era share a kind of common aesthetic sense. The next section is a follow up of it throughout a brief history of architecture.

### ***The Transformation of Aesthetics over Time***

Architectural aesthetic differs depending on era. When talking about the aesthetic of pre-modern architecture, we have to think in terms of the shape of details embodied in the ornament rather than the overall building form. Historical styles had their favoured motives that very often took the shapes of natural world in that climate. As Nature used to be the most common source of sensory input before the industrial revolution, it provided a familiar set of formal vocabulary for people. At the same time, geometrical ornament is primordial

among decorative elements. By the growth of culture and knowledge, a set of geometrical artistic forms has gradually developed based on the form of cultural artefacts (Meyer, 1957). Up to Art Nouveau, ornament – either organic or geometric – has been at the centre of aesthetic debates. Then the first notable shift came with the Modern movement: from the aesthetic of decorative details to the aesthetic of the overall building. In the machine age, ornament was eliminated and emphasis was put on the function of the building that most often had a simple geometric form. Due to the development of science and technology, the new aesthetic of the “white cube” – the symbol of Modern architecture – has spread independently from climate or culture, to deserve the name “International Style”. For decades, architects have been working on the subconscious promotion of its canon through the continuous broadcast of the “white cube”-image to the public all over the world.

As everyday life became more and more complex, the subject of aesthetic gradually shifted from simple forms to complex forms. In order to study how to attain meaningful perceptions in the chaotic world, Gestalt psychology was re-employed in architectural and urban theories. In Gestalt, form was considered not as a simple assemblage of parts but as an “organization of patterns and objects” based on specific laws, which architects of the era were eager to apply for the built environment. Arnheim explored the perceptual consequences of order and disorder in architecture (Arnheim, 1954). Lynch applied Arnheim’s ideas to urban design, and examined the possibilities to make the city “imageable” through proposing a set of complex relations among its elements (Lynch, 1960). Meanwhile, urbanization involved the concept of ‘mobility’, and the aesthetics of complexity has transformed into the aesthetics of change. As a result of economic development, sudden population overgrowth resulted in an uncontrollable urban sprawl in big cities. To keep pace with the continuous growth of cities, architects had to think in terms of enlargement and to invent the concept of ‘growing forms’. To foster the image of ‘growing form’, analogy from Nature was borrowed again. The new analogy was, however, entirely different from the pure imitation of natural shapes. It evoked the image of nature in a more abstract way: through referring to the process of growth of living organisms. The next big shift in architectural aesthetic is obviously approaching. But how will the aesthetic of an environment-conscious era look like? Does sustainability have its own aesthetics at all? To help the answers, this paper examines what kind of representations seasonal adaptation have, and how it fits in the history of the aesthetics of architectural form.

### **Analysis of the Examples of Seasonal Adaptation**

Built examples, general ideas and unbuilt prototypes are analysed here in terms of the relation between the concept and the architectural form. Projects are categorized according to the different analogies of seasonal adaptation in nature. Type1 contains projects that refer to the general idea of ‘changing dwelling according to season’. Type2 contains projects that are based on the concept of ‘flexible building layout’ to provide optimum condition for every season. Type3 contains projects, which relate to the idea of ‘smart building envelopes’ in some ways. Since this idea covers a wide range of related concepts however, Type3 is subdivided into a) Removable Building Skin, b) Double Skin, c) Self-orienting Solar Roof, d) Mechanical Brise Soleil and e) Smart Materials. ‘Removable building skin’ includes projects that respond to seasonal change through casting off the building envelope. ‘Double skin’ includes projects that respond to seasonal change through switching the ‘behaviour’ of the building envelope. ‘Self-orienting solar roof’ and ‘mechanical brise soleil’ includes projects that respond to seasonal change due to the movement of some parts of the building envelope

depending on the location of the Sun. ‘Smart materials’ includes projects that respond to seasonal change through the change of the physical features of the building envelope.

### Type1 – Changing Dwelling According to Season

Changing dwelling according to seasons is not a new idea. In Japan, already in the Kofun period (A.D. 3rd Century–538) the pit house for winter coexisted with the raised-floor house that was used from spring to autumn. Although the idea itself could have hypothetically infinite formal representations, building form was constrained by the level of technical development of that period. The circular or rectangular thatched roof of the pit house was constructed above an underground hole. It was supported by a wooden log frame covered with soil (Fig.1). Soil, as a seasonal heat storage, stored the summer-heat and kept the house warm in winter. On the contrary, the raised-floor house most often had rectangular thatched roof supported by vertical wooden walls from the elevated floor. Its floor was laid some ten centimetres above the ground across horizontal wooden beams, which were supported by small wooden columns (Fig.2). The raised-floor promoted air circulation below the house, and it therefore had moisture protection and cooling effect in the hot and humid summer.

### Type2 – Flexible Building Layout

The embryo of the concept of ‘flexible building layout’ has already existed for long. Strategies like changing bedroom, limiting bedroom only to sleeping or rearranging the room layout seasonally have often been used for making the living environment comfortable in the hot-summer/cold-winter zone. As the improved interpretations of the original idea, there are recent projects where the location of rooms, their interrelations, or the orientation of some rooms can change depending on season. E.g., *Dynamic House* by D\*House (London studio) is a bold proposal to fold a building into several configurations, based on the logic puzzle of H. E. Dudeney. Four distinct shapes correspond to four parts of the house: a living room, a bath room and two bedrooms. The four parts can have eight configurations with different layouts. Depending on the layout, internal walls become façades and external walls become internal ones outside windows become inside doors and vice versa. In winter, the building has the most compact form to minimize heat loss. From winter it gradually unfolds, and have the biggest surface in summer. From summer to winter, the building gradually transforms back again (Fig.3). *Dynamic House* has some limitations in terms of shape because of the most compact shape constraints of the specific mathematical puzzle. However, the concept itself to fold a building into different configuration does not restrict the architectural form.

### Type3 – Smart Building Envelope

Among sustainable architecture issues, smart building envelope that can adjust to changing conditions has been receiving special attention. Most common examples include Climate Adaptive Building Shell (CABS), which “has the ability to repeatedly and reversibly change some of its functions, features or behavior over time in response to changing performance requirements and variable boundary conditions, and does this with the aim of improving overall building performance” (Loonen, 2013). CABS has many different types. Among them, proposals related in some or other ways to seasonal change are taken here.

#### Removable Building Skin

The idea to adjust to seasonal change through casting off the building skin or a part of it one among CABS ideas. By using very simple technical devices, buildings can ‘moult’ to have cooler conditions for the summer and wear an additional ‘coat’ to have warm condition for the winter. This simple analogy is used in *Sliding House* by dRMM (London studio) among others. *Sliding House* consists of a garage, a guest annex, the main house with a roof terrace bathroom and the attached glass living room, as well as the sliding house (skin) itself (Fig.4). Except the garage that stands independently, other parts of the composition are connected through some rail tracks. In summer, which is not too hot in that area, the skin of the building can be removed to let the glass living room to collect sunshine and the bathroom to have a nice view. The sliding skin is an autonomous structure, which incorporates a thick insulation. By moving the skin into the position to cover the living room, the inside can be kept warm in winter. Movement is ensured by electric motors incorporated in the thick walls. Buildings of the composition have conventional forms defined by the simple pitched roofs. Because of the overlaps of different buildings depending on time, the size and the shape of the buildings are necessarily adjusted to each other. However, the concept itself does not restrict the architectural form: similar effect can be expected through any kind of building shape.

#### Double Skin

“A double skin façade can be defined as a traditional single façade doubled inside or outside by a second, essentially glazed façade. Each of these two façades is commonly called a skin. A ventilated cavity - having a width which can range from several centimetres to several metres - is located between these two skins” (Loncour, 2005). By mechanically controlling the movement of air in the cavity, the building can adjust to different climatic conditions. *One Angel Square* by 3Reid and Waagner Biro is a classic example of it. In, summer fresh air enters the cavity between the two skins from below. As it is warmed up by the Sun through

Figure 5. *One Angel Square* by 3Reid and Waagner Biro.

Source: <http://www.archdaily.com/337430/1-angel-square-3d-reid>

the glass skin, it raises. Hot air leaves from between the double skin at the top of the façade. This way of soaking up air passively reduces cooling costs. In winter, the upper side of the cavity closes automatically, and the air layer – stuck between the double skins and warmed up by the Sun – works as insulation, reducing heating costs. The shape of the overall building is often compared to a sliced egg centred around a diagonal slice, the central atrium topped by a glass roof (Fig.5). But it does not directly refer to the concept of the double skin itself, which could allow hypothetically infinitive kind of formal representations.

### *Self-orienting Solar Roof*

Self-orienting solar roof is a roof with solar panels, which can self-adjust its angle to the position of the Sun in order to acquire maximum amount of solar energy by minimum effort anytime. *Casas Em Movimento Solar Homes* by the University of Porto is one of the representatives of this ideas. It is a simple box dwelling enclosed by a metal truss system covered in photovoltaic panels from three sides (Fig.6). The basic idea is the combination of because of the mechanical system integrated in two kinds of movements: the rotation of the with solar panels. The building can rotate up to 180 degrees overall building and the pivoting of the truss the truss. The movement of the house is set to track the sun automatically. At the same time, the truss-roof is able to pivot by up to 60 degrees for even better solar exposure. The shape of the building is basically not related to the idea of two-dimensional movement, but the truss should adjust to the geometry of the building by technical reason, and the surface of the roof is better kept flat for good energy performance.

### *Mechanical Brise Soleil*

The original idea of Brise Soleil is to reduce heat gain by shading of large glass façades. Through mechanizing the idea, however, Brise Soleil can already adjust also to seasonal difference: the incorporated intelligent equipment can detect the exact position of the Sun all through the year. *Al Bahar Towers* by Aedas Architects is the modern version of the *Arab World Institute* in Paris by Jean Nouvel's. Due to the extremely hot weather, proper shading for the high glass tower was a big challenge. A traditional Islamic lattice shading device – the *mashrabiya* – was used as model. The geometries of the façade panels were designed based on the calculated Sun exposure and angles of the specific day and time. The skin with the façade panels works as a curtain wall supported in front of the glass wall by an independent frame. Panels respond to the movement of the Sun, and close when it has the most critical angle. They are composed of triangular-shaped components, and when they open, their

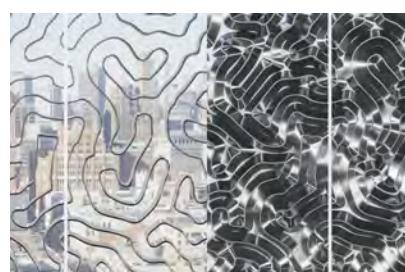

Figure 8. *Homeostatic Façade System*. Source:  
<http://internationalfacade.com/news/general/homeostatic-building-facade/>

composition is similar to several of opening morning glory flowers (Fig.7). Purely in terms of shading, however, several other shapes would work as well. In turn, the formal geometry of the towers was designed to complement the shading effect. The cylindrical shape was decided as the most efficient one in terms of wall-to-floor area that also ensures the largest volume with the least surface area. It can therefore be said that although the overall shape is not a direct derivative of the original concept of shading, it is partially influenced by it.

### *Smart Materials*

In general, smart material can react to the changes of their environment on their own, through a change in their volume, colour or viscosity, etc. Smart building materials are various, but it is beyond the scope of paper to discuss all in detail. Here an unbuilt prototype, which can react for seasonal change of the temperature and light conditions is taken. Homeostatic Façade System by Decker Yeadon architects is a muscular structural façade, which can reduce solar gain by changing the configuration of the structure of its material. The façade consists of a mess of silver-colour squiggles that open and close in response to temperature change to regulate interior temperature. The material used in the façade is an electroactive polymer that transforms electric energy into mechanical work to change shape. When it is hot, electricity deforms the squiggles that expand, and when it is cold, squiggles are contracted (Fig.8). As a result, façade pattern changes, but it does not influence the overall building form.

### **Conclusion**

Based on the analyses, it was found that the idea of seasonal adaptation does basically not limit the architectural form, at least not in a direct way. Only in an indirect manner, Type3 was found to incorporate certain constraints that were somewhat related to the original idea. In case of a) Removable Building Skin, the forms of the parts were slightly restrained, but only in relation to each other to make it possible for the different parts to be overlapped. In case of c) Self-orienting Solar Roof, keeping the roof panel flat for better performance seems reasonable, but these constraints have little influence on the overall shape. In case of d) Mechanical Brise Soleil, although the overall shape of the building is partially influenced by the aim of shading, it is not really the direct derivative of the concept of mechanical brise soleil. At the same time, the representation of the concept of seasonal adaptation was revealed in the change of the form and/or function according to seasons in all the projects. In Type1, Type2, as well as a) Removable Building Skin and c) Self-orienting Solar Roof of Type3, the overall form or a large part of it changes according to seasons. In d) Mechanical Brise Soleil, the form of small building parts, and in e) Smart Materials the texture of the building envelope changes. But in case of b) Double Skin, the representation of seasonal adaptation is limited only to the functioning of the building envelope, and is basically not recognizable on the architectural form. One can thus assume that – except the case of b) Double Skin – the common characteristic of the projects can be seen in the concept of periodical change of form. Moreover, seen in the history of architectural aesthetics, the aesthetics of seasonal adaptation can be understood as the next link in the chain of (i) the aesthetics of details (shape), (ii) the aesthetics of the whole (simple form), (iii) the aesthetics of complexity (complex form) and the (iv) aesthetics of gradual change (growing form). Although its form-image is also dynamic, it is different from the gradually changing (growing) image of form that was invented to adjust to the growing population. It is a kind of fluctuating form, changing periodically according to seasons. The aesthetics of seasonal adaptation can therefore be referred as (v) the aesthetics of periodical change (fluctuating form).

All in all, one can say that the concept of seasonal adaptation might not have any concrete form, but it has the abstract image of form as periodically changing entity. Although this conclusion is limited to the concept of seasonal adaptation, by the similar logic it can be assumed that sustainability – which is an even vaguer concept – nor can have any concrete formal representation. However, judging from the tendency of architectural education, an aesthetic canon of sustainability will probably be fostered and handled unconsciously to the public through continuously exposing them to some familiar set of images from Nature.

## Design of Low-energy Homes using Thermal and Daylight Simulations in Interactive Generative Parametric Modelling

Steffen Petersen<sup>1</sup>, Lonnie Rou<sup>1</sup>, Pil Brix Purup<sup>1,2</sup> and Poul Henning Kirkegaard<sup>1</sup>

<sup>1</sup> Department of Engineering, Aarhus University, Aarhus, Denmark, pil@eng.au.dk

<sup>2</sup> NIRAS A/S, Aarhus, Denmark, pibp@niras.dk

**Abstract:** There is an increasing effort to integrate building simulation tools into architectural CAD tool environments to enable evaluation of the effect of architectural considerations on other building performance issues such as energy use, thermal indoor climate, and daylight conditions, during the early design stages. One approach is to generate design advice using the concept of *generative parametric modelling* (GPM). GPM approaches often make use of an optimisation algorithm to automatically generate solutions that fulfils some predefined boundary conditions set by the designer – including architectural rules. The designer can revise the generated solutions and accept or discard any solutions e.g. from an architectural perspective. GPM setups where the designer has facilities that give direct control over the GPM input and output are sometimes referred to as *interactive GPM*. This paper presents an example of how a proposed interactive GPM framework can be used for generating prescriptive information to designers of a low-energy detached single-family home in Denmark. In relation to this, it is investigated how a set of architectural rules identified from an analysis of prevailing architectural styles may affect the solution space.

**Keywords:** Building design, Architecture, Parametric modelling, Energy use, Daylight, Indoor climate.

### Introduction

There is an increasing societal pressure on the building industry to produce low-energy homes without compromising on function, aesthetics, comfort, cost, and other performance considerations. As a consequence, building designers must become increasingly aware of how potential design decisions affect the fulfilment of energy performance targets. Computer-based building energy modelling (BEM) is ideal for generating this information. Within the recent years, there has been an emerging development towards coupling BEM tools with architectural CAD tools, for example DIVA-for-Rhino (2017), Openstudio (2017) for SketchUp, Green Building Studio (2017) for Revit, and ICEbear for various CAD tools (Lauridsen and Petersen, 2014). The immediate benefit is that building designers now have access to in-model BPS-based predictions, and consequently do not need to spend time on making and updating parallel geometric models in third-party BEM tools. However, this development needs to embrace realisations from the past, namely that simulation tools used for an evaluative purpose is an inefficient use of BEM (Petersen and Svendsen, 2010). Instead, BEMs should be used more prescriptively in the design process to generate design advice; by doing so, designers may find that they save time perusing design paths doomed to fail, and instead uncover unprecedented possible design options.

There are various proposals for procedures and methodologies on how to use BEM tools for generating design advise, see e.g. overview in Petersen and Svendsen (2010) and

Østergaard et al (2016), but there is not much knowledge on whether these proposals are adopted by designers or design teams in real building design projects (Petersen et al, 2014). The notion is that it is rare, and a reason might be that current proposals for procedures and methodologies are only assumptions of, or they interpret wrong, what architects actually need (de Souza, 2011). However, there is emerging evidence that integration of BEM into architectural CAD tool environments might be a catalyst for the use of BEM-generated design advice in actual architectural design practice (Petersen et al, 2014). One approach to generate this form of design advice is the concept of *generative parametric modelling* (GPM).

### ***Generative parametric modelling in architecture***

Generative parametric modelling (GPM) in architecture is basically a concept that seeks to exploit the capabilities of computer-based modelling to automatically generate prescriptive design advice rather than using models for sheer performance evaluation in a manual trial-and-error design process. A more formal definition of the digital design framework that GPM can be considered as part of is provided by Oxman (2006). One of the earliest reported uses of BEM-based GPM – though not called GPM at that time – was the work by Radfort and Gero (1980) who used a thermal simulation tool and optimisation to generate design advice in the form of trade-off diagrams for performance-decisive parameters. Examples of more recent endeavours, e.g. Ullrich et al (2013) and Lauridsen and Petersen (2014) within thermal and daylight simulation and Watson and Wonka (2008) and Vangeas (2010) in urban planning, also couple models to optimisation algorithms to generate prescriptive design advice; however they may vary in optimisation objective, constraints, choice of optimisation approach, and presentation of results.

There seems to be a notion that the ‘raw’ script-based nature of GPM poses an inhibition threshold for many designers and visual artists which is why interactive GPM systems have been developed. Lipp et al. (2008; 2011) gave designers direct and persistent control over the generated solutions from a shape grammar approach to architecture, Merrell et al (2011) enabled the user to set up rules before GPM automatically generated suggestions for furniture arrangements in rooms, and Lauridsen and Petersen (2014) proclaimed that their proposed GPM framework “does not work without human designer to formulate the rules of an architectural idea and its boundary conditions”.

The major components in CAD-based GPM in architecture seem to be: 1) a CAD model of the geometry/shape to be investigated, 2) coupling the CAD model to an optimisation algorithm and, optionally, a performance predictor (e.g. BEM), and 3) ensuring that designers can interact with the GPM input and/or output.

### ***Aim of this paper***

This paper presents an example of how a BEM tool integrated in a CAD tool in principle could be applied for interactive GPM-based architectural design of low-energy detached single-family homes in Denmark. The example takes offset in a short analysis of the historical development of the typical Danish detached single-family home that seeks to identify a set of long lasting architectural traits – or “rules” – which also can be regarded as valid for today’s design practice. The purpose of identifying these rules is to make this study a more practice-oriented example of how GPM can be used to help designers meet low-energy performance targets while respecting conceptual rules for an architectural style.

## Method

### *The GPM setup*

The interactive GPM setup in the case example of this paper followed the method described in Lauridsen and Petersen (2014). Rhinoceros (2017) was used as the architectural CAD tool for design of the single-family house. The Rhinoceros model of the single-family house was parameterised using Grasshopper (2017). Each thermal zone in the parameterised geometric Rhinoceros model was individually and independently linked to the BEM tool ICEbear (Lauridsen and Petersen, 2014), the solar algorithm Viper (DIVA-for-Rhino, 2017), and the daylight calculation tool DIVA-for-Rhino (2017). This enabled integrated climate-based daylight and thermal performance simulations of the modelled house, i.e. to simulate electrical lighting control as a function of the daylight level. Finally, the model was linked to the optimisation tool Galapagos (2017) which facilitates the *generative* part of GPM while respecting the user-defined inputs. The overview of the GPM setup, see Lauridsen and Petersen (2014).

### *Architectural rules of typical Danish detached single-family homes*

Successful implementation of GPM seems to rely on a meaningful interactive link between the architect and GPM input and output. By analysing the historical development of the typical Danish detached single-family home, this section seeks to identify a set of long lasting architectural traits – or “rules” – which also can be regarded as valid for todays’ design practice. These rules are used to parameterise an architectural CAD model of a home to obtain a more practice-oriented example of how GPM can be used to help designers meet low-energy performance targets while respecting conceptual rules for an architectural style.

The aesthetic and functional traits of todays’ detached single-family homes seem to draw upon traditions from three overlapping time periods with distinctive different styles and trends. A brief historic background for the definition of these styles is given in the following. Focus is on describing traits in external appearance, the plan geometry, and how these may influence each other. Figure 1 sum up the historical background of todays’ prevailing architectural styles in Danish single-family homes in pictures, and briefly outline the architectural rules that seem to be prevailing for the styles – rules that could be used for GPM in an architectural CAD tool.

The style *Classism* (Figure 1 top) is based on traits from the Patrician villas (1860-1930) and the Master Mason villas (1910-1930) which have an external appearance characterised by symmetry and rhythm in window placement, the use of many mullions, bay windows, porches, cornices, and high quality materials (Lind and Møller, 2014) (Hede, 2008a). The functional layout is also characterised by symmetry around a dual axis. The Patrician villa has an extravagant ceiling height and a high prevalence of ornamentation which the later Master Mason villa did not have. Furthermore, the original Master Mason villas have no bathroom or toilet inside the house.

The style *Functionalism* (Figure 1 middle) can be defined by the traits from the Bungalows (1920-1940) and the Funkis villas (1930’ies). The external expression is simple and clear, with no cornices and hardly any ornamentation. Windows and doors are located freely in the facade with respect to functional requirements such as light or view out rather than respect for symmetry and rhythm. Most windows are squared with slim or no mullions, but some were round to break the angular look. There are almost always windows in the

façade corners. The Bungalow has sloped roofs and a pronounced overhang while the Funkis villas have flat roofs and no overhangs. The Funkis villa façade is often plastered and basically stripped from ornamentation whereas the Bungalow is made of yellow brickworks with simple details such as patterns made of different coloured bricks. While the Bungalow often has a single-floor quadratic floor plan symmetrically arranged around a chimney, the Funkis villa allows the floor plan to be asymmetric if it would fit the everyday life of the residents (Jensen, 2007). Furthermore, the Funkis villa has more rooms, including a big living room and smaller work-related rooms (Thorsen and Degnbol, 2008). Many of the Funkis Villas has a first floor which was found very functional because upstairs rooms do not have any sloped walls due to the cubic shape and flat roofed building form. Living rooms, balconies and entrance to the garden are often placed to the south to enable the residents to enjoy the sun in these primary housing functions. The layout of houses from the *functionalism* period included bathroom, toilet and central heating.

Original villas	Todays' styles	Architectural rules	
Patrician 	Master Mason 	Classism 	Symmetry in window placement. Mullions in the windows. No significant overhang. Decorations on the façade allowed. Often bay windows, balconies and halfhipped roof with dormer. Symmetric plan around an double-axis
Funkis 	Bungalow 	Functionalism 	Windows are located with respect to indoor functional requirements. No mullions in windows. The façade is flush, monochrome in color with no decorations. Flat or very small roof slope. May have overhang. The plan may be asymmetric if functional.
State Loan 	Standard 	Standard House 	Windows are located with respect to indoor functional requirements. No mullions in windows. Sloped roof. Often a significant overhang. The façade is with no ornamentation. Functional rather than symmetric plan.

Figure 1. Todays' prevailing architectural styles and rules in Danish single-family homes.

The style *Standard House* (Figure 1) emerged from the style of the State Loan houses (1938-1958) which is considered a simplified version of the Master Mason Villa (Hede, 2008b). The external appearance is walls of red bricks with wood in top of the gables, and simple pitched roof which often creates an overhang. Windows with no mullions were placed according to function (as in the style *functionalism*); they often have big windows facing the backyard (private areas), and smaller high-placed windows towards the street (public area). The plan areas is relatively small for the time (less than 100 m<sup>2</sup>), and had therefore room geometries inspired by the style *functionalism*; living room and secondary are connected directly without any corridors to maximize functionality of the scarce space. The room height was relatively low compared to earlier styles but a more spacious feeling was sometimes achieved by letting the ceiling follow the slope of the roof. All State Loan houses have a bathroom and a toilet. In the period 1960-1980, many families wanted to move from the cities and into the suburbs. This led to a mass production of *Standard Houses* in this period; approx. 40 % of detached single-family houses in the current Danish building stock are from this period (Statistics Denmark, 2016). These houses were 'catalogue products' i.e.

not designed for the specific user or site but they are a rather universal in terms of function (Hede, 2008c). They were also rather cheap and fast to build as they were made primarily from prefabricated elements. The external appearance and window placement is quite similar to the *State Loan House* but the plan area was larger and varied in geometry. The larger and sometimes more diverse geometries often resulted in the need for less functional transportation areas.

### Case example

The design of a new house in the style *Functionalism* (see Figure 1) is chosen to illustrate interactive GPM. The example is kept simple: the floor plan is fixed according to Figure 2, while window area, window placement, and overhang are parameters that may vary according to simple architectural rules defined for two different types of façade ("A" and "B" in Figure 2). Two different set of rules were investigated: Scenario 1 has no architectural rules attached to the window geometry and placement parameters, while the window geometry and placement parameters in Scenario 2 are constrained by the user to follow the architectural rules identified for the style *Functionalism*. See Figure 2 for details. In both scenarios, the home had highly insulated constructions ( $U<0.15 \text{ W}/(\text{m}^2\text{K})$ ), low-energy windows ( $U_g=0.53 \text{ W}/(\text{m}^2\text{K})$ , SHGC=0.5,  $U_f=1.38 \text{ W}/(\text{m}^2\text{K})$ , frame width=0.054 m,  $\Psi=0.06$ ), mechanical ventilation with heat recovery ( $0.3 \text{ l/s/m}^2$ , SFP=800 J/m<sup>3</sup>, HR=0.85), and low infiltration rate ( $0.1 \text{ l/s/m}^2$ ).

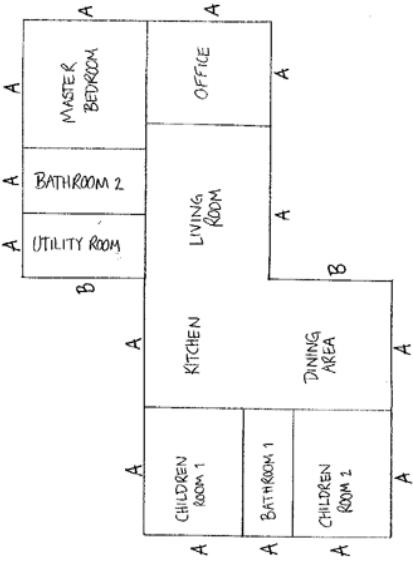

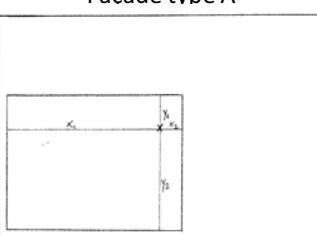

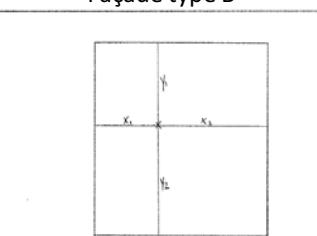

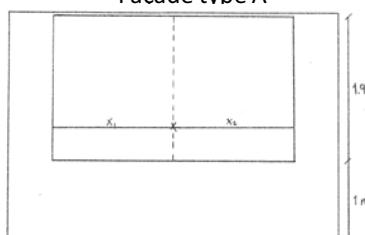

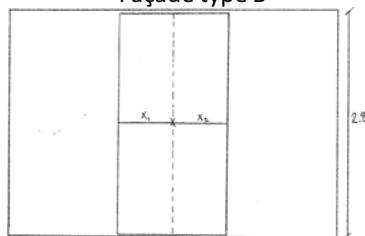

Floor	Scenario 1 (no rules)	Scenario 2 (functionalism)
 <p>"A" and "B" refers to the façade types</p>	<p>Façade type A</p>  <p>Window may vary in size and placement.</p> <p>Façade type B</p>  <p>Window may vary in size and placement.</p>	<p>Façade type A</p>  <p>Fixed parapet (1.0 m). Fixed window height (1.9 m). Window always centered in wall (<math>x_1=x_2</math>). Only width may vary.</p> <p>Façade type B</p>  <p>Fixed window height (2.8 m). Window always centered in wall (<math>x_1=x_2</math>). Only width may vary.</p>

Figure 2. Case example. Left: The floor plan. Right: Architectural rules for the variable parameters.

The GPM was run for both scenarios with the objective to minimise primary energy use for building operation, e.g. space heating, mechanical ventilation and cooling, circulation pumps and domestic hot water, as defined in the European Performance of Buildings Directive (EPBD, 2010). The minimisation was constrained by an indoor operative temperature requirement of maximum 100 hours above 27 °C, and maximum 25 hours above 28 °C per year. Furthermore, the glazed area of a window cannot be less than 15 % compared to the floor area of the room to ensure a minimum of daylight. The described thermal and daylight constraints are analogue to the recommendations provided in the Danish building regulation (BR15, 2015).

## Results and discussion

Table 1 shows the architectural solution spaces for each room in both scenarios, i.e. the number of solutions for each room that ended up fulfilling the thermal and daylight constraints while the GPM minimised the energy use. In principle, each solution consists of a unique combination of window geometry, window placement, and overhang.

Table 1. Architectural solution spaces and their energy performance.

	Scenario 1 (No rules)		Scenao 2 (functionalism)	
	Solutions (-)	Energy use (kWh/m <sup>2</sup> /yr.)	Solutions (-)	Energy use (kWh/m <sup>2</sup> /yr.)
Living room	678	28.7±1.0	24	27.0±0.8
Master bedroom	686	33.6±0.9	138	35.0±0.9
Room 1	124	30.2±1.3	32	31.2±1.2
Room 2	342	38.0±1.0	58	39.1±1.2
Bathroom 1	326	35.4±0.2	90	36.0±0.2
Bathroom 2	408	39.8±0.6	185	40.4±0.7
Office	46	36.7±1.7	8	38.2±0.6
Utility room	517	51.1±1.0	19	54.0±0.6
TOTAL (average)	-	36.7±6.5	-	37.6±7.4

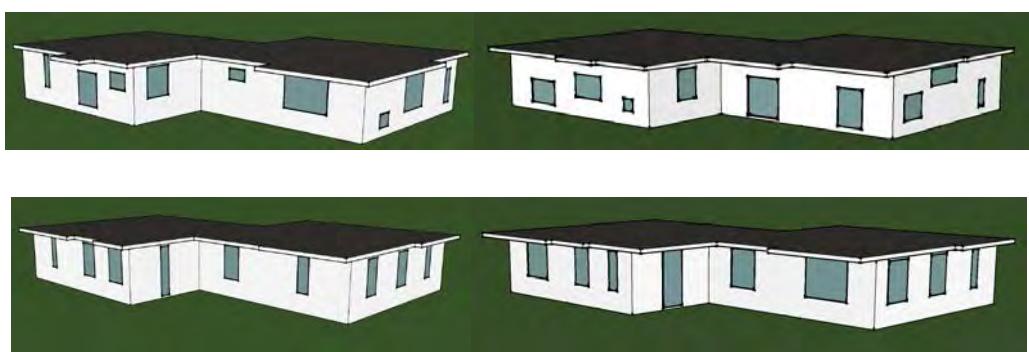

Figure 3. Solutions with different architectural expression. Top: scenario 1. Bottom: Scenario 2.

The architectural rules added in Scenario 2 had a significant influence on the amount of possible solutions generated by the GPM, and they also increased the average energy consumption slightly. When browsing through the possible solutions on room level, many of them are only slightly different in architectural expression but there are also solutions with different architectural expressions to choose from as illustrated in Figure 3. In general, the typical façade solution in Scenario 2 has a calm rhythm, is readable, and has a sense of an

architectural idea in the external appearance whereas the more random window placement and size of a typical solution in Scenario 1 seems to be rather coincidental and without the sense of an architectural idea in its external expression.

The average energy performance of the rooms in the population of possible solutions could probably be lowered even further by increasing the amount of insulation and decreasing the infiltration rate. However, changing these energy-related boundary conditions would also remove and/or add possible solutions to the architectural solution space. Furthermore, the geometry of the overhang is rather random in both scenarios and could from an architectural point of view maybe benefit from following a certain line of rules. This would also affect the architectural solution space generated by the GPM.

## Conclusion

The example of this paper demonstrates that an interactive GPM concept is able to automatically generate numerous of solutions with minimised energy use while respecting user-defined requirements to the quality of the thermal indoor climate and daylight conditions – but also while following certain user-defined architectural rules. The designer may now choose one of the generated solutions to refine further, or to go back to the GPM, revise the requirements and rules, and generate a new set of possible solutions to choose from. However, new studies are required to assess whether this GPM-based approach is considered useful to practicing designers working on real life building projects.

*Design to Thrive*

## Frames and Finishes: The Evolution of a Performance Based Aesthetic

Craig Robertson<sup>1</sup>, Nic Crawley<sup>1</sup>, Julia Yao<sup>1</sup>

<sup>1</sup>Allford Hall Monaghan Morris Ltd, Morelands, 5-23 Old Street, London, EC1H 9LV.

**Abstract:** New working patterns, changing legislation, developing technology and economic uncertainty has pushed designers and clients to think more collaboratively about how commercial buildings are designed. This paper describes the evolution of a performance driven aesthetic through designed and built by Allford Hall Monaghan Morris architects. The narrative uses mixed POE data and environmental modelling to discuss integrated performance metrics including energy, productivity and economic return. A study of the economy, robustness, flexibility and longevity of Victorian warehouses led to the development of a series of modern incarnations. A suite of design techniques is used, including: integrated structure and services in a speculative office with minimal applied finishes, re-purposed flexible structures, sophisticated engineering and control mechanisms in new factory-style offices, all integrated to deliver optimum performance. This thinking is explored in three design stage buildings that share a further development of this approach and aesthetic. The buildings are in London, Bristol and Salford. Discussion focusses on how resource efficiency, low energy consumption and user control has driven the development of this aesthetic. Conclusions include the need for greater design collaboration combined with articulation of economic benefits to deliver high performance integrated architecture.

**Keywords:** Aesthetics, Performance, Energy, Resources, Integration.

### Introduction

The market for commercial office space is increasingly competitive, with a recent flattening of demand in London particularly, the competition for tenants is fierce ([www.rics.org](http://www.rics.org)). Commercial buildings account for some 26% of UK's total CO<sub>2</sub> emissions (p. 110. [www.theccc.org.uk](http://www.theccc.org.uk)) and while CO<sub>2</sub> emissions are the focus of the building regulations, the metrics defining performance are shifting towards a more complex measure of occupant focussed performance like wellbeing or productivity (World Green Building Council, 2014).

With a more rounded view of the environmental impacts of buildings and within the budgetary and supply chain pressures of the commercial office market, Allford Hall Monaghan Morris architects (AHMM) have developed an expressive architectural approach focussing on energy, daylight, user interaction, resource use, quick turnaround of tenancies, low construction waste, maximised comfort and return on investment (Robertson and Idzikowski-Perez, 2016).

This paper describes the development of an aesthetic for commercial office space driven by these various performance criteria based on the historical precedent of urban warehouses. Warehouses are re-purposed throughout the UK to house creative and office based industries. The qualities that allow this functional adaptability and attract potential tenants include low capital and operational costs, tall ceilings, large daylit volumes, the ability to condition space passively through use of thermal mass and large span, flexible floor plates.

The following case studies illustrate the evolving aesthetic through five complete or completing buildings focussing on an aspect of performance.

### **Tooley Street – Energy**

160 Tooley Street in South London is a six storey, 18,600m<sup>2</sup>, part new build, part refurbished mixed-use speculative development completed in 2008 that embodies progressive thinking about commercial architecture.

The brief was to embrace sustainability, enhance the character of the existing buildings and maximise net lettable area. Focus was given to utilising modern methods of construction where high levels of prefabrication would lead to cost efficiencies and waste reduction.

Figure 1. New façade.

Figure 2. Exposed mass.

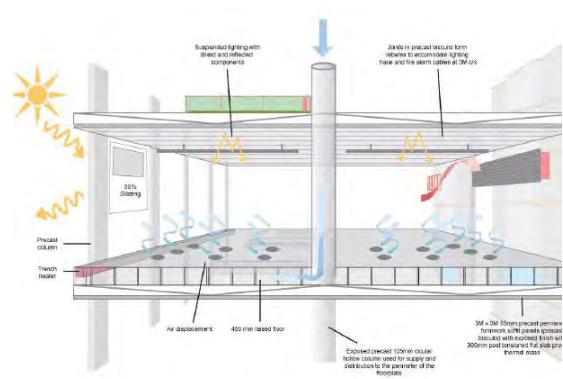

Figure 3. Illustrated servicing strategy.

The materiality of the new facades responds to the urban context, materials are hard and glazing ratios are driven by solar gains (figure 1). Internally, a new offices aesthetic becomes apparent, driven by the building's energy strategy. Exposed concrete takes advantage of the thermal capacity of the material by absorbing daytime heat gains. Lighting and other services are exposed and carefully detailed, adding to the new aesthetic (figure 2).

A displacement air conditioning system with centralised extract removes grilles from the ceilings. 'Structural ducts' deliver air to underfloor plenums. Air travels down from roof level so as the capacity of air required reduces, the structural need increases (figure 3). This reduces riser space in the core and integrates architecture, structure and services.

Tooley Street represents an aesthetic driven by energy performance, challenging the prevailing aesthetic of suspended lightweight aluminium ceilings. The space delivers a commercially attractive internal environment (it is fully let) integrated building physics, structure, services and architectural expression.

### **Morelands - Indoor Environmental Quality (IEQ)**

Morelands Rooftop is a part new-build, part re-use BREEAM Outstanding penthouse office on top of former warehouses on Old Street, London. The structurally light new 5<sup>th</sup> floor complements the heavyweight refurbished 4<sup>th</sup> floor. Both are large volumes that maximise natural light and ventilation and minimise the use of applied materials.

The façades were insulated and rendered, unifying the external appearance of the two floors and improving the thermal performance (figure 4). The space is naturally ventilated via occupant controlled windows at low level on the perimeter walls and at high level to central

light wells (figure 5). The exposed concrete soffit on the 4th floor helps with night cooling and external blinds are linked to UV sensors reduce external gains.

Figure 4. External render.

Figure 5. Interior.

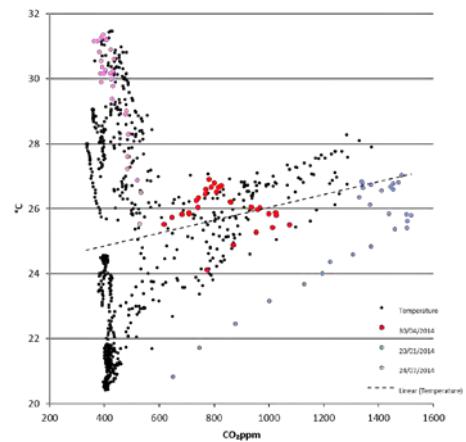

Figure 6. Indoor air quality.

Temperature monitoring shows that the spaces are generally much warmer than they were designed to be. Figure 6 shows three different weeks of data comparing CO<sub>2</sub> concentrations with internal air temperatures. Occupants appear to open windows when temperatures reach around 25-26°C regardless of CO<sub>2</sub> concentrations. Reducing concentrations of internal pollutants requires earlier, lower temperature engagement with windows and ventilation (Robertson et al, 2015). Management strategies have been developed to mitigate this.

The environmental approach to Morelands drives the aesthetic but temperatures are generally outside of CIBSE standards. A pleasant space means happier occupants but needs managed to deliver comfortable conditions (Idzikowski-Perez, 2015). A performance based aesthetic must make occupant led management strategies explicit.

### ***Tea Building - Economics***

The Tea building is the reuse of an existing warehouse building in Shoreditch, London (figure 7). Initially approached as a demolish and rebuild project, due to an economic slump the design approach shifted towards a cheaper, more flexible solution. The finished building houses a variety of commercial spaces and has become a byword for economic regeneration of existing buildings.

The aesthetic in this case was driven by economics, both capital expenditure and return on investment providing a range of spaces that were not only cheap to build but cheap to let. Acknowledging that the building was refurbished in a changing market – lease rates trebled in the first ten years of occupation – the building was designed with ease of change and evolution built in.

Ongoing improvements include window upgrades, through wall controllable background ventilation, solar control blinds and insulation of the facades, lighting control systems and night-time purging. An active hybrid system was also implemented through installation of a high efficiency rooftop heat exchanger which provides a hot & cold water thermal loop through the building that can be connected to provide heating, cooling (or both) to any unit.

Figure 7. The Tea building.

Figure 8. Interior at the Tea building

The Tea building represents an aesthetic driven by economic performance. Refurbishment of the existing building has brought back into economic use a perfectly good warehouse building (figure 8). The rough and ready aesthetic allows for gradual upgrade of the building as rental value increases and market expectation changes.

#### ***University of Amsterdam - Low resource use***

The University of Amsterdam project is the regeneration of a post-war campus in central Amsterdam. The project involved the re-invention of an existing building (figure 9), with substantial structural alterations and replacement of the facades.

AHMM's approach focussed on the movement of people around, through and into the building, integrating the structure into the streetscape. New public rooms encourage the non-university users into the building (figure 11) and newly formed colour-coded mini atria help orientate building users and provide opportunity for social interaction.

Figure 9. Retained concrete

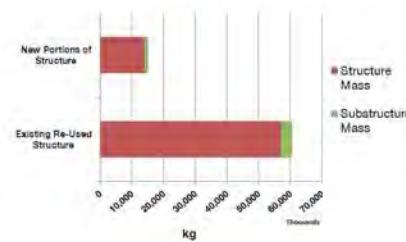

Figure 10. Retained mass.

Figure 11. New public room and low energy concrete.

Re-using the existing concrete frame meant that the most embodied-energy intensive, and massive, part of the building was already in place (figure 10). To further reduce embodied energy, new concrete structural components used cement replacement with GGBS (ground granulated blast furnace slag) content of over 67%.

The heat capacity of the existing frame is used with night ventilation as a thermal store to reduce the need for mechanical cooling. In addition to the embodied and operational energy savings, retaining the frame and utilising off-site manufacturing helped reduce construction waste, saving 60,000 tonnes of rubble, and the resultant thousands of tipper truck journeys across the city.

The University of Amsterdam represents a project that has an aesthetic driven by resource reduction and the retained structure. The existing frame is the structure, the internal finish and is engaged in the energy performance of the building.

### ***White Collar Factory - Integration***

As a naturally-ventilated sixteen storey spec-office with a focus on smart servicing, flexibility and adaptation to future uses and climate, the White Collar Factory (WCF) at Old Street Yard is a bold iteration of the new commercial aesthetic. Featuring long spans, flexible floor plates, operable windows, generous volumes and robust construction, the climate control benefits of the building's passive design eliminates the need for air conditioning.

Figure 12. WCF Exterior.

Figure 13. WCF Interior.

The WCF uses Concrete Core Cooling (CCC) as its primary method of conditioning the office environment. The cooled slabs provide radiant cooling and thermal mass to absorb internal gains. The design principles are an evolution of the warehouse derived characteristics: high ceilings, a passive façade with openable windows that respond to orientation through varying the amount of shading, activated thermal mass though the CCC, highly flexible floor plates and a deep plan to maximise opportunities for adaptation.

The relatively low technology approach of the environmental strategy – which relies on simple building physics – is combined with a high-tech series of data display systems that allow building users to interact and control their space. A simple traffic light system that lets occupants know when the building is in hybrid mode and windows should be opened. The

relationship between architecture, controls, technology and the physical systems drive the integrated aesthetics of the building system.

### Three New Buildings

#### *Manchester - Regeneration*

New Bailey Square in Salford will provide flexible working environments referencing the spirit of Salford's industry. It will be a 21st century warehouse for work (figure 14). The performance principles of this building are to maximise active frontages, create a unique identity, clean and open floor plates and maximised daylight and views out. This is expressed through a standard and efficient material palette that expresses materiality honestly, intelligently and sustainably.

Figure 14. Exterior.

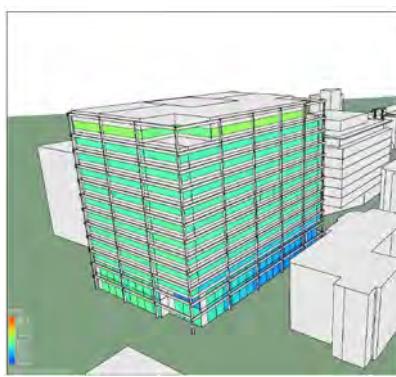

Figure 15. Solar Gains assessment.

Figure 16. Elevation.

The steel structure is exposed and held 600mm from the facade. This performs several functions. It provides solar shading in a market that demands a maximally glazed envelope (although this building is at around 55% glazed due to included solid spandrel panels), which in turn means higher G-Values are possible, reducing glass costs and improving visible light transmittance. The frame, its construction and the shadows it casts becomes the main architectural expression of the elevation allowing the 'skin' to be a much more economical component than would be otherwise possible. Cold bridges are dealt with using resin plates at the point of penetration. Our energy model was analysed to explore the aesthetics' relationship to performance criteria. The external steel frame helps to reduce solar gains by 10% while not significantly impacting on daylight levels or views out (figure 15).

Servicing systems are expressed in the interior and openable windows improve occupant comfort. Minimal applied finishes reduce resource use (figure 16). The street frontage is activated by a mix of complementary uses and each floor level enjoys generous private outside decks.

The aesthetic of simple, cost effective flexible floor plates is reflected in benefits in energy consumption and flexibility. The developing masterplan demands quick and economical construction, this approach delivers a building that can meet these requirements.

#### *London - Efficiency*

This new build speculative office forms part of an emerging masterplan in London. The building comprises of 10 storeys of office use above ground floor of retail and reception. An

external steel frame expression (figure 17) has been pursued, creating an architecture that reflects how the building is made and functions. This results in a universal building that is economical and performs significantly better than briefed environmental targets (figure 18).

Figure 17. Elevation.

Figure 18. Interior.

Figure 19. Energy Savings.

Early studies investigated opening window provision and findings suggested that there were significant benefits to incorporating opening windows as part of the controllable aesthetic; energy reductions were potentially as high as 90% (figure 19). The steel frame performs a similar range of functions as New Bailey Square. The shading effects of the frame on this project are a near 10% reduction in gains.

This aesthetic is an expression of efficient, lean, low resource use which drives low energy in operation, however the opportunities of such an approach require explicit statement in management guidance.

#### ***Bristol - Integrated Aesthetic***

Assembly in Bristol is a mixed-use scheme on Bristol's floating harbour awarded planning permission in early 2017. The proposals provide new flexible office space for up to 3,000 people. Sustainability has been an integral part of the design process, emphasis has been placed on passive design measures.

Figure 20. Exterior.

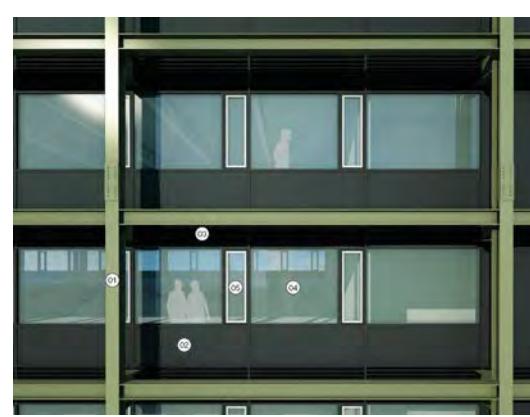

Figure 21. Elevation.

The strategic thinking behind this project has developed to include specific architectural expression of materiality, construction techniques and environmental performance (figure 20). The building again uses an exposed steel frame and develops this aesthetic with an

exploration of dry construction techniques, CLT floor plates, and visually expressed opening windows (figure 21).

The architectural aesthetic reflects these multi-faceted performance aspirations and allows for flexibility in the design to aim for multi-faceted performance targets. Adaptability to climate, function and servicing, low waste and unitised construction and occupant control.

## Discussion

The deliberate, strong expression of construction materials and methods and integrated environmental strategies represents a departure from mainstream commercial building design, where identity is typically defined by a shallow wrap-around skin of limited visual interest.

Expressing the structural elements reflects the nature of manufacture and fabrication of a semi-industrial aesthetic, a language of construction that is appropriate to the 21st century urban workplace. Internally, a language of limited applied finishes, occupant controlled environments with open, simple floor plates creates a connection between user, architecture and environment.

The strong character of such buildings is defined by multiple functions and performance metrics of energy, economy, low resource use, flexibility and adaption. Internal spaces can change and evolve whilst being comfortable, productive and efficient now and in the future.

In complex urban environments with many conflicting performance targets spanning economy, environment and human impact, an integrated aesthetic than synthesises and expresses these with simplicity, economy and delight has emerged.

# PLEA 2017 EDINBURGH

*Design to Thrive*

## Presence of energy concerns in the conceptual approach of Fernand Pouillon in the 50s: The Case Study of Pouillon's Housing Estate in Algiers

Mohamed Tehami<sup>1</sup> and Karima Anouche<sup>1</sup>

<sup>1</sup> Faculté d'architecture et de génie civil, Université des Sciences et de la Technologie d'Oran Mohamed Boudiaf, USTO-MB, BP 1505, El M'naouer, 31000 Oran Algérie ;

**Abstract:** After the Second World War, several responses were proposed through the CIAM charters about the future of mass construction of housing. It was through standardization and the use of new materials as well as industrialized techniques and construction processes similar to the mass production system. Sustainable development and the reduction of energy consumption were not their primary concerns. In the 1990s, energy concerns were part of the quality problems of buildings in the architectural design. However, the solutions proposed were mostly isolated and purely technical. Meanwhile, in the 1950s, Fernand Pouillon introduced new ideas and a new vision concerning the future of the mass construction of housing, bearing in mind the built environment and the durability of the material. He developed a design process based on an industrialization of construction processes by *simple element* instead of *heavy prefabrication* of the housing. Through the analysis of the housing estate of Fernand Pouillon's "*Climat de France*", we will try to show his modern vision of the future of housing and the presence of energy concerns in his conceptual approach.

**Keywords:** Sustainable development, Fernand Pouillon, Climat de France, industrialization by simple element

### Introduction

The philosophy of sustainable development applied to architecture is based on the design of a sustainable building that respects the environment through its constructive process, building materials and conceptual approach. After the Second World War, a major acceleration in the reconstruction process began to rebuild what the war had demolished. Heavy industrialization was the absolute answer for modern architects of the time. However, this industrializing had negative repercussions on the natural and built environment. In 1987, in the report "Our Common Future", European Commissioner Harlem Brundtland set up a new concept: "Sustainable Development", aimed at "reducing social inequalities, while preserving the environment in a sustainable manner, Economic development". Therefore, it is a development that "must meet the needs of present generations without compromising those of future generations" (Tolba & Biswas, 1991).

Meanwhile, Fernand Pouillon introduced new ideas and a new vision for the future of the construction of mass housing, which were criticized by most of his colleagues. He called into question what the masters of the modern movement saw as the only way towards modern architecture. He concretized his ideas thanks to Jacques Chevalier newly elected mayor of Algiers at the time, who entrusted him with the construction of more than 7000 apartments divided into three complexes: Diar Es Saada, Diar El Mahçoul and Climat de France.

He resumed all the issues that were discussed by the modern movement. The most fundamental is the question of mass production of housing; "*I struggled alone so that the neglected part of the architecture finds life, spirit and love*" (Pouillon, 1968).

We will try in this manuscript to draw a small panorama on the development of post-war architecture until the emergence of the notion of sustainable development. In parallel, we will show the new vision of Pouillon in the 1950s for the future of the massive construction of housing that is concerned with the impact of architecture on the natural and built environment, as well as on the inhabitant.

### **Panorama on the development of the architecture since the post-war period until the emergence of the notion of sustainable development**

The housing crisis of the 1950s favoured the borrowing of the industrialization way to deal with the quantity problem. The industrialization of the building began after the first world war of 1914-1918 with some pioneers, architects and builders, impressed by the results achieved in the automotive and aeronautical industry such as Walter Gropius, Voisin (constructor of airplane), Henri Sauvage and Jean Prouvé (builders), Le Corbusier and Marcel Lods (*Sociétés des architectes préfabriquateurs*), Beaudoin and Auguste Perret. (Chemillier, 2002)

However, the disastrous situation of France in 1945 after the second world war accelerated the process of industrialization of the building. The solution for building a lot, quickly, and inexpensively was the factory prefabrication such as in the automotive industry with reinforced concrete as the preferred material. This need of building obliged the architects of the modern movement to find other alternatives. This situation has favoured the search for new paradigms that go along with this industrialization. Le Corbusier invented the free plan with the constructive system in domino and opposed it to the paralyzed plan resulting from the constructive system in bearing wall (Le Corbusier, 1994).

The success of industrialization in the automotive field is based on the control of the production chain, the large quantity of production, and the continuity of the production process in the same place. In the building, the last two elements were a problem. Despite the large quantity of built housing, they were dispersed in several sites. To solve this problem, the France government launches the ZUP (zones à urbaniser en priorité) which means in English "areas to be urbanized as a priority". It allows to group together a large number of dwellings to be built in a single site to get even closer to the image of automotive industrialization. (Chemillier, 2002). It should be noted that this industrialization was efficient in terms of quantity. The annual production of housing in France rises from 46,000 units in 1951 to 360,000 in 1964 (2002).

In the late 1960s, the demand for housing in France fell sharply, forcing the state to halt major operations. The exchange solution is the grouping of orders (in 1969 a threshold of 200 dwellings was imposed for the HLM<sup>1</sup>) and the use of the models (a model project is established by an architect and contractor who is approved by the state and used to ensure a large housing order).

However, the urban forms generated by this type of construction has begun to be rejected due to a monotonous architecture of models in the early 1970s. The large amount of housing generated by industrialization processes required quality management as in the automotive industry. Therefore, the architects have started talking about quality, which has

---

<sup>1</sup> "Habitation à loyer modéré" which means in English "Low-income housing"

become an important criterion just as quantity. Once again, the quality management of the manufacturing industry was taken as a model to develop quality measurement approaches in the building sector (Gann, Salter, & Whyte, 2003). The building is still considered as an industrial product.

The end of the 80s and the early 90s stands out for the concept of sustainable development and respect for the environment in construction. It has been found that the industrialization of the building has created problems with architectural quality, integration into the context and respect for the built environment. In the last 50 years, we were only concerned with the quantity of the building while neglecting its impact on the environment.

A return to the vernacular architecture has become very encouraged to rediscover the noble, sustainable, and ecological materials, as well as an architecture that respect context ,and the built environment.

At the same time, in an industrial vision, researchers propose technological approaches to make building sustainable (Kibert, J. C, 2016). However, these steps are very costly. As a result, ecology and sustainable development have become trademarks. These approaches concerned only parts or components of the building following an industrial vision. These are mostly very expensive technological solutions that have been integrated into the building. These solutions rely on the principle that the overall management of the building is the sum of the management of its various parts. While the architectural whole is more than the sum of its parts (Dehan. P., 2009).

Whereas back in the 1950s there was Fernand Pouillon, an architect who found sustainable and ecological solutions at the time to respond to the housing crisis. While his colleagues saw the future of construction in heavy industrialization, he returned to the architecture of traditional cities. He has opted for the industrialization of construction processes by simple element (Barazzetta, 2001) of noble and durable materials like dressed stone and terracotta. He has developed a design process to reduce the ultimate deadline and cost of construction with remarkable architectural quality. It had even become a slogan for him. For the operation of 200 housing units in Aix en Provence in France, he said that I will build 200 homes in 200 days for 200 million francs.

Even though there was no mention of sustainable development at the time, Pouillon was concerned about the impact of its architecture on the built environment and its inhabitants. The three pillars of sustainable development are present in the architecture of Pouillon; Reducing social inequalities by building monuments for the poor and delivering equipped homes in the Diar Es Saada operation; Preserving the environment in a sustainable manner by building with noble and sustainable materials while respecting the built environment; And finally build at a lower cost and in a short time without constraint on economic development.

### **Climat de France**

Climat de France is the third and last housing estate built by Pouillon in Algiers between 1954 and 1957 (figure 1) in the working-class district of Bab-el-Oued. The complex is located on the heights of Algiers with views on the sea, on sites selected exclusively by Fernand Pouillon. The complex is part of a political project for the equality of Muslim and European citizens. They are part of an HLM program to make up for the housing deficit in the capital, on one hand; and they are aimed at getting rid of the slums in Algiers and at giving a new urban image to the capital, on the other hand.

Figure 1 : Climat de France ground plan

Source : « la fondation des pierres sauvages de Fernand Pouillon

We will try to show in this part the presence of the three principles of sustainable development in the architecture of Pouillon in the fifties, when at that time; worrying about the environment and the durability of the materials of construction was not an important issue.

### ***Reducing social inequalities***

Reducing social inequalities, as it is the first pillar of sustainable development, it was also one of the most important objectives for Pouillon. He is known as a social and humanist architect. "I had focused my life on the social role of architecture: first of all, to build cities for the improvement of the condition of men, putting comfort and beauty within everyone's reach" (Pouillon, 1968). He was able to concretize his vision by building monuments for the poor of Algeria of the 50s, which was a French colonization at the time, to try to equalize between the Europeans and the Muslims of Algeria. It is the dignity of men that interests him. He said in his "memoires": "I had only one goal, one only: to impose by number and quality, a form of human and generous architecture, to create an example." (1968)

### ***The respect of the environment by building in a perennial way***

The second principle that concerns the respect of the environment by building in a perennial way is present in the architecture of Pouillon. His preference for dressed stone and terracotta brick as building materials avoids the additional costs of coating and maintenance as in reinforced concrete constructions. In addition, stone is a noble and durable material unlike concrete. He said about this: "I had been interested in materials for a long time. I hated the ugliness of render, the colour of concrete. For me the century of reinforced concrete posed problems of appearance, of surface, of the skin of the building ". (Caruso, 2014)

Pouillon's choice of the stone to solve the housing crisis in the fifties was contrary to common practice, where an overwhelming majority of architects and engineers, supported by administrative and political apparatus, have opted for industrial prefabrication (Lucan, 1996). Even based on the principle of repetition and standardization like his colleagues, Pouillon escapes the monotony and the standard-project which poses the problem of

integration in context. In Climat de France, Pouillon was inspired by the cities of the M'Zab and the Casbah of Algiers, and the fact that there is a single traditional house that repeats itself in the most human aspects, with a maximum of fantasy, without no feeling of boredom or monotony (1996). The complex of Climat de France is designed with the same housing unit that of Diar El Mahçoul. He relied simultaneously on two principles of composition, the principle of bilateral symmetry and the principle of the picturesque.

Moreover, Pouillon has also invested in ventilation mechanism, natural lighting and thermal insulation to reduce the energy consumption of his buildings for the poorest inhabitants of the poor Algeria of the time. Pouillon focused on purely architectural solutions that are durable and passive. Pouillon opted for the closed order to compose his complexes. This conceptual choice consists in the arrangement of buildings around a place to create an interior landscape. Whereas at the time, modern architects abandoned the closed order with the spatial organisation of city blocks and the traditional street, or *rue-corridor* (Caruso, 2014). They opted for the open order based on the hygienist principle and the optimum orientation of the buildings in relation to the sun's path (Lucan, 1996).

We will not dwell on the details that concern the two principals of architectural composition. We will focus instead on bioclimatic advantages of the principle of the closed order.

#### *Natural ventilation*

As far as natural ventilation is concerned, two principals have been implemented: cross ventilation (through flats) and chimney ventilation.

Cross ventilation is assured as all apartments of Climat de France are through apartments (figure 3) except of a single building where the apartments are separated by a patio in the middle. This design choice highlights the comfort of the inhabitants by the variety of sights and sensations of space even in small rooms.

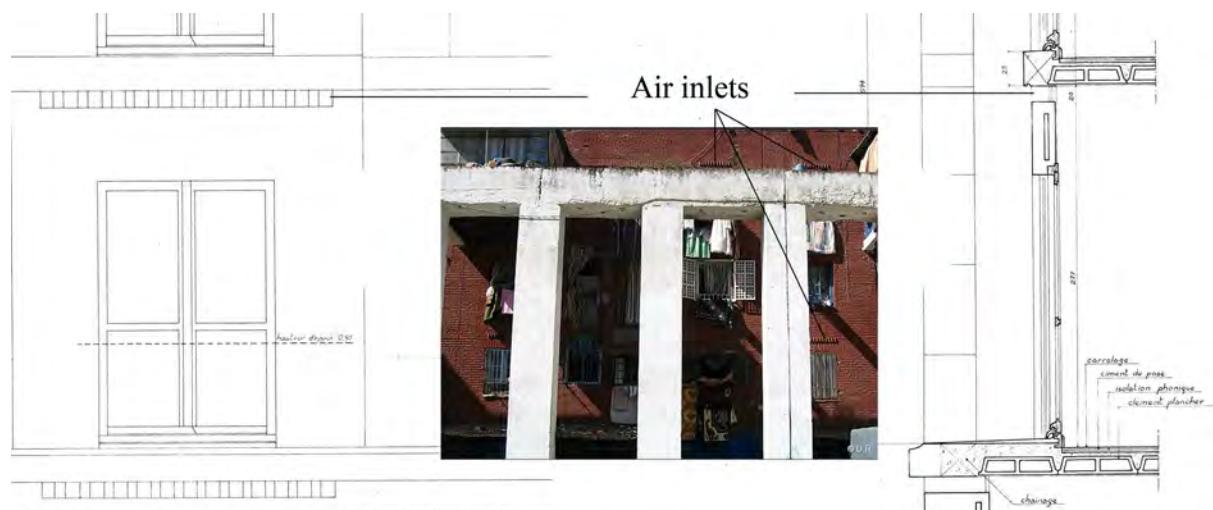

Figure 2: Air inlets in the façade's windows of Climat de France  
Source : « la fondation des pierres sauvages de Fernand » edited by the

While in chimney ventilation, the air moves due to the differences in wind pressure between the façades of the building and the difference in the density depending of its temperature without any mechanical equipment. It is the stack effect (thermal draft) where the air penetrates by the air inlets that Pouillon has laid over the façade's windows (figure 2)

and will be evacuated by the vertical ducts that are placed between the kitchen and the bathroom that Pouillon called "la courrette".

The different squares in the complex of Climat de France allow to reinforce the nocturnal ventilation during the summer by playing the role of the courtyard in a single house (figure 3). During the night, the internal temperature of the rooms surrounding the square rises due to the dissipation of the heat stored in their walls, due to their exposure to the sun during the day. As soon as the windows are opened, the air is renewed automatically. Fresh air in the shaded place is transmitted through the low openings to the inside, thus evacuating hot air through the high openings (stack effect).

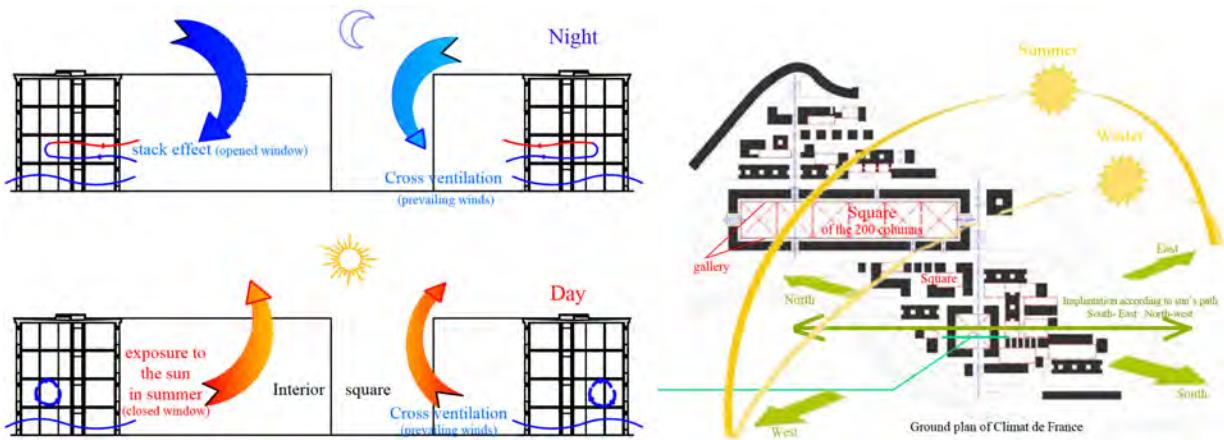

Figure 3: Natural ventilation (cross and chimney ventilation) and lighting in Climat de France

#### *Natural lighting*

Natural lighting is also ensured by the fact that most of the apartments are floor-through apartment, which allows to have windows in all rooms, as well as an implantation of the complex according to sun's path (South-East, North-West)(figure 3).

The desire to control and minimize solar radiation entering the living space in arid zones such as in North Africa, for example, often results in a decrease in natural lighting. The square offers the possibility of reconciling these two contradictory constraints. In the building of the 200 columns (the largest building of Climat de France), Pouillon surrounds the square by a shaded gallery (figure 3) which contributes to reducing the impact of solar rays on the exterior walls of the building.

#### *Thermal insulation*

For thermal insulation, Pouillon takes advantage of the density of the dressed stone to protect itself from large fluctuations in temperature. However, even if the dressed stone slows down the entry of the cold through its inertia, after a certain time it does not become more insulating than a thin wall and thus constitutes a source of wastage. That is why Pouillon added an insulation consisting of a thin wall of terracotta brick in the interior face of the facade with an air gap in the middle.

On the urban scale, the shaded squares and the traditional streets that offer the composition according to the principle of the closed order allows an autonomous protection of the sun during the summer. The arrangement of the buildings around the squares greatly reduces the surfaces exposed to the sunshine in the image of the concept of introversion adopted in the medina.

### **Constructing at a lower cost and in a short time without constraint on economic development**

The third principle of sustainable development is the most important in the architecture of Pouillon. Constructing at a lower cost and in a short time without constraint on economic development was Pouillon's slogan.

The design of the Climat de France differs completely from the different complexes built at the time. Although Pouillon has industrialized the construction of mass housing, he has not followed the same heavy industrialization as in the operations that marked the era. Whereas Pouillon has opted for an industrialization of construction processes by simple element (Barazzetta, 2001). It means industrialize constructive elements such as dressed stone or terracotta brick. The stone constructive system was traditional at the time; Pouillon had to develop a new constructive wall system with dressed stone as building material to gain in construction time, cost and architectural quality.

This constructive system is very economical in time and cost, but it is possible only because the walls are bearers. If we want to describe; it is a floor composed of 14cm of marmite<sup>2</sup>; which is a prefabricated slabs, hollow but closed square that pose upside down on the closed and smooth face to constitute a finite lost formwork (figure 4). Marmites are placed against each other to form a grid like a chocolate bar. The reinforcing bars are placed in the gaps between marmites in both directions of the grid, and there will be which is called a floor with crossed ribs. After the concrete will be poured into the ribs to fill the void between marmites and constituting thereafter joists. The first rows of bricks will be laid before pouring the compression screed to use the grid as a reference frame for walls of the internal partition. (Sayen, 2014)

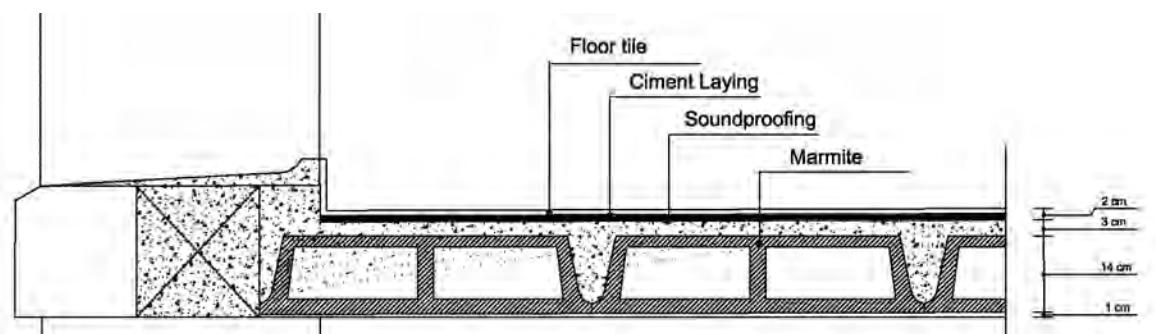

Figure 4: The constructive system of Pouillon

Source : by the author

It should be noted that in the late 1970s, heavy prefabrication was replaced by a policy aimed at developing the use of 'component' in construction. A component was defined as an element of the building manufactured in a workshop independently of a particular project and integrated into the structure without having to undergo shaping on the site (Chemillier, 2002). This is the same principle of industrialization of construction processes by simple element that Pouillon followed in the 50s, which proves once again that his answers were ahead of his time.

<sup>2</sup> A *marmite* is a hollow square, part of the floor structure invented by Pouillon made of staff (a mixture of plaster and fiber) or cement, through which a steel frame and concrete pass, like ribs, to support the floor.

## Conclusion

After this brief passage on the architecture of the 1950s and the vision of Pouillon on the future of housing construction, we have seen that the notion of sustainable development in the 1990s was a reaction against the repercussions of heavy industrialization on architectural quality and the environment. Moreover, even if this way of industrialization in the image of the automotive industry solved the problem of quantity, it had negative repercussions on the architectural quality of the construction and on its environmental impact. In order to maximize its industrialization, the building was considered as an industrial product rather than an architectural object. Despite all this, we have never managed to industrialize the building in 100%. Moreover, the good results that were achieved in the 1950s and 1960s were in artificial conditions favoured by the strong commitment of the state (Chemillier, 2002). Pouillon had another vision of the future of massive housing construction; he opted for an industrialization of construction processes by simple element considering the building as an architectural object more than industrial product. Instead of making a clean sweep of the architecture of the ancestors, he took the best of the traditional cities architecture of 17th and 18th century and updating it according to the technological means of the time. The principles of sustainable development were present in his architecture even before the existence of the report "Our Common Future". This is because the architecture before its heavy industrialization was sustainable and ecological. We needed only to update its construction processes according to the new technological means with keeping in mind that the building is an architectural object and can never be an industrial product like the automotive.

## From lightweight pioneering steel houses to zero energy buildings

Francesca Thiebat<sup>1</sup>, Andrea Veggia<sup>2</sup> and Luca Raimondo<sup>3</sup>

<sup>1</sup> Dipartimento di Architettura e Design, Politecnico di Torino, Turin, Italy. Correspondence email francesca.thiebat@polito.it; <sup>2</sup> PAT. architecture sustainability urban design, Turin, Italy. <sup>3</sup>Architect, Turin, Italy.

**Abstract:** In XX Century California, three generations of architects pushed the boundaries of language, experimenting the use of then uncommon materials to build lightweight, modern houses. It all began with Neutra in the 30's, who achieved the ideal of the house made like a car, building his Lovell house out of steel framing and sprayed concrete at a time when his European counterparts applied machine aesthetic to houses who still were brick and mortar below the clean coat of white plaster. Architects such as Ellwood, Eames, Soriano and Koenig produced a fascinating skin and bone aesthetic, making no nonsense use of commercial steel sections in order to produce economical yet refined buildings. However, it was not just their fascinating aspect, but the logical, almost scientific, approach that makes those buildings so appealing. Today's knowledge of materials, energy conservations and building dynamics can produce high performance buildings that greatly improve on yesterday's standard. A case study shows how sites and building technologies work together. Sites was studied to minimize excavations and exploit prevailing breezes in order to minimize use of HVAC. A dynamic analysis of the building was run to determine the composition of walls and roof and glazed surfaces.

### Lightweight Californian steel houses

#### ***Innovation in the twenties***

In his History of Architecture of 1899, Auguste Choisy wrote that "styles do not change following the whimsies of fashion, variations are the results of changes in the construction process". In the early twentieth century, the industrialization of processes in most spheres of man made products, led progressive architects to promote a new wave of industrialized buildings. "If houses were built industrially –wrote Le Corbusier in 1920- in line, as automobile frames, we would quickly see the rise of unexpected, yet healthy, forms, and the aesthetic would be formulated with surprising precision". On the same page we find Richard Neutra, who preached that "the house of the future will be built out of standard steel components, assembled like a car, and it will take on a beauty which will not be based on the old decorative forms, but on a new beauty of rhythm and order" (Neutra, 1931).

However, if Europe was the one pushing the ideal of the "house built like a car", it was America who made this dream possible. Between 1927 and 1929, at a time when his colleagues back home were applying machine aesthetic to houses which were still brick and mortar below the clean coat of white plaster, Neutra was building the Lovell House out of steel and sprayed concrete (fig. 1).

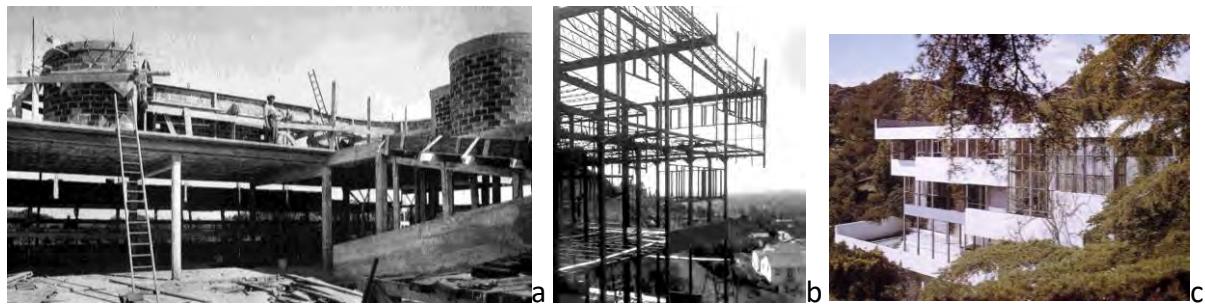

Figure 1 a/b/c. (a) Le Corbusier-Jeanneret, Ville Savoye, 1928-31. (b) (c) Neutra, Lovell House, 1927-29

Neutra's biographer Thomas Hines claims it to be "the first steel framed residence in America". This is a well-established notion, but it is not true. In fact, a research published in 1930 by the America Institute of Steel Construction<sup>1</sup>, records six steel framed homes in 1927, 42 in 1928 and 65 in 1929. In fact, although the first steel framed residence in America was built near New York almost thirty years earlier, what makes the Lovell House stand out and steal the limelight is well summarized by Kenneth Frampton, who defines it the apotheosis of International Style, thanks to an architectural expression directly derived from a steel frame, clad by a light synthetic skin (Frampton, 1980). Design of Steel Buildings by Harold D. Hauf, first published in 1932 and probably the first manual on steel construction in the US, is a good meter of the Lovell House achievement. In fact, studying this manual, it becomes clear that technological and aesthetical innovation did not go hand in hand: besides the framing, the steel buildings were not different from most current production.

### ***Developing a language***

To develop a language that fully exploits the potential of new materials and technologies takes time. If the Lovell House, with its steep site, free flowing plan and big glazed surfaces was making full advantage of steel, it was not yet the epitome of the light steel and glass pavilions associated with California lifestyle. This is mostly due to one reason: steel profiles were not visible in the finished building if not as window mullions (fig. 1b and 1c).

The minimal skin and bone aesthetic, defined by Reyner Banham "The Style that Nearly...", was to appear another thirty years later, at the peak of Arts and Architecture Magazine Case Study Houses program (Banham, 1971). It was the development of a process of expression of the steel frame which allowed Raphael Soriano to show most of it in the forties, and Pierre Koenig to show it all in the fifties. In between these experiences are those of Charles Eames and Craig Ellwood. Eames built for himself a house which was of great consequence, especially in Europe, where it came to epitomize the potential of a residential architecture made out of off-the-shelf components, dry assembled (fig. 2b). Ellwood built some significant specimens which helped define the new architecture vocabulary, before shifting towards Miesian mannerism.

---

<sup>1</sup> Facts and Figures about Steel Construction

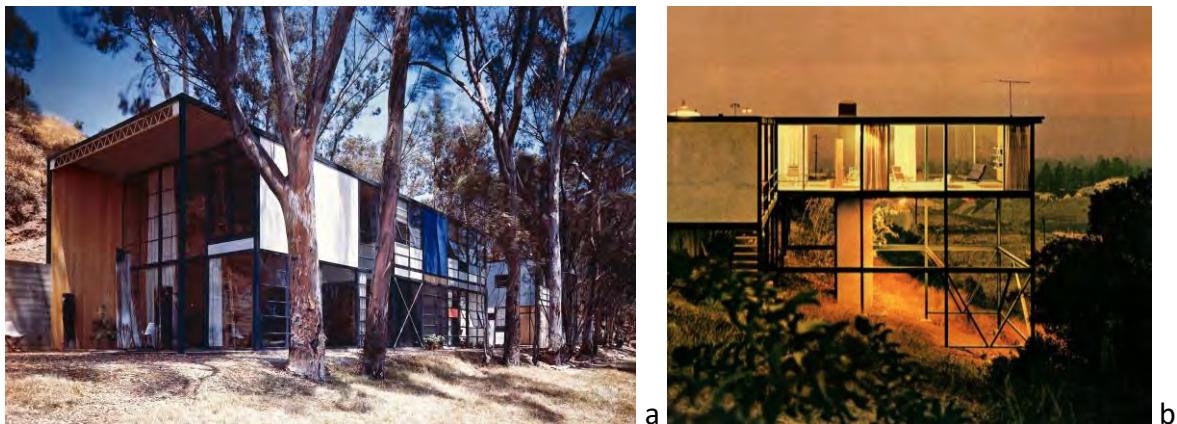

Figure 2 a/b. (a) Charles Eames, Eames House, 1949 (J. Shulman/C© J. Paul Getty Trust). (b) Craig Ellwood, Smith House, 1958 (© Marvin Rand)

Whilst Soriano tested the use of steel in houses more than anyone else before him, proving it was possible to use the material within ordinary budgets, it was Koenig who delivered the most memorable shot in the CSH #22, hovering above West Hollywood and incarnating modern lifestyle in countless movies and commercials (fig. 3a and 3b).

Figure 3 a/b/c. (a) Raphael Soriano, CSH #1950 (J. Shulman/C© J. Paul Getty Trust). (b) Pierre Koenig, Case Study House #22, 1959-60 (J. Shulman/C© J. Paul Getty Trust). (c) P. Koenig, Case Study House #21, 1958 (©author).

Still, Koenig did not limit himself to fully developing a convincing aesthetic for steel in residential buildings, but moved one step further in pioneering the use of passive means to cool his houses at a time when steel and glass buildings were made possible not only by the materials themselves, but by the massive use of HVAC systems. The fact that these passive means became so inextricably tied to what makes the best Koenig's buildings iconic is proof of how the conscious use of energy and available resources can the final look of a building in a successful way. In CSH #21, his most successful demonstration of a repeatable building for mass production, he relied on the orientation of the building to block the sun, completely blinding facades on the East and West, where solar radiation is more difficult to control, and using a vertical external sunscreen on the South and North facades (fig. 3c). He adopted wide overhangs in CSH#22, which worked especially well in giving the house a "floating" quality over the dramatic hillside site.

### ***Moving forward***

Although fascinating on their own, buildings by Soriano and Koenig share a logical, almost scientific, approach that makes them especially appealing. Each is a step forward in pushing the progress of a specific building type. Whilst Soriano devoted over 20 years of his professional life to releasing the potential of steel, in his later years he applied himself to exploring the application of the even lighter aluminum, while Koenig moved forward on the

path of exploiting passive means of getting rid of HVAC, establishing the Natural Forces Laboratory at USC. The interest in bioclimatic design already present in his work of the fifties was further developed in projects such as the house he built for himself in the mid-eighties, where free cooling techniques were tested.

The first Californian experiences of bioclimatic and low-energy houses of the 60s and 70s were joined by the “intelligent building” concept of the 80s, when several buildings gradually included the control of various equipment and systems. From these experiences, the US Department of Energy (DOE) launched the Zero Energy Home Initiative (ZEH) in 2003 and the Building Technologies Program (BTP) in 2008 (Panagiotidou and Fuller, 2013). For the ZEH, five demonstration projects have been developed, most located in California. For the BTP, the aim is to introduce a common national Zero Energy Building definition with supporting nomenclature and guidelines to facilitate its use. Crawley et al. (2009) has provided the first definition of ZEB as “a residential or commercial building with greatly reduced energy needs through efficiency gains such that the balance of energy needs can be supplied with renewable technologies”. A broadly accepted definition of ZEB metrics and boundaries is foundational to efforts by governments, utilities, or private entities to recognize or incentivize zero energy buildings, and would have a significant impact on the development of design strategies for buildings<sup>2</sup>. Then, the net Zero Energy Building is not a building where the energy demand is zero, but a building for whom the energy delivered is equal to the exported energy for 1 year of operating.

### **The Case Study: the Grand View drive House GVH**

Lessons from the former generations along with new building design technology aids were applied to the design of a new single family residence in the Laurel Canyon area of Los Angeles in 2013<sup>3</sup>. Here, the constraints posed by site, accessibility and building codes made for a small project of amazing complexity, located in a high fire hazard severity zone in a region whose seismic risk ranks among the highest in the world. The lot is steep and narrow, sloping South to North on top of the ridge of the hill above West Hollywood. It is an interesting coincidence that the site at 8413 Grand View Drive sits on an ideal line joining Case Study House #21 and #22 by Pierre Koenig.

The themes developed in those seminal houses overlap in Grand View: the site shape calls for a building orientated on the North/South axis as in CSH#21, and the challenge of building on a slope, dramatized in CSH#22, is even more demanding here. Yet, the steep slope and the height limit regulation implies that a single story pavilion as the CSHs is out of question, thus linking Gran View House GVH to other precedents in the off the shelf prefabricated steel framed houses lineage: Helmut Schulitz’s own house in nearby Beverly Hills and Koenig’s Gantert House in the Hollywood Hills (fig. 4). Dimitry Vergun, structural engineer for the latter and Grand View House, is an even more direct connection ring.

---

<sup>2</sup> <https://energy.gov/eere/buildings/zero-energy-buildings>

<sup>3</sup> Gran View House, Los Angeles (USA). (PAT. architects, 2013)

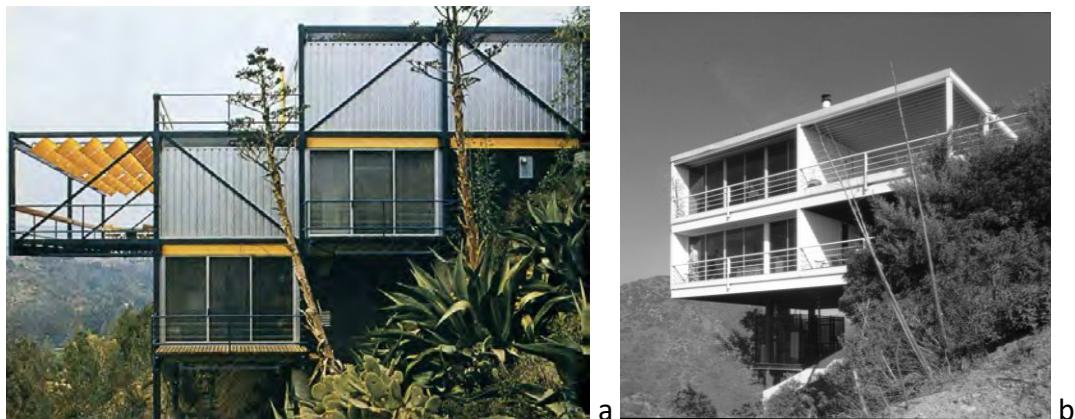

Figure 4 a/b. (a) Helmut Schulitz, Schulitz House, 1976. (b) Pierre Koenig, Gantert House, 1981 (J. Shulman/© J. Paul Getty Trust).

From the road the lot slopes downhill facing the Canyon. Early studies explored the potential of the building to grow in height trying to reach city views versus the temptation to cantilever a simple box on the size of the hill, minimizing excavations. The final massing is composed by a three storey “tower” and a two storey “box” separated by a pool. The garage at street level is on top of the tower, a studio/recreation room is at level -1, a storage at -2, which is the level the “box”, partially cantilevered, is accessed. Served and servant spaces are separated and clearly articulated. Not only service spaces such as storage and garage are separated by the living quarters, but also vertical circulation and toilets are moved to the periphery of the building and become both a mean for architectural expression and a way to fit the trapezoidal contour of the lot.

Figure 5. PAT. architects, Grand View House, 2013 (@patdesign.it).

### ***Integrated design: architecture, technology, structure and systems***

An integrated design team was assembled for the task and worked with an holistic approach to nurture synergies and interactions. The case study shows how site and building technologies worked together to improve building efficiency. The Site was studied to minimize excavations and exploit prevailing breezes in order to minimize use of HVAC. The building was oriented on the North-South axis, with sides facing East and West almost completely blinded in order to control solar radiation, while North and South facades, easier to shade, are glazed and open to cooling breezes. Lightweight, dry assembled techniques, typical of the Region and appropriate for the task of building on a hillside, were preferred. Nevertheless, it was deemed appropriate to have some mass for thermal comfort. The use of PCMs, summing up lightness and passive cooling properties, was explored and eventually

discarded. Steel bays spanning 26 feet support composite metal floors, whose screed is polished and exposed in order to avoid further finishing and exploit the thermal mass. A dynamic analysis of the building provided the basis for determining the composition of walls and the roof and the specs for glazed surfaces. The analysis led to discard the use of SIPS panels, originally envisioned for their ease of construction, LEED credential and high R value, and opt instead for a multi layered ventilated facade clad in galvalume sheets.

All the design strategies contribute both to reduce the energy needs enhancing energy efficiency with passive and active technologies, and to generate on-site energy balancing cost and benefit. In term of ZEB strategy, table 1 summarized the measures applied in the case study presented.

*Table 2 – net Zero Energy Building strategies of the Grand View drive house*

ENERGY EFFICIENCY	DESIGN STRATEGIES
site and orientation	Orientation on the North-South axis, with sides facing East and West almost completely blind in order to control solar radiation.
advanced thermal insulation	Dry assembled envelope highly insulated and without thermal bridges.
high thermal mass	Dry assembled envelope with high density insulations and exposed screed to exploit the thermal mass.
sun-shading and ventilation	Glazed North and South facades, shaded by the balconies and overhangs, opened to cooling breezes and natural light.
mechanical ventilation	Efficient HVAC system embedded in ceilings and walls and integrated with passive night cooling. It takes benefit from the building thermal mass.
comfort outdoor	The presence of the pool cools the air on the outdoor spaces
water demand	System for collecting and reusing grey and rain water
ON-SITE ENERGY PRODUCTION	
solar thermal collectors	Domestic hot water production
photovoltaic panels	Electricity for systems, lighting and home's appliances

### ***Dynamic analysis***

A dynamic analysis of the building under study has been carried out in order to determine both the composition of its walls and roof and the thermal specs of its glazed surfaces. A dynamic analysis requires little extra effort at the design stage and bring advantages such as: the optimization of the envelope system and its relationship with the mechanical systems, reducing operational energy loads; it allows to earn extra points in voluntary environmental assessment tools and the related economic benefits.

From its early stages the design of a nZEB building requires an integrated approach involving different professionals and a careful evaluation of the thermal flows needed to determine the overall building energy balance. The design is aimed at assessing and controlling the future winter and summer thermal performances reducing the load on air-conditioning plant systems and ensuring high hygrothermal comfort.

The design choices of Grand View Residence were all supported by thermal analysis derived from simulation models and characterized by different detail levels on the basis of the specific project needs and phases. For each component of the building envelope, both winter and summer thermal behaviour parameters were compared with the project targets so as to validate or reject the choice made for stratigraphies and constructive nodes. Table 2 allows us to compare the values of thermal transmittance (U), periodic thermal transmittance (Y), phase shift ( $\phi$ ) and attenuation (a) of specified building roofs (R) and walls (W) with the target values assumed by the designers. The building components adjoining the external environment and exposed to sunlight, are characterized by high thermal lag values: more than 7 hours for walls and more than 12 hours for horizontal roofs

being particularly affected by solar radiation in the summer and therefore potentially responsible for the interior overheating. The choice of using insulating materials characterized by a low value of thermal conductivity, high values of mass density and specific heat, enables a lightweight dry assembled structure to get high summer thermal performances.

*Table 2 - Performance characteristics of the individual components.*

	U [W/(m <sup>2</sup> K)]	U <sub>target</sub> [W/(m <sup>2</sup> K)]	Y [W/(m <sup>2</sup> K)]	¶ [h]	¶ <sub>target</sub> [h]	a [ - ]	ENVIRONMENT
W01	0,225	< 0,4	0,082	7h 01'	> 7 h	0,3637	SUN
W02	0,223		0,062	7h 54'	> 7 h	0,2808	SUN
W03	0,388		-	-	-	-	GROUND
R01	0,386		0,235	5h 01'	-	0,6098	SHADE
R02	0,365		-	-	-	-	GROUND
R03	0,182		0,046	12h 19'	> 12 h	0,2539	SUN
R04	0,190		0,047	12h 58'	> 12 h	0,2482	SUN
R06	0,183		0,023	7h 59'	-	0,1233	SHADE

The design choices with regards to the shape, orientation, and the exposure of the building, as well as the envelope technologies and facilities, were supported by an hourly thermal evaluation (dynamic analysis), through the use of TRNSYS software - Transient System Simulation Tool. The calculation has been carried out for a full calendar year in order to quantify both winter and summer thermal loads, temperature profiles in the absence of air conditioning and air conditioning operating hours to maintain comfort levels. Table 3 shows the boundary conditions used for the TRNSYS computation.

*Table 3 - Boundary conditions used for the computation*

Parameter	Values
Temperature	20°C heating 26°C cooling
Local employment / operating systems	24/24h, 365 days
Internal thermal contribution	5 W/m <sup>2</sup> (50% convective, 50% radiative);
Ventilation	0,5 vol/h

Figure 5 illustrates the results of the simulation analysis of two types of insulated and low-emissivity glass: A)  $U_g = 1,4 \text{ W}/(\text{m}^2\text{K})$  and  $g = 0,59$ ; B)  $U_g = 1,26 \text{ W}/(\text{m}^2\text{K})$  e  $g = 0,4$ . The choice of glass B) allows to reduce solar radiant contribution: as a consequence air conditioning load is reduced by 33% in the summer, thermal requirement is reduced by 36% in the summer even though, in the meantime, it is increased by 16% in the winter.

The building as a whole, has a thermal requirement of:

- Summer: 20,98 kWh/(m<sup>2</sup>year)
- Winter: 18,33 kWh/(m<sup>2</sup>year)

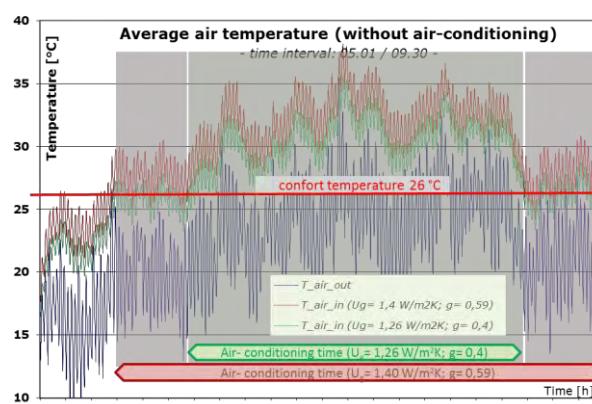

Figure 5. Dynamic simulation analysis of two types of insulated and low-emissivity glass: A)  $U_g = 1,4 \text{ W}/(\text{m}^2\text{K})$  and  $g = 0,59$ ; B)  $U_g = 1,26 \text{ W}/(\text{m}^2\text{K})$  e  $g = 0,4$

## Conclusion

Following in the footsteps of Auguste Choisy, Raphael Soriano said that “the process of questioning, validating, and designing for performance is what bring progress in architecture” (Laskey, 1988). New aesthetics can arise as a result. Advances in construction techniques and computer aided design, along with a rising conscience of the centrality of an integrated design approach can foster both efficiency and the development of an architectural language. But aesthetics by itself does not tell the whole story.

Looking at picture 6, a comparison between the stratigraphy of CSH#21 and GVH highlights how the complexity has increased below the skin of buildings.

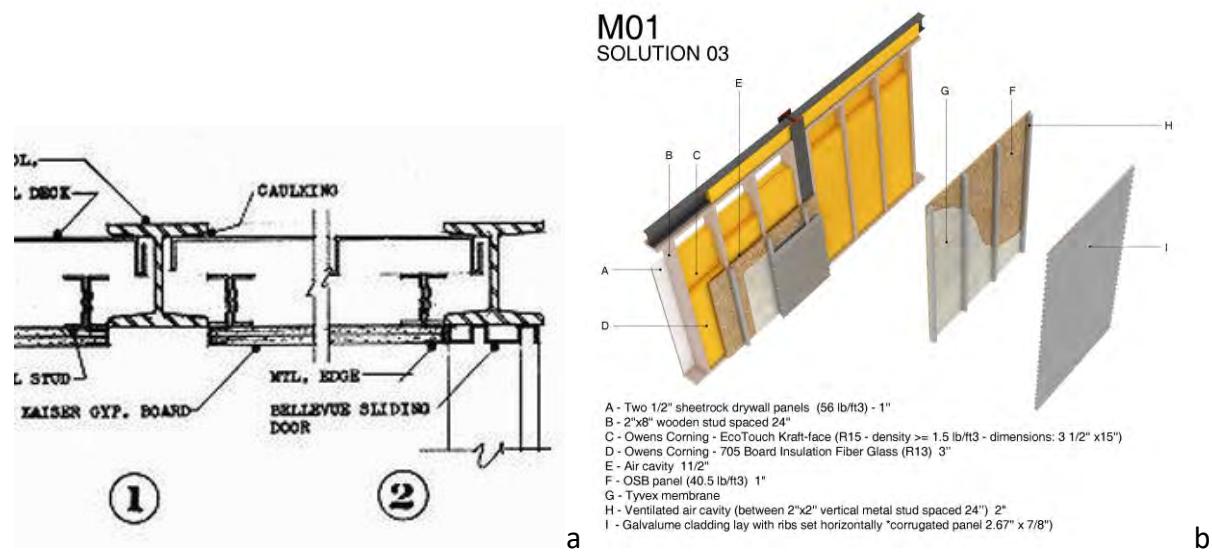

Figure 6 a/b. (a) Koenig, CSH#21, 1958 (b) PAT. architects, Grand View House, 2013 (©patdesign.it).

New software allow to verify design hypothesis, guiding choices toward maximum performance and improving the understanding of the building over its entire life cycle. An interesting outlook of the research could be the comparison of several recent buildings of the same typology in order to recognize benchmarks and improve the state of the art.

## Outsider ethics and marginalized aesthetics: The value of contemporary environmental philosophies for designing sustainable architecture

**Andrea Wheeler**

Department of Architecture, Iowa State University, Ames, 50014, Iowa, USA  
[andrea1@iastate.edu](mailto:andrea1@iastate.edu)

**Abstract:** In this paper, I will explore the work of two contemporary environmental philosophers: Gernot Böhme, celebrated for his philosophy of architectural atmosphere although less known for his work on ecological aesthetics, and Luce Irigaray, a French philosopher renowned for her work inspiring a generation of feminist scholars but less well discussed for her work on environmental ethics. For Böhme, our designed environments are experienced through atmosphere; we feel our own presence in a built environment and feel the environment in which we are present. His approach to design depends on feeling experienced through being in space rather than seeing space or imagining it. Irigaray, on the other hand, now in her eighties, distinguishes experience as different between the sexes, not as already cultural, but rather to be cultivated. Her philosophy is provocative and challenged by many; while on the margins of Parisian intellectual society, she still works, teaches, and writes prolifically about environmental ethics. This paper examines how these two marginalized ecological philosophers can benefit the field of environmental design.

**Keywords:** philosophy, ethics, aesthetics, environment, architecture

### Introduction

What relevance has mood or atmosphere to the discourse of sustainable design? What is the perceived importance of feeling to an architecture that can engage and communicate with users the problems of sustainable development? These questions are seldom raised in the discourses associated with green and sustainable architecture, but feeling connects us with our environment and while the science of climate change produces statistics distancing the problem, and the workings of an environmentally sustainable building can remain obscure to many, feeling is immediate, physical, every day; it is about how we experience our environment in the moment.

According to Gernot Böhme, a contemporary German philosopher, our designed environments are experienced through feeling; we feel our own presence in space and feel the space in which we are present. He establishes an approach to understanding architecture that he describes as an aesthetic dependent on feeling, experienced through being in space rather than seeing or imagining it. Similarly, in his eco-aesthetics, we feel our relation to nature: We feel nature's crisis because we feel the nature we are ourselves.

Luce Irigaray, on the other hand, is an influential feminist philosopher whose work has been pivotal to feminist thinking, shaping a generation of feminist theorists. Liberation is to be experienced, she argues, with our bodies and intimate feelings, in our environments, in place. Irigaray's philosophy is radical and provocative and challenged by many. While on the margins of Parisian intellectual society, with her works refused in her native language, and

challenged by those seeking liberation in post-human identities (I describe her philosophy as post-post-human), she teaches and writes prolifically about sexual politics and environmental ethics.

The intention of this paper is thus to examine how in the context of environmental concerns social aspiration is limited, in particular in the literature on sustainable development. The aim is to address the question of design's role in the engagement and communication of environment awareness through feeling and to carefully and critically examine texts of Böhme and Irigaray to evaluate how these rich relational and ecological philosophies, engaging with ethics and aesthetics, mood or feeling, can supplement the discourse of sustainable development to benefit the field of sustainable design.

### **Sustainable development and social aspiration**

Sustainability can be explained in many ways, but sustainable architecture is focused on how we live. It can be ethical and aspirational. It can ask us how we can live in ethical relationships with other living beings without excessively exploiting our shared environment, but this is most typically expressed as a concern for assessing performance. While sustainability is a social construct, meaning different things to different people across cultures and locations, it is also an environmentally sensitive and responsible expression of our relationship to other living and non-living things. Sustainable design is about our social relationships as well as our relationships to nature and, moreover, it is about how we would like them to be.

In 2013, the United Nations (UN) created the Sustainable Development Goals, replacing the previous Millennium Development Goals, as a definitive statement on aspiration for human development. The Sustainable Development Goals (SDGs) (United Nations, 2015) are a set of 17 global goals with 169 targets among them, including ending poverty in all forms everywhere, ending hunger, ensuring healthy lives for all at all ages, and ensuring inclusive and equitable education. The goals address gender inequality, and goal 5, in particular, states: "Achieve gender equality and empower all women and girls" (see Table 1; United Nations, 2015). Other goals concern access to energy, water, productive employment, resilient infrastructure, and safe cities, addressing climate change and environmental degradation, and promoting sustainable consumption and peaceful society. These SDGs are ambitious, and they supersede the eight Millennium Development Goals (MDGs). Furthermore, the *2030 Agenda for Sustainable Development* asks world leaders to begin efforts now to achieve the SDGs by 2030.

Initiated by Ban Ki-moon, the SDGs are a shared vision for humanity and a social contract between the world's leaders and the people; they constitute a to-do list for people and planet. They include 17 goals to transform our world for the better. However, there are criticisms, and the very number of goals and targets has been called into question. The degree of accountability of all the parties who have voluntarily adopted the agenda is vague and like the scientists' statistics for climate change they are distant goals. The SDGs represent a common aspiration as a policy tool.

Table 1. Sustainable Development Goals (from United Nations, 2015)

Goal 1	End poverty in all its forms everywhere
Goal 2	End hunger, achieve food security and improved nutrition and promote sustainable agriculture
Goal 3	Ensure healthy lives and promote well-being for all at all ages
Goal 4	Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
Goal 5	Achieve gender equality and empower all women and girls
Goal 6	Ensure availability and sustainable management of water and sanitation for all
Goal 7	Ensure access to affordable, reliable, sustainable and modern energy for all
Goal 8	Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all
Goal 9	Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
Goal 10	Reduce inequality within and among countries
Goal 11	Make cities and human settlements inclusive, safe, resilient and sustainable
Goal 12	Ensure sustainable consumption and production patterns
Goal 13	Take urgent action to combat climate change and its impacts
Goal 14	Conserve and sustainably use the oceans, seas and marine resources for sustainable development
Goal 15	Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
Goal 16	Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
Goal 17	Strengthen the means of implementation and revitalize the global partnership for sustainable development

### **Feeling, ethics, and sustainable design**

So, if architecture as a discipline invites engagement and inhabitation, how can architects and designers invite users to engage with the problem of sustainable development? Architectural aesthetics is a discourse positioned somewhat at odds with the performance agenda of sustainable design, including that it might have some of the same distant social and humanitarian aspirations as the SDGs. However, researchers recognize diverse ways of constructing knowledge, even in the field of construction, and, moreover, within the field of construction research, scholars are increasingly challenging methods adopted to collect performance data, questioning tools and measures, and highlighting the complexity of the impact of any building on its environment, including its social and economic contexts. Nevertheless, these are experimental studies with little impact as yet on the industry and professions. Such studies are themselves aspirational. Confronting accounting perspectives that promise to build future ecological worlds is a difficult challenge in light of biases of the architectural and construction professions.

So, what is design's role in engaging and communicating the problem of sustainable development? Also, can eco-aesthetics be separated from architectural ethics? What is really at stake with such questions?

We feel nature and we feel its destruction. We feel it as the nature we are ourselves. This is Böhme's argument. So, we might be able to feel, and feel intimately, our own impact on the environment. We can thereby act ethically toward the nature that we are ourselves. We can better feel our lived environment, we can feel ourselves in our environments, feel the reality of our existence in relation to our environments and, in this way, cultivate a more

intimate ethic toward the environment. This is a powerful perspective as a way of engaging people with the problem of environmental crises and motivating action. As designers working in the built environment, the important addition to sustainable design becomes one of communication.

This sort of dialogue, this understanding of our own nature in relation to nature, Böhme has described as an eco-aesthetic discourse (*ökologische Naturästhetik*). According to Böhme, nature must be recognized as our partner and we should gradually adapt to such a partner relationship. Nature is not something we have left in our becoming civilized; nature and the natural in us are not to be overcome. As he argues, "...it is only now that we realize that what has been carried out as the domination of nature is, in fact, a totally impossible project" (Wang, 2014).

Nevertheless, Irigaray is of a similar age to Böhme and she is known for her work on sexual difference, or rather her ethics of sexual difference, that which she calls *sexuate* difference. Her philosophy is not without some contestation, and she similarly describes starting with the nature we are ourselves, returning to ourselves, discovering a natural belonging, but importantly for Irigaray this is also *sexuate* belonging: It is the discovering of the life that we are ourselves in relation to *sexuate* difference rather than in our cultural descriptions and designations (Irigaray, 2015, 101). It is a rethinking of relations from intimate relations and this means rediscovering a living embodiment in ways not yet culturally recognized. Like Böhme, she argues that "...the first ecological gesture is to live and situate ourselves as living beings among other living beings in an environment that allows life to exist and develop" (Irigaray, 2015, 101). So, she adds to an eco-aesthetic a perspective difference in feeling between the sexes, an 'ethic' to be culturally recognized.

Hence, if we feel nature, as Böhme suggests, we feel our relation with the natural environment, we feel ourselves as nature; Irigaray asks, do man and woman feel in the same way, and can we engage with such questions without falling into stereotypes? Moreover, is this a development of an ethic that can cultivate the emergence of at least two equal and different subjectivities? We can reflect on our social experience, our relationships and our sensory experience, and we can find excitement in the post-human and futuristic; many different perspectives engage and incite. The document that describes the United Nations Sustainable Development Goals is, after all, entitled *Transforming Our World: The 2030 Agenda for Sustainable Development*. However, entering the world of these philosophers is not the same work as developing the SDGs. So, why bring tricky outsider ethics and marginalized aesthetics into the field of sustainable architectural design? The value is one of criticism, but the validity of such criticism is immediately at risk because of its outsider status. This is an argument about feeling, every day, immediate, physically embodied; however, the merit of such is yet to enter into the dialogue on sustainable design.

In her most recent publication *To Be Born* (2017), Irigaray writes, "Who could maintain, that he or she is not in search of their origin in their dreams regarding the future, their amorous desires, their aspirations for the beyond? ... who is able not to make up one's mind according to a secret nostalgia for at least understanding in what one's origin consists?" (Irigaray, 2017, 3). These feelings are understood through cultural traditions, through language, poetry, art, often lamenting the loss of a truly natural environment, but the feelings seduce, romance us, and are artificial. Our reality is, as Irigaray argues, that we are made not from one apparent source of such nostalgia, to which we long to return, for refuge, for peace, a desire characteristic of so much of environmental philosophy, but our

existence is "...an actualization of the elusive event of a meeting between two humans" (Irigaray, 2017, 4). Feeling is key to Irigaray's philosophy, and feeling is how we can rethink environmental awareness. However, this is the ecological reality of an as yet to be recognized and cultivated relationship between at least two human subjects in a relationship of equality and difference. She writes:

*...so as long as we do not consider the two ec-stasies from which we can exist as humans: the ec-stasis with regard to our origin, and the ec-stasis for which our desire calls us. These two different ec-stasies, in a way these two not being must be taken on in order that we can discover what means our 'to be' as human and endeavour to incarnate our own destiny* (Irigaray, 2017).

So, we need to question our reality and discover our own ecological and sexuate belonging; this is a radical perspective, albeit one that also critically situates body and feeling, mood and feeling, in questions of environmental and sustainable design. Outsider ethics and marginalized aesthetics have some value, not only to serve as a critical lens but also to enrich the discourse of sustainable architecture through the reevaluation of feeling.

### **Outsider Ethics and Marginalized Aesthetics in Sustainable Design**

We design buildings to be energy efficient and to be ethical. We design them to be beautiful, and yet we tend not to ask people how in actuality they feel in buildings or how they understand their built environments. We do not fully recognize the power of the sensory dimension in our methods, in our predictive energy modeling tools that shape how we understand design, or in how we assess buildings and their performance in actuality. With the few exceptions of theorists who are described as engaged with humanities perspectives on climate change (Hume, 2011, 2015; Barnes et al., 2003; Ingold, 2011), architects and scholars following research methods that challenge dominant intellectual or policy research perspectives (Divine-Wright, 2005) and researchers examining and adopting innovative methodologies in construction science (Pink et al., 2010), the dominant perspective from which we view the problem of environmental design and, moreover, sustainable design in architecture is that of the sciences.

The need to widen our perspective on research methods is, nevertheless, being explored in building and construction research. Pink et al. (2010), for example, describe their work as a response to a more thorough application of social science theory and methodology to industry research. They argue that approaches to research can even be designed to enable sensory ethnographers to share other people's experiences and "...to generate closer and empathetic understandings of these experiences" (Pink, 2010). However, there is still some need to step back and engage with philosophers and philosophies, and with humanities perspectives, that are driving such motivations. The call to re-envision a human future and ecology is radical and, as Irigaray writes, "... it would be advisable to wonder about what being alive signifies, and whether we are really living, or how we could be or become living" (Irigaray, 2015, 101).

Furthermore, while social theories of behavior change are developing and Gill et al. (2010) argue the field is a major untapped route for energy savings, the varying knowledge, attitudes, and abilities of users or occupants nevertheless present a fundamental barrier to strategies of education and building performance optimization. Building researchers tend to conceive the problem of sustainable design as a technical challenge to which acceptance needs to be solicited. Moreover, future strategies to educate users require, they argue, "...a

thorough interdisciplinary understanding of attitudes and behaviours due to their inherent complexity and impacts" (Gill et al., 2010, p. x). Behavior, of course, is a person's response as a consequence of complex interactions between internal and external factors, which for all intents and purposes, describes how affect, the vague feeling of being in a building, motivates action. These factors, they argue, might include "... emotional, moral, habitual, contextual, attitudinal, social, normative, and control factors" (Gill et al., 2010, 496). There are methodological questions to be directed to the field, but while the question of feeling is raised in performance-based studies of energy-efficient and sustainable design, the question of feeling is not addressed *as* feeling. Feeling in terms of an emotional connection to place, however, is not new to architecture (Seamon, 2000; Manzo, 2003). It is just that the fields are disconnected and Böhme and Irigaray are new philosophers to enter the conversation on environment and place and to offer perspectives on questions of co-existence between us and in relation to the natural environment.

Böhme's eco-aesthetic describes a relationship between the human and nature, but Irigaray questions the very feeling for such an original relationship and indeed the ethics of the feeling. She argues that romantic feelings for nature are artificial and created by cultures, which at their foundation are unethical with respect to the environmental. We might say that her radical philosophy challenges the reality of Böhme's eco-aesthetic, as well as the ethics of his approach. It also challenges the value of environmental philosophies and the traditions to which they belong and questions, radically questions, the human condition. Also, perhaps without articulation, Irigaray's is also contested by both feminist philosophies and those working with the tradition.

## **Discussion**

So, what should we do about feeling, this dimension of experience with competing philosophical perspectives? The dominance of a technical point of view in sustainable building design is shaping a growing alternative conversation, which includes provocative and political philosophies, but design is also emerging as a method by which to address these questions. Why examine this field through the work of these two philosophers – Böhme and Irigaray? Why is this sort of radical, this sort of outsider, significant? Both seem to address questions of coexistence (of man and nature, man and building, man and woman, man and woman, and nature), together with the felt, bodily or experiential reality of our environmental crises. However, for Böhme, what counts in terms of our environmental crises is that we can rediscover our identity as natural beings "...and develop the consciousness that our body is the nature that we ourselves are" ("Der Leib ist die Natur, die wir selbst sind") (Wang, 2014). He argues that we must recognize that we care about nature because it affects us, it has been affecting us, and it will continue to affect us. He states that "...finding ourselves involved in environmental degradation, it is our own nature that is being affected" (Wang, 2014). What current environmental conditions have destroyed is thus not the object that is the environment, or that of our own nature, but our relationship with it. For Irigaray, the tradition of philosophy, a patriarchal tradition that has excluded socially marginalized voices, including women, does not value questions of embodiment or the rediscovery of embodiment or the reality our ecological co-dependency, the intimacy of our sharing of the world. It is this tradition that has destroyed our relationship to our environment. She writes: "This tradition has, in this way, rendered us extraneous to our environment, extraneous to one another as living beings, and even extraneous to ourselves" (Irigaray, 2015, 101).

Böhme's major works on eco-aesthetics or ecological aesthetics of nature (*Ökologische Naturästhetik*) are largely untranslated, but they include *Für eine ökologische Naturästhetik* (1989), *Atmosphäre: Essays zur neuen Ästhetik* (1995), and *Die Natur vor uns. Naturphilosophie in pragmatischer Hinsicht* (2002). The difference between the co-existence suggested by Böhme and that offered by Irigaray rests in the intimacy with which we experience a natural or ecological belonging. According to Böhme, our interest in nature and in our environmental crises is not motivated by a selfless concern to save the earth, but by a concern for ourselves: It is our own nature being affected. Irigaray, however, calls for a deeper intimacy and an ethics toward the environment by considering social relationships first and discovering a way to recognize the embodied versus sexuate difference.

So, which should be the preference for the field of design, if indeed sustainable development is aspiration? Is Böhme's approach, mediated by an understanding of nature and our human experience, steeped in tradition, the real correspondence with nature, or is Irigaray's the more ethical approach and more attentive to cultural and sexual differences?

Böhme's *ökologische Naturästhetik* is not a visually focused aesthetic view about whether nature is beautiful or not; it is about how nature influences our own feeling of being there, our locatedness (*Befindent*). He argues that it is through our senses that we feel the environment in which we are located and it is the atmosphere of an environment that brings the human situation and the quality of the environment together (Wang, 2014). According to Irigaray, however, we have subjected this world, our world, within ourselves as well as outside ourselves, to a fabrication, an artificiality, one that prevents us from finding ourselves, our locatedness (Irigaray, 2015, 102). While the senses still offer a way to cultivate feelings, our senses are, she writes, "...one of the mediators through which we can pass from a mere natural belonging to a cultured humanity, because they represent a privileged access to our communication with the world and with the other(s)" (Irigaray, 2015, 102). Even to value our embodiment and recognize the value of our sensory experience, we need to co-construct a culture which understands an intimate co-existence: We need an eco-aesthetic of sexuate co-habitation. Environmental and sustainable buildings can be pleasurable to live in, beautiful at a sensory level, and this may be an immediate and physical way to engage with people and communicate the importance of environmental awareness and motivate action. This would be Bohme's argument. However, is this an eco-aesthetic and ethical theory in terms of our own feeling of being there, for both man and woman? Can a more intimate approach appeal more as philosophy that considers the variety of social inequalities in experience and cultural differences, including those of women? Böhme's thinking about architecture and atmosphere suggests an experience through all the senses: a multisensory experience. Architecture is best understood through feeling. Böhme discusses sexual difference as a discovery in relation, but this is not the same sort of intimate discovering or embodiment and relationality that Irigaray describes. Living beings are sexuate, Irigaray argues, and if we continue to consider ourselves as neutered individuals, if we sustain a misrecognition, we cannot behave in an ecological way (Irigaray, 2015, 103).

There is a trail of implications, not the least of which is the failure of sustainable building design in actuality if we continue to disregard the social dimension of sustainable design and how architecture can engage and communicate. Buildings do not use energy, people do; the growth of knowledge about energy use and user behavior in buildings is not leading to better user education. As Janda argues, "...no one is accepting responsibility for

the education of the 99.3% of the population who use buildings" (Janda, 2011, 20). The problem does not simply involve communication, it also involves intimate engagement. Without exploring the significance of complex interactions of building and user, without a reason to include the affective dimension of our environmental experience, and without a theory regarding how such affect shapes our understanding, architects and other building professionals will continue to underestimate its power of feeling to engage and communicate the problems of sustainable development. I have put forward an argument and I want to conclude with the idea that radical thinking is needed; outsider ethics and marginalized aesthetics can provoke the building sciences and can present a critical perspective of value to the conversation on sustainable design. We need critical thinking, not simply for the sake of criticism, but so that we can regain our humanity, our aspirations, our feeling, in these current crises. This is not the end of an argument but only the beginning: To be an environmentalist, to claim oneself to be an environmentalist, before questioning our cultural traditions does not really make sense (Irigaray, 2015, 101). Sustainable architecture needs philosophy as well as science.

## Biomimetics in architecture

**Barbara Widera<sup>1</sup>**

<sup>1</sup> Faculty of Architecture, Wroclaw University of Science and Technology, Wroclaw, Poland  
barbara.widera@pwr.edu.pl

**Abstract:** The purpose of the paper is to analyse and discuss the concept of biomimetics in contemporary architecture. Special attention is given to the attitude towards nature and environment. Biomimetics provides an information transfer from biology to technical disciplines, such as architecture, with aim to understand natural systems and processes developed through evolution, and to implement them in concepts and structures designed by human. The author proposed and applied methodology for multilevel analysis intended to check various aspects of biomimetic approach to the building perceived as a system.

The notion of biomimetics is presented with regard to architecture. Multilevel theoretical model is constructed, based on 3 basic elements related to systems: structure, metabolism and skin. Specific solutions for each of these elements are distinguished and analyzed, under passive, active and hybrid operation mode. The particular examples of selected architectural objects are presented to illustrate the practical application of the research model.

The author looks at relations of the building and environment, comparing them to biological relationships: parasitism, neutralism and commensalism. The discussion leads to remarkable conclusions and provokes some very interesting questions about the role of architecture. Final conclusions address the issues of innovative perception of the built environment as well as shifting baselines regarding ecosystem, climate and sustainability.

**Keywords:** biomimetics, climate responsive, energy efficiency, sustainable building, climate change.

### Introduction

The purpose of the paper is to analyse and discuss the concept of biomimetics as one of the most actual phenomena in contemporary architectural design. The popularity of the topic may be attributed to the development of close links between biological sciences and the technological development. The second reason why we continue looking for inspirations in nature is the changing attitude towards environment, climate and sustainability. The term biomimetics was first used by Otto Schmitt in 1969 in the context of opportunities arising from applying observations from the field of biology in medical engineering (Schmitt 1969). Since then biomimetics has been fast developing tendency, which provides an information transfer from biology to technical disciplines, such as architecture, with aim to understand natural systems and processes, developed through evolution, and to implement them in concepts and structures designed by human (Gruber 2011). This allows for deeper understanding of natural processes developed through the way of evolution, while the analysis of biological phenomena results with systematic transfer of various construction principles and problem solutions into technical applications (Anthony 2014).

Biomimetic approach to architectural design is related to the ability to draw correct conclusions from the natural systems behavior analysis, such as exchange mechanisms

between external and internal environments, including light, energy, gas and liquid (Widera 2016). The purpose of biomimetic design is to create new, complex solutions, based on the biological systems with the assumption that the simple copies of natural models would not work correctly and the deeper research is necessary (Vincent 2006). The author of the paper proposed and applied methodology for multilevel analysis, intended to check various aspects of biomimetic approach to the building perceived as a system.

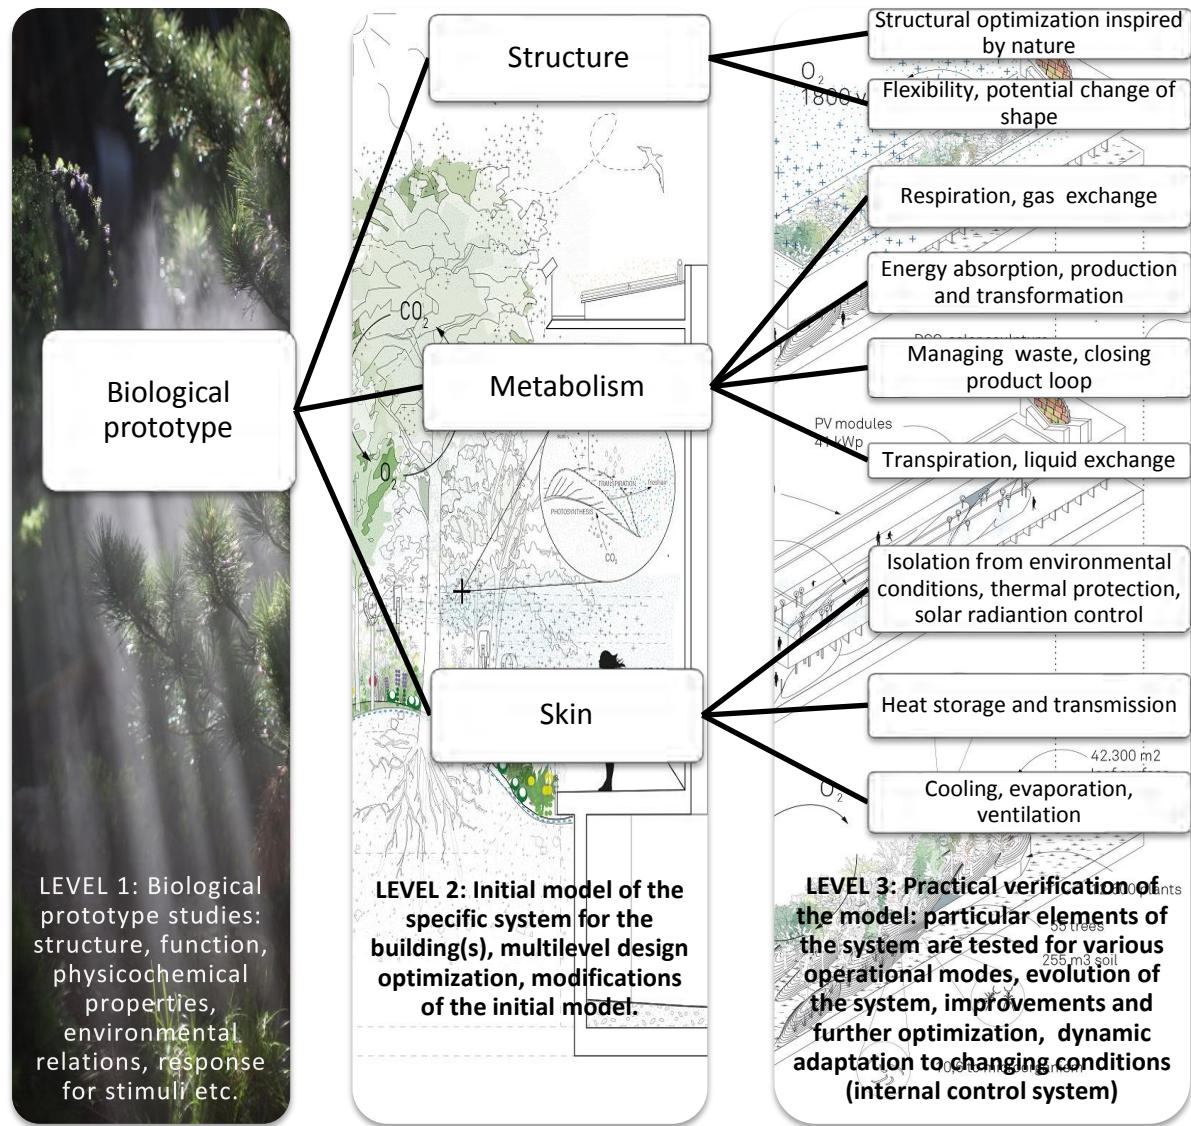

Figure 1. The model of biomimetics in architecture (by Author).

### The model of biomimetics in architecture

In purpose to illustrate the information transfer from biology to the built environment at the beginning of 21st century, the multilevel theoretical model of biomimetics in architecture was constructed (Fig. 1). The starting point of biomimetic design is always a biological prototype. The first level of the model includes studies of selected prototype(s) with respect to its structure, function, physicochemical properties, environmental relations, response for stimuli etc. At the second level the 3 basic elements related to specific system are distinguished as structure, metabolism and skin. Each element is analyzed both

individually and at the system level. Based on the research results, the design optimization process is carried out. Initial model is modified and the developed knowledge is applied to improve the functioning of the building. At the third level passive, active and hybrid solutions are tested to provide practical verification of the model. Particular elements of the system are checked for various operational modes. That leads to the evolution of the whole system, i.e. continuous improvements and optimization. The complete biomimetic architectural system is designed for dynamic adaptation to changing conditions with the application of the internal control system.

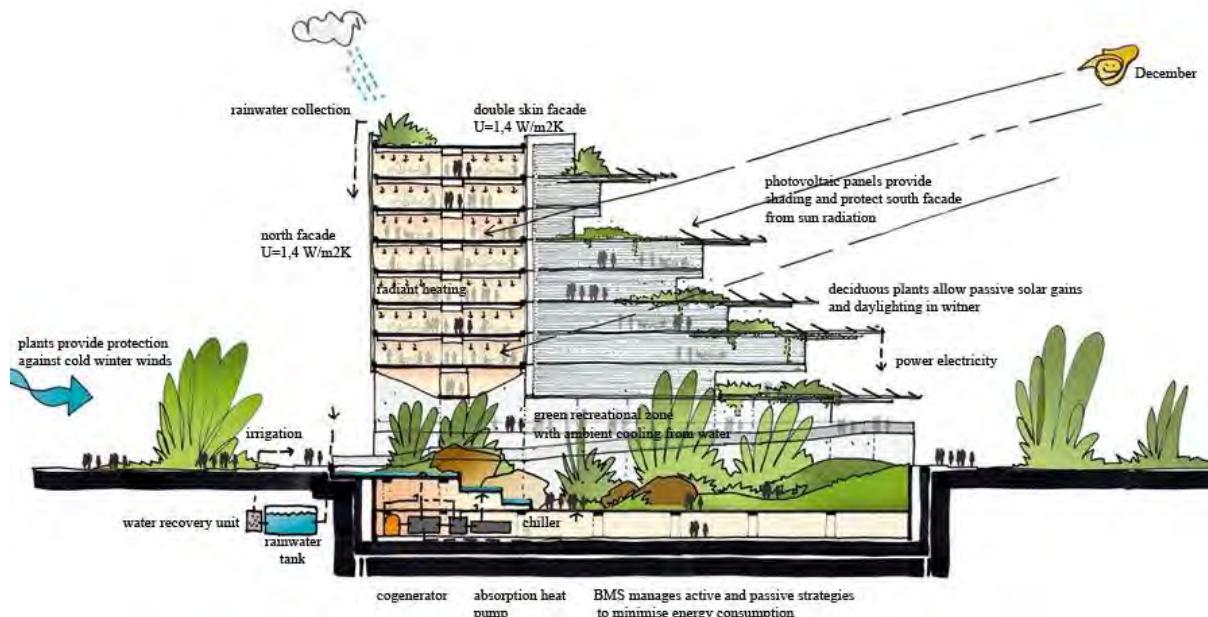

Figure 2. Environmental strategies in Sino-Italian Ecological and Energy Efficient Building (SIEEB), 2005-2006, Beijing, China, designed by Mario Cucinella Architects. © MCA Archive

### **Structure**

Biomimetic structural systems are inspired by the natural ones. Patterns derived from biological prototypes are often optimized with advanced methods, including mainly parametric tools. The important note is the observation of the natural tendency to minimize the need for resources necessary for life (Watts 2001, p 132). Actual technological abilities allow for creation of flexible construction systems that adapt their structure and shape to changing climate conditions (e.g. wind direction and force), similarly as living organisms do. Proposed solutions can be based on passive, active or hybrid concepts. The examples of passive biomimetic structures can be found in buildings designed for particular angle of sun rays during the year, such as Sino-Italian Ecological and Energy Efficient Building (SIEEB), 2005-2006, Beijing, China, designed by Mario Cucinella Architects (Fig. 2). Active structural solutions developed the ability to provide adequate reaction for external stimulus. These are often pneumatic systems, based on synthetic and biosimilar membranes. Complex membrane hybrid systems combine the durability of synthetic membranes with the selectivity of cell membranes, underlying the construction of biomimetic sustainable architecture. The biomimetic structures can also apply advanced strategies for heating and lighting, connected with e.g. phototropism. They are usually combined with adaptive

building skins and properly stimulated metabolic processes within the edifice and its environment.

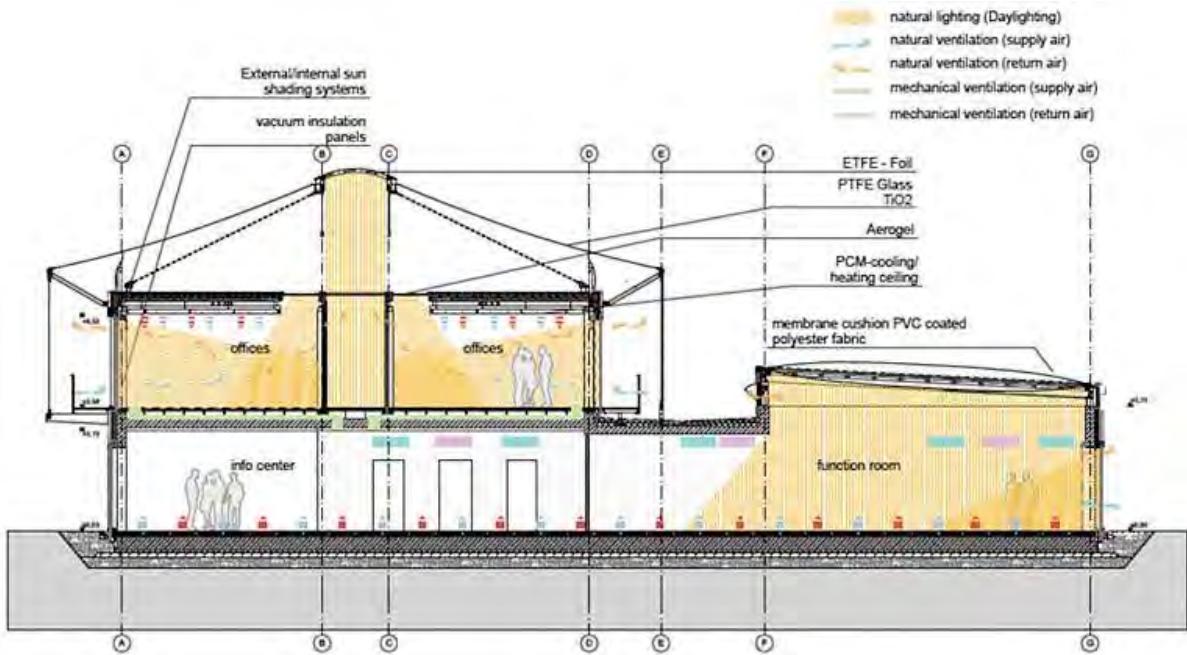

Figure 3. Hybrid thermoregulation in Energy Efficiency Center (2013) Würzburg, by Lang Hugger Rampp Architects and Center for Applied Energy Research (ZAE Bayern, Würzburg). © Lang Hugger Rampp Architects.

### **Metabolism**

Biomimetic systems in buildings involve the exchange of gas (breathing, photosynthesis), liquid (evapotranspiration) and energy (absorption, production and transformation) as well as waste management and closing the loop of materials. Recycling of waste products in order to drive the systems in the building is often considered. Advanced Building Management Systems (BMS) are compared to the nervous system, which provides also a source of inspiration, especially for hybrid solutions (Watts 2011). Some of the very interesting, already existing applications in buildings, are the ones that implement hybrid thermoregulation strategies inspired by the heterothermic organisms. They include e.g. the heat storage in phase change materials as well as heating and cooling with the use of infrared radiation technology (Lang et al. 2014). Such methods were applied and tested in Energy Efficiency Center (2013) in Würzburg, designed by Center for Applied Energy Research (ZAE Bayern, Würzburg) together with Lang Hugger Rampp Architects (Fig. 3). Building hybrid thermoregulation involved Passive Infrared Night Cooling (ZAE Bayern) which uses water flowing freely from the top of the roof and being cooled to the dew point in the nighttime (due to convection and evaporation). This method is completed with adsorption cooling cycle (with a hygroscopic concentrated salt solution) that enables for dehumidification and cooling of the incoming air. The third element of the system is a heat storage layer with phase change materials (PCM), which can store large amounts of heat in the narrow temperature range (because all absorbed heat is required to break the bonds of the crystal lattice). This improves the thermal stability of the premises and helps to avoid undesired short-term temperature rising. Water cooled at night is used for PCM regeneration. Some other examples of metabolic processes are closely related to advanced biomimetic building skins.

## **Skin**

Contemporary adaptive building skins apply schemes of gas, liquid and energy exchange, developed on the basis of biological prototype analysis. Cooling is achieved through controlled natural processes such as radiation, convection and evaporation. Green roofs and façades provide insulation and contribute to better air quality (oxygen partial pressure, humidity). Other research activities in the field of biomimetic building skins involve e.g. integrated hybrid flow control systems for energy harvesting (Dyson et al. 2004). Integrated Concentrating Solar Façade is an active system inspired by phototropism that uses Fresnel lens and polygonal photovoltaic cell. The activation mechanism of photovoltaic cells is linked to solar modules, allowing to adapt the position of the solar modules to the sun rays direction (Dyson et al. 2004). This experimental system is tested in Zero-Energy Corporate Headquarters by SOM and Rensselaer Polytechnic Institute.

Some innovative skin building solutions involve also 3rd generation of solar panels, such as Organic PV Cells with emerging thin films or amorphous silicon, Dye Sensitized Solar Cells, Perovskite cells or Quantum Dot organic/inorganic hybrid PV cells with high absorption nanoparticles. Transparent photovoltaic cells, with Concentrating Photovoltaic and Thermal Hybrid Systems combined with ventilated photovoltaic modules allow for recovery of the part of solar energy that is not converted to electricity (Mocerino 2016).

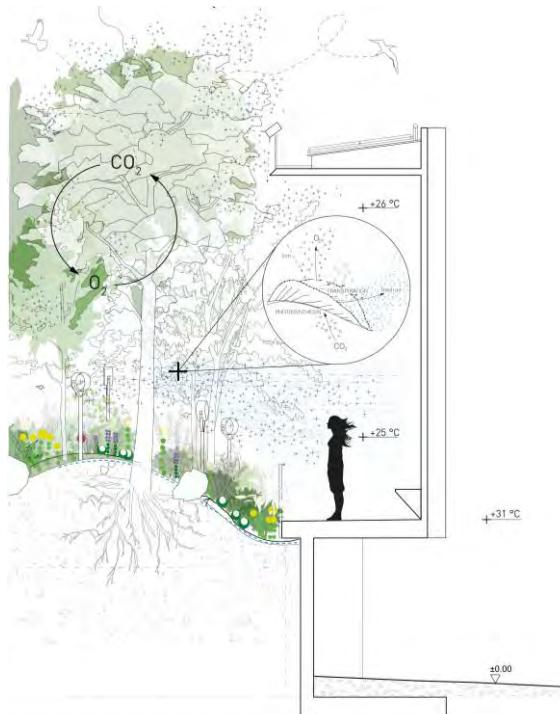

Figure 4. Integration of biology and technology in breathe.austria (Milan 2015) by team.breathe.austria.

## **Practical application of the research model**

Multilevel analysis methodology based on the model of biomimetics in architecture and intended to check various aspects of biomimetic approach to the building perceived as a system was applied to examine the concept of biology and technology integration in breathe.austria project. This edifice was designed and constructed by the interdisciplinary group team.breathe.austria lead by Klaus Loehnert in Milan (Austria Pavilion for EXPO 2015). The biological prototype of the building was the Austrian mountain and foothill forest ecotype. At the first level of the research, the studies of biological prototype involved

structure, function, physicochemical properties, environmental relations, response for stimuli etc. In effect of the initial model analysis results, the specific system for the building was created. This system was analyzed at the second level of the model. The research showed that the controlled interaction between the natural and built environment was developed. This resulted in the climate active building, in which clean, humid and cool air is constantly produced (Fig. 4). It was possible through the combination of leaving and healthy forest ecosystem with high level of biodiversity, i.e. with over 190 various biological species, including flowering plants, small shrubs, mosses and even 12-meter high trees (Terrain 2015). Thus created ecosystem works almost identically as in natural conditions. The only important difference is that the natural processes, such as evapotranspiration and photosynthesis, are supported by active technologies powered by solar energy. Multilevel design optimization and modifications of the initial model were directed towards the achievement of comfortable indoor microclimate. The relevant methods were selected based on an analysis of local bioclimatic conditions (high temperatures during the day, dry air, dust, high CO<sub>2</sub> concentrations due to the large number of visitors).

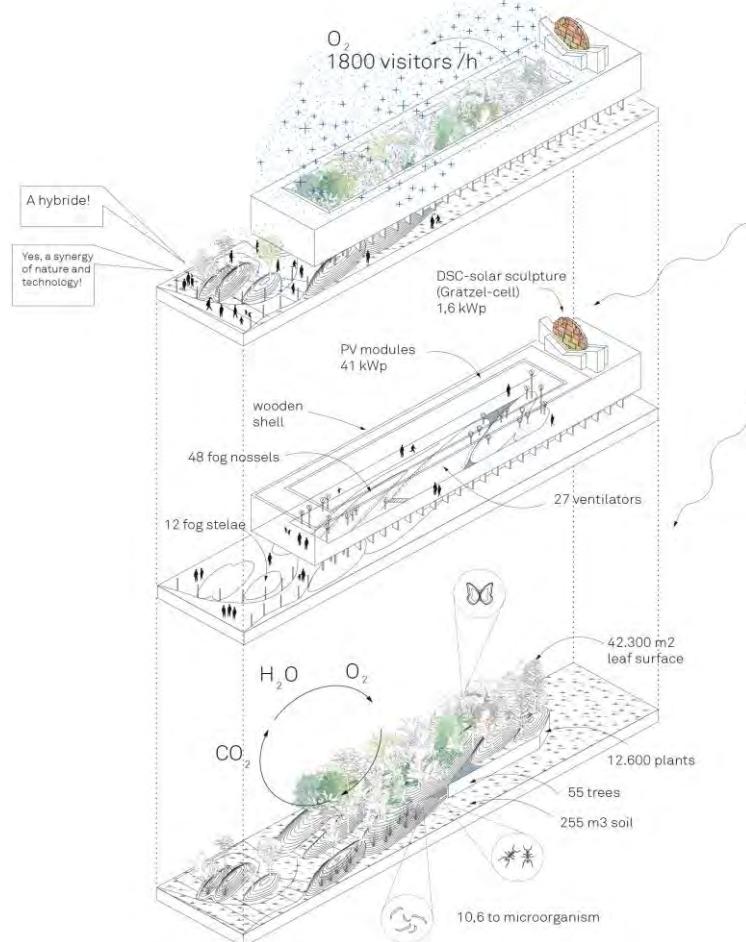

Figure 5. Illustration of biomimetic design concept in breath.austria (Milan 2015) by team.breathe.austria.

At the third level of research, the practical verification of the system was carried out. Particular elements were tested for various operational modes. The internal control system allows for dynamic adaptation to changing conditions, both internal (e.g. the number of visitors) and external (the temperature outside). The response to external and internal conditions is possible with the hybrid indoor air humidification and cooling method that

applies natural evaporation of moisture from the plant and soil surface, aided by the 130 thermodynamic fog nozzles with high-pressure jets. As the part of active technology mode 27 fans improve the air distribution throughout the pavilion. The combination of passive (natural) and active (technological) systems brings effective results. For example the temperature in the pavilion is about 5-7°C lower than the ambient temperature.

The whole building system was designed to enable the evolution. To obtain optimal indoor microclimate conditions, both for ecosystem and human needs, the biological phenomena of photosynthesis was used. The appropriate calculations were carried out for the system optimization. In effect, the amount of oxygen produced by plants corresponds to the breathing demand of 1.800 visitors per hour. For this purpose it was necessary to create the green plants surface with a total value of approx. 43.000 m<sup>2</sup>. The area of ecological growth and metabolic processes in the pavilion equals to 560 m<sup>2</sup> of wooded area (Terrain 2015). Further improvements and modifications were done for the active technological solutions, namely the arrangement and operation of fans, water jets, fog nozzles and fog steles, powered by electricity from PV cells placed on the roof and produced with especially designed Dye Sensitized Solar Cells (Grätzel cells or DSCC, which use the photoelectrochemical process similar to photosynthesis). This innovative concept was in line with the consistent use of biological systems in combination with the currently available technologies (Fig. 5).

### **Relations between the building and environment**

As the building industry represents around 40% of global CO<sub>2</sub> emissions and similar level of global energy consumption, it is crucial to take measures towards significant improvement of relations between the building and the environment (ecosystem). If we compare the previously developed activities in the field of contemporary human settlements to biological relations, in many cases it would be analogous to parasitism. With the knowledge and technological development of today, we should achieve at least the minimal level of well-balanced competition and proceed towards neutralism and commensalism. The ideal option, and hopefully vision of the future biological architecture, would be to learn how to achieve the homeostasis based on symbiosis. The main principle of the relationship between a man and other species inhabiting the same ecosystem, should be to minimize the negative impact of human activity on the environment with regard to its long-term effects. Ability for the climate responsive multilevel building adaptation to the ambient conditions resembles biological models, in which such factors as body temperature and humidity, gas and fluid exchange, flexible change of shape and colour etc., allow for natural adjustment of the organism to the environment without any harmful effect nor excessive resource consumption. In practice, this will enable active metabolism, including e.g. the improvement of air and water quality, building energy management, filtration of pollutants, waste management and reuse, and so on. Building functioning on the basis of solar technologies and active metabolism effects in carbon dioxide absorption and oxygen production, natural cooling, humidification and air purification. Hybrid interaction of biological processes and technology should be seen as a prototype for climate change mitigation and further reduction of negative effects of human activities on the environment,.

### **Conclusions**

The author of the paper analysed and discussed the concept of biomimetics in contemporary architecture. The research showed that the application of biomimetics in

architectural design allows for correct conclusions from the biological systems behavior analysis, in purpose to create new, complex solutions, based on the biological models. Various aspects of biomimetic approach to the building, understood as a system, were checked with the innovative methodology. The model was based on 3 levels. Within the first level, the studies of biological prototype involved its structure, function, physicochemical properties, environmental relations, response for stimuli etc. In effect of the analysis of selected initial model, the specific system for the building was created. This system was analyzed at the second level of the model, where 3 basic elements were distinguished: structure, metabolism and skin. At the third level of research, the practical verification of the system was carried out. Particular elements were tested for various operational modes which resulted with various shape, structure and process optimization. The evolution of the system involved many improvements, e.g. enabling for dynamic adaptation to changing conditions with the use of internal control system. The whole building concept resembles the leaving organism. It combines natural and technological processes in the most effective and efficient way. The main conclusion from the research is that it has been proved that with contemporary knowledge and technology it is possible to create the building that is operating on the basis of multilevel biomimetic model, being safe for the environment and comfortable for users. The novel perception of the built environment is related to shifting baselines regarding ecosystem, climate and sustainability. The role of architecture in the future may evaluate from *sustainable* or *less harmful* relation to *thrive* and *endosymbiotic leaving environment* based on properly developed biomimetic models.

## Acknowledgments

The author of the paper wishes to thank all the Authors of the presented projects for their kind support and cooperation.

## Renovating Abandoned Houses for Sustaining a Declining Community in Japan

Kentaro Yagi<sup>1</sup>

<sup>1</sup> Graduate School of Education, Hiroshima University, Higashihiroshima, Japan,  
yagik@hiroshima-u.ac.jp

**Abstract:** This paper explores efforts to sustain rural communities in the Inland Sea of Japan, which are often referred to as “marginal communities,” especially focusing on the renovation projects of abandoned houses. Uninhabited Japanese wooden houses rapidly decay and negatively affect the community. To prevent this, artists and architects joined to renovate two abandoned wooden houses utilizing local, traditional and recyclable materials and building tectonics while eliminating energy-consuming technologies and materials. The results of this case study present a local prototype for passive low energy house design. Two abandoned houses were renovated. The first was mostly renovated using a DIY approach (except where legally enforced), while the second utilized a contractor. Although the two renovation projects adopted quite different construction schemes, they had common design policies in terms of material preferences and construction waste control. These case study projects revealed that traditional materials and tectonics are still favorable and promising in our era, as they realized the low life-cycle cost and low energy consumption model. Such solutions contribute to preventing the extinction of insular marginal communities and to sustaining the future of our society.

**Keywords:** renovation, rural community, marginal community, the Inland Sea of Japan,

### Introduction

The trend of depopulation and aging communities have been observed in many rural areas in Japan and in other developed countries for decades. These issues have become more serious since the beginning of the 21st century, however, and many rural communities are at stake. The term “marginal community” has emerged, and the issue has rapidly attracted public attention in Japan—especially after the Japan Policy Council issued the so-called Masuda Report (Masuda, 2014). Although some people consider these communities to be less efficient than urban communities, there are still reasons to sustain such areas. These communities can even provide promising ideas for future society, and there are people who hope to move from urban areas to such rural communities.

Following periods of depopulation, there have been discussions of counter urbanization in some European countries—especially in the UK (Cloke, 1985 and Cross, 1990). Japan is no exception; signs of counter urbanism have emerged in rural areas. The Inland Sea of Japan is one of such destination (Yagi, 2010a). Accordingly, this paper explores efforts to sustain such a community located on a small island in the Inland Sea of Japan, focusing on the renovation projects of abandoned houses in the insular neighborhood.

### *The Inland Sea of Japan*

The Inland Sea of Japan, lying between Mainland Japan and Shikoku Island, has 727 islands within a circumference of larger than 0.1 km. It was once renowned for its beautiful landscape,

featuring numerous tourist attractions, and was established as one of the first Japanese National Parks in 1931 (Figure 1). The Inland Sea used to be an important artery of the Japanese maritime economy. Many industries, such as shipbuilding, refining, salt and other chemical industries, flourished in the area, as did most of the communities within. Although about 300 islands are inhabited, many have faced severe depopulation. Very few of the shipbuilding companies and refinery plants remained on some of the major islands following a drastic change of industrial structure, and it is believed that most of the minor and smaller communities will eventually be extinct.

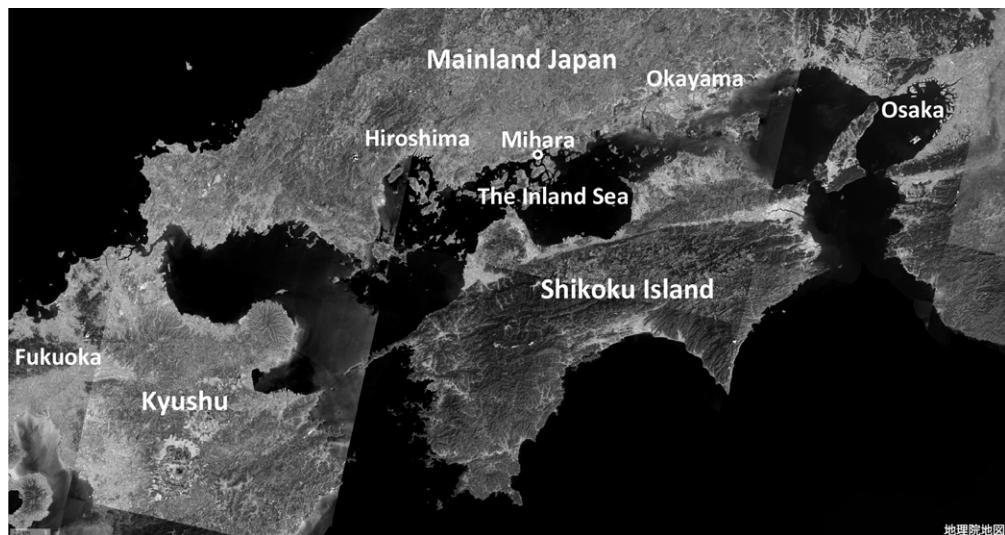

Figure 1. Location of the Inland Sea of Japan.  
Based on the image published by Geospatial Information Authority of Japan.

### ***Subject Community***

The community that this research focuses on is in Kosagijima, which is part of Mihara City in the Hiroshima prefecture. Kosagijima is a small island that is about 3.2 km in circumference and located approximately 3 km south from downtown Mihara City. Although the shipbuilding industry attracted more than 100 residents during the modernization period, the island contains four households and a population of five as of 2017.

The once-flourishing, large-scale shipbuilding enterprise did not last long in Kosagijima, and the population quickly declined. Although the small shipbuilding industry on the island continued until the late 1960s, there has been no manufacturing industry on the island since then. The current major industry there is agriculture; citrus fruits, beans, potatoes and other vegetables are grown. Potatoes used to be the staple food on the island. The residents must make regular journeys to downtown Mihara City in order to purchase daily necessities and acquire medical services.

In 2010, there were 23 houses in Kosagijima. Some of the vacant houses are still visited and maintained by the house owners or by relatives. Many others, however, have been left unvisited for a long time, and two have been almost completely abandoned (Yagi, 2010b).

### ***Case Study Houses***

Uninhabited Japanese wooden houses rapidly decay and start destroying the community (Figure 2). Two houses abandoned in 2010 have already collapsed to the ground, and other uninhabited houses will meet the same fate. To help prevent this, artists, designers and

architects set up a project and team to renovate these uninhabited wooden houses utilizing local, traditional and recyclable materials and building tectonics while eliminating energy-consuming technologies and materials.

Figure 2. Typical uninhabited house almost collapsing.

A private company in the Hiroshima prefecture offered to sponsor the project, and two abandoned houses have been renovated in the community. The first project was mostly renovated using a DIY approach (except where legally required to employ professionals), while the second project utilized a contractor. Although the two renovation projects adopted different construction schemes, they shared fundamental construction policies: a preference for traditional, local, recyclable materials whenever possible; minimal construction waste; and the adoption of passive air conditioning utilizing the microclimate.

### ***Design Build Project Studio***

The first project, a house facing a small inlet port, was initiated in early 2010 (Figure 3).

Figure 3. A vacant house selected for the pioneering renovation project.

The house owner lives in the mainland Mihara City, rarely visits and barely maintains the house. The roof was damaged and leaking, and the interior had started to decay. These problems needed to be immediately handled. However, construction work could not start until the end of 2010.

Although design work was completed by the spring, it took much longer than expected to dispose or hand over the former residents' private belongings. Furthermore, the project team struggled to raise funding and thus elected to do a DIY renovation. Several artists, art

students and architecture students joined the design build project. Because the project team intended to minimize the construction waste throughout the renovation process, the former residents' private belongings remained unused in the house had to be appropriately handled. It took more than six months to clean the house.

Since the project team was required to transport building materials and construction waste by themselves, a minimal amount of new building material was used (Figure 4).

Figure 4. Transporting building materials and construction waste via private boat.

Renovation work finally began at the end of 2010. First, all modern industrialized sidings and interior finishes added to the original structure were taken down. The original clay wall, which was still in good condition, was discovered under the exterior wooden grain metal sidings and plywood interior finishes. Most of the detached building materials and other materials were stored for later reuse (Figure 5).

Figure 5. Damaged Tatami mats were reused for insulation.  
Less damaged floorboards were carefully removed and saved for exterior work.

Concrete blocks were crushed and reused for the pavement base of the entrance approach (Figure 6). Metal sidings were replaced with traditional wooden sidings, which are very popular among Inland Sea communities (Figure 7). The original clay wall was mostly still intact, so we decided to keep it uncovered for humidity and thermal control. A very steep slope right behind the house provided sufficient cold air flow in the summer. The project team successfully removed the air conditioner from this house (Figure 8). The project was completed in spring 2011. The house has since been used as project team's studio space.

Figure 6. Concrete blocks were crushed and reused for the entrance approach.

Figure 7. Wood siding exterior. Fully open toward the water.

Figure 8. No air conditioner to use electricity, but there is a wood burning stove.

### ***Contractor Model***

The second project was initiated right after the design build project was completed. The house owner had not visited the house for a long time because his parents, who had lived there, passed away. The roof of the storage space was also damaged, but the main part of the house was preserved in relatively good condition (Figure 9).

Figure 9. The second vacant house to be renovated.

The renovation design concept for this house changed several times. This project was originally planned to be a guest house for the sponsor company and expected to be remodeled as another design build project. Although the condition of the building structure was much better than the first project, far more furniture and other belongings were left in the house. It took much longer to clean, which was not done until spring 2013. After a series of revisions, the guest house design was mostly finalized by the end of 2013. The project team predicted that construction would start the following spring.

In the meantime, the sponsor proposed to hold an art exhibition in early 2015 to showcase their art collection and encourage the community. The renovation plan was again revised to meet the requirements of the art exhibition. Because the new design would likely not be completed on time, they decided to hire a contractor. However, the fundamental concept of respecting local traditions and materials remained. An old potato storage space under the floor was remodeled as a small gallery to showcase the insular lifestyle (Figure 10).

Figure 10. The gallery utilizing a former potato storage space.

An art piece occupying the premier space in the main room welcomes visitors to the gallery house (Figure 11). Although the main gallery is air conditioned to preserve the artworks, the rest of the house is not air conditioned. Moreover, all light sources were replaced to use LED light bulbs (Figure 12). The exteriors were almost untouched, but the metal siding material was replaced with wooden siding, as done with the first project (Figure

13). Renovation work was completed in February 2015—a month before the exhibition opened. Thousands of visitors came to the small island during the two-month exhibition.

Figure 11. Hiroshi Senju's painting rests in the main gallery. The clay wall was untouched.

Figure 12. Dining and meeting space open to the forecourt.

Figure 13. Exterior with Japanese plaster and traditional wooden sidings.

### ***Eliminating Energy Consumption***

These two examples show how energy consumption can be eliminated at different stages of the renovation process. To avoid dumping personal belongings and minimizing construction waste, the recycling of construction materials on site remarkably reduced the usage of surface

transportation, which consumes a huge amount of fossil fuels. Clay walls covered by the plywood were uncovered and repaired to be utilized as thermal walls. Some of the interior walls were also relocated, utilizing the microclimate to control the breezeways. Both projects successfully eliminated the use of active air conditioners, though carbon neutral biomass stoves were introduced. As a result, we achieved much lower energy consumption.

## Conclusion

The results of this case study present a local prototype for passive low energy house design. Our project members frequently stay in the studio and recognize that our design approach was appropriate for this environment. The sponsor company has established a foundation to help the community on the island, and their staff reside in the gallery house.

These case study projects revealed that traditional materials and tectonics are still favorable and promising in our era. The renovated houses naturally fit in the local context, as they have been there for a long time. They also successfully realized a low life-cycle cost and low energy consumption model. Such solutions can contribute to preventing the extinction of insular marginal communities and to sustaining the future of our society.

## Passivhaus: The Architectural Typology of Low Energy Housing

Jill Zhao<sup>1</sup> and Kate Carter<sup>1</sup>

<sup>1</sup> Edinburgh School of Architecture and Landscape Architecture, University of Edinburgh, UK,  
Jill.V.Zhao@gmail.com

**Abstract:** The growing number of Passivhaus buildings in the UK suggests an increasing acceptance of the low energy design methodology. Post occupancy evaluation shows that the energy use in Passivhaus homes are generally very low, and that running costs are considerably less than standard housing. However, the move to adopt Passivhaus Planning Package (PHPP) as a mandatory standard has been resisted in many areas with a belief that the benefits are outweighed by the limitations imposed on architectural design when using PHPP. Case study analysis of 42 Passivhaus homes has been conducted to examine the architectural typologies that are generated from the use of PHPP in the UK. This research explores the impact of the Passivhaus design approach on orientation, fenestration, size and spatial relationships of the buildings and determines the impact that it has on architectural design. Qualitative research with the occupants of these homes provides a further understanding of the lived experience of Passivhaus and how users adapt to the technical systems that are required to achieve Passivhaus certification. The case study analysis reveals connections between adaptations made in those living in a Passivhaus to achieve comfort, and questions how different this is to standard housing.

**Keywords:** Passivhaus, architectural design, adaptation, case study, overheating

### Introduction

The beginning of the year 2003 saw a rapid growth in the number of Passivhaus projects around the world. It has been estimated that 30,000 Passivhaus buildings have been realised, with the majority being residential projects. The total number of Passivhaus projects in the UK is estimated to be around 400 units (94 projects), 380 of which were residential (at the time of March 2016). However, the move to adopt Passivhaus Planning Package (PHPP) as a mandatory standard has been resisted in many areas with a belief that the benefits are outweighed by the limitations imposed on architectural design when using PHPP. In this research, 42 Passivhaus homes have been surveyed in which 10 projects have been studied in detail to examine the architectural typologies that are generated from the use of PHPP in the UK. This paper explores the impact of the Passivhaus design approach on orientation, fenestration, size and spatial relationships of the buildings and determines the impact that it has on architectural design. Qualitative research with the occupants of these homes provides a further understanding of the lived experience of Passivhaus and how users adapt to the technical systems that are required to achieve Passivhaus certification. The case study analysis reveals connections between adaptations made in those living in a Passivhaus to achieve comfort, and questions how different this really is to standard housing.

## Contextual background

The layout and arrangements of domestic space have been in a constant state of change with the development of technology. It was suggested by Wright (1964) that heating devices, including fireplaces, stoves and chimneys, have influenced social activities and space arrangement in domestic spaces. On the other hand, the mechanical service system has also been developed in line with advances in technology and the socially constructed idea of comfort. The result of this development suggests that a particular lifestyle is shaped by a combination of factors concerning technology, comfort and architecture.

Study on the post occupancy of Passivhaus began during the last decade in Sweden. According to Mlecnik (2012), a considerable amount of German-language research has been carried out regarding occupants' experience. The results showed that the majority of occupants living in Passivhaus expressed high levels of satisfaction in terms of comfort and energy saving. However, recent research has shown a significant risk of summer overheating in Passivhaus in the UK, with 72% of the surveyed Passivhaus households exceeding the benchmark (Tabatabaei S. et al, 2015). The same research also indicated the importance of household behaviour in the prevention of overheating. Since the current Passivhaus standard sets a fixed threshold temperature as the overheating benchmark (25 degrees for more than 10% of the total occupied hours) without consideration of external conditions or household characteristics (such as old age), the design method does not give an accurate prediction of summertime indoor temperature. Rojas's (2015) study of 18 Passivhaus suggested that most significantly exceed the Passivhaus certification criterion (i.e. 10%  $\geq 25^{\circ}\text{C}$ ). The research also found that top-floor flats were much more vulnerable than those on other floors.

Research on Passivhaus tends to focus on energy performance, and very rarely focuses specifically on architectural design. A study focusing on the occupants of a house and their daily interactions with it may thus reveal a deeper connection between architectural design features and users of Passivhaus.

## Sampling and data collection

42 new-build residential buildings occupied since 2011 have been selected to form the basic sampling pool. In examining the 42 projects together with previous literature, five basic categories have been established into which these projects can be grouped. The five categories are floor area, ownership, building type, construction type and bioclimatic region

Table 2. Comparison of the window-to-floor ratio of three case studies

Floor area (m <sup>2</sup> )	No. of projects	Ownership	No. of projects	Building type	No. of projects	Construction type	No. of projects		
<100	15	Privately owned	26	Detached house	24	Timber	26		
100-200	19			Semi-detached	8		12		
200-300	6	Social rental	16	Mid-terrace	10	Mixed	4		
>300	2								
Bioclimatic region	Scotland N	Scotland W	Scotland E	England E & NE	England W & Wales N	Midlands	East Anglia	England SW/Wales S	England SE/Central S
No. of projects	1	2	4	6	5	5	3	6	10

Of the 42 projects, more than half (24 projects) are single-family detached houses, a majority of which are privately owned. The remaining 18 projects are multi-family dwellings, of which six were developed privately. The treated floor area of the projects ranges from 52 m<sup>2</sup> per household to 408 m<sup>2</sup> per household. The majority of the projects have a floor area of around 130 m<sup>2</sup>. The two main structure systems are timber and masonry.

All 42 projects were contacted during the data collection period from March 2014 to October 2015. A total of ten projects (15 households) responded with an overall response rate of 23.8%. Among the ten cases, the seven single-family projects are all detached, privately developed houses. Their areas range from 151 m<sup>2</sup> (House ST) to 219 m<sup>2</sup> (House SA). The three multi-family projects (including DO, SL from the social rental sector and a cohousing project LA) appear to have relatively smaller floor areas ranging from 65 m<sup>2</sup> (House LA 2bedroom) to 102 m<sup>2</sup> (House DO 3bedroom). The multi-family dwellings are either semi-detached houses (Houses DO and SL) or mid-terrace houses (House LA). The ten projects are located across the UK, as shown in the following figure.

Figure 1. Location map of the studied cases

## Quantitative analysis

In the Passivhaus design guide, several design features are highlighted as being the most important in terms of their effect on the performance of the Passivhaus. These are orientation and shading; building form and form factor; U-value; and airtightness. Those factors became the focus of the quantitative analysis. The design recommendations for a Passivhaus include a focus on achieving the standard's energy performance. In comparison, the studied cases exhibit similar properties in the U-value of external envelope and airtightness. The main differences occur in their form factors and orientation.

### ***Orientation and shading***

In the PHPP, the climatic data used to calculate thermal performance is based on 22 climatic regions across the UK, as specified by the BRE. It also makes adjustments for altitude (-0.6 degree for every 100 m increase in altitude). Aside from guidance in the PHPP, a Passivhaus design guide – the BRE Passive House Primer – has also been widely used for building practitioners aiming to achieve the Passivhaus standard. It is recommended in the BRE Passive House Primer that the orientation of a building should aim to maximise its solar gain, which

means the main façade is oriented within 30 degrees south. A poor orientation can increase annual heating demand by 30% to 40% (McLeod et al.).

A majority of the projects (6 houses) are oriented due south. The remainder, with the exception of the SL and SA projects, are oriented within 30 degrees south. The SL project in East Lothian and the SA project in Durham face 57.7 degrees and 46.6 degrees southwest respectively. Very few of the projects have any natural shading from vegetation or adjacent buildings. Cases FO and TO have moderate shading to the west side, and the SL project is heavily shaded from natural sources to its southwest side. Case LA has heavy shading for a low-angle solar path (winter shading) from vegetation on the other side of the river. It can also be observed that every project has adopted other shading strategies such as a roof overhang, deep window reveal, brise-soleil, balcony, canopy and external/internal blinds or curtains. The design to maximise solar gain has evidently been influenced by the requirement specified in the Passivhaus design guide. One exception can be seen in the SL project. This unit containing four flats is not only designed to reside outside the boundary of recommended orientation, but the site is also heavily shaded on the southwest side.

### **Form factor**

Building form and form factor have been used to optimise the floor area, the footprint of the building, the plot ratio and other parameters. They have also been widely adopted to optimise the energy consumption of the building. Generally speaking, a smaller ratio of external envelope area to the volume of the building (A/V ratio) indicates a lower probability of heat loss and more efficient energy consumption. It has been recommended that 'a favourable compactness ratio is considered to be one where the A/V ratio  $\leq 0.7\text{m}^2/\text{m}^3$ ' (McLeod et al.). This principle can be extended to indicate the complexity of building geometry. Because smaller buildings tend to have a higher A/V ratio, it has been recommended that small buildings be kept as simple and compact as possible, whereas larger buildings can have a slightly more complex shape.

This rule simplifies the certification procedure but also means that the performance of individual households varies. Using an estimation calculation tool developed by BRE, calculations have been carried out to examine the form factors of the studied cases. The calculations show that with the exception of the HI and HA projects, the studied cases have all achieved the benchmark of 3 for the form factor. In terms of the A/V ratio, the three multi-family projects, DO, LA and SL, achieved a ratio of no more than  $0.70\text{ m}^2/\text{m}^3$  (0.7, 0.58 and 0.6 respectively), whereas the single-family projects all scored slightly above the average A/V ratio, with the largest occurring in the ST and TO projects.

### **Qualitative analysis**

Following the quantitative analysis of design factors, the correlational analysis below involves a cross-examination between the physical properties of each Passivhaus project and the corresponding interview data. The analysis has gathered the discomfort/problems highlighted in occupants' interviews in order to identify the design issues that contributed to those problems. For the purpose of this paper, one major issue concerning overheating is discussed.

In the interview, moderate or mild overheating was reported as a discomfort in almost all of the case studies in this research, including both the northernmost and southernmost projects. It can be observed that despite the geographical locations or bioclimatic regions of the building, certain design features of Passivhaus buildings make them more vulnerable to

heat, resulting in the overheating issues seen in those projects. The analysis compared the interview data with the design features of each project. The results reveal the three main issues most likely to be contributing to the issue of overheating for eleven households in this research. These are glazing in relation to room size (W/F), the effectiveness of shading and design for natural ventilation.

### ***Glazing in relation to room size (W/F)***

In the PHPP, the criteria for checking overheating is specified as:

The frequency of overheating is the percentage of hours in a given year that the temperature exceeds 25 degree. For Passivhaus certification this must not exceed 10% of the year. (Lewis, 2014 p.58)

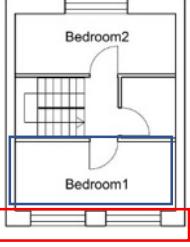

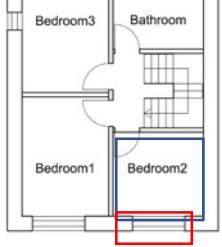

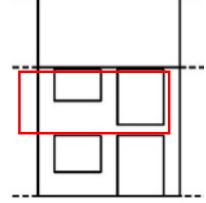

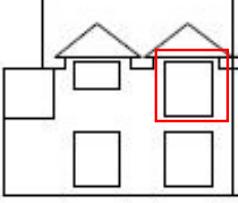

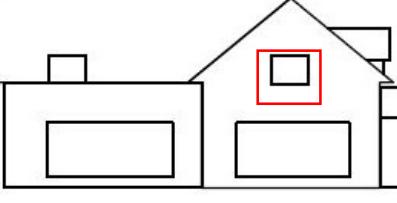

However, when calculating heat gains, the PHPP software distributes heat evenly across the whole building, hence it does not take into account the direct relationship between the size of the windows and the corresponding room size. The certification also means that the overall temperature of the building can remain below 25 degrees for the entire year, while a specific room (usually a small bedroom on the first floor with a large south-facing window) may potentially be above 25 degrees for more than ten per cent of the hours of the year. In this research, analysis was carried out specifically focusing on the window-to-floor ratio (W/F) for the smallest habitable room in each case. The following table (Table 2) shows a comparison with some extremes from the calculation.

All six occupants in the LA and DO projects reported overheating issues. The problem occurs especially in the bedrooms on the first floor. Calculation of the W/F revealed very high ratios of 0.51 and 0.4 respectively in comparison with a lower ratio of 0.21 in the TO project, where no overheating issue was reported. Each project has received its PHPP certification; however, it can be observed that the TO project has a more favourable W/F in each room, which prevents the problem of overheating. The LA and DO projects, in contrast, are more vulnerable to increased temperatures in the summer.

### ***Effectiveness of shading***

In addition to the size of the glazing, in most of the cases natural shading was designed to be just outside the site as a way of maximising the benefit of solar gain. The only building among the case studies to employ natural shading on the south side is the SL project. Not surprisingly, in the interview, the occupants suggested no discomfort/overheating problems in relation to the indoor environment during the summer. For the remainder of the case studies, certain types of external shading were integrated into some of the projects during the design phase. Deep window reveals and roof overhangs were also used quite commonly in most of the case studies. The shading devices used also included internal blinds and/or curtains installed post occupancy in every case study for the purpose of adding both shading and privacy. The integration of various shading devices in each project appeared to be aimed at moderating and eliminating overheating issues; however, the actual observations revealed otherwise. In terms of effectively controlling overheating, the effectiveness of the shading devices employed is more important than simply having a variety installed.

Table 2. Comparison of the window-to-floor ratio of three case studies

Plan			
	LA1 first floor	DO1 first floor	TO first floor
Elevation			
W/F	0.51	0.4	0.14
	LA1 bedroom 1	DO1 bedroom 2	TO bedroom 2

For instance, in the PL project, as the occupants did not understand the function of the shading, they never used it to control overheating. On the other hand, in the HA project, it was suggested by the occupants that the brise-soleil installed was effective in shading most of the summer sun. However, it was insufficient to provide enough shading to control the sunshine at a lower angle in the late afternoon. Thus, the external shading in each of these three projects does not effectively serve its design intention.

Meanwhile, internal shading devices such as blinds or curtains have been adopted in all projects. The effectiveness of these devices for controlling indoor temperature was proved to depend largely on the proper installation of the shading as well as on the behaviour of the occupants. It was observed that the design details of window blinds can play an important role in supporting the occupants' behavioural adaptation to control overheating. Two examples are selected from the case studies as shown below. In most of the case studies, classic 'tilt and turn' windows are used as openable windows. This type of window features two methods of inverted opening. Both opening methods are difficult to use in conjunction with a traditional installation of curtains, and they are even more difficult to use with blinds. This means that natural ventilation cannot be achieved at the same time as shading. This can be a particular problem for Passivhaus in the UK as shading is needed from the low-angle sun during long summer days, while cool air is also needed in the mornings and evenings for ventilation. The window detail in the SL project has further restricted the options in the way that the tilted roof prevents the installation of a curtain rail. However, a more considerate design in the HA project has achieved a better integration of shading and natural ventilation. The design has attached the blinds directly onto the 'tilt and turn' window frame, so that a tilted opening is not disrupted by the drawn blinds.

Figure 2. Comparison of blind arrangement in SL project (left) and HA project (right)

Therefore, it can be observed that the control of overheating using shading devices depends to a great extent on the environmental conditions and also on the occupants' behaviour. The effectiveness of either external or internal shading needs to be considered in the design phase in relation to the prevailing weather conditions, window detail and the occupancy.

### **Cross and stack ventilation**

Natural ventilation using windows on both sides of the house is regarded by all occupants to be the most effective way to control overheating and the most preferred way to ventilate. However, it is worth repeating that in order to sufficiently control overheating by natural ventilation, cross ventilation needs to be designed in conjunction with proper control activities practised by the occupants. In this research, several cases can be listed as examples of such a design feature, including cases CR, FO and HA, as well as the DO project. The overheating problems in these projects were resolved through effective ventilation, with the support of fair cross ventilation and, wherever possible, stack ventilation design and an active adaptation of behaviour in controlling the windows.

Taking CR project for example, in order to control overheating, an observable behavioural adaptation, a newly developed routine of combining natural ventilation, shading and mechanical ventilation was performed:

*[...] In the summer we do open the windows in an intelligent way so early in the morning we open north facing windows on the ground floor, let the cool air come in and walk its way upstairs. So we pull blinds down to keep away the mid-day summer sun out when necessary, we also use the MVHR system to do night time purging. [...] From about mid night through to 6 am, [...] by the morning the house is quite cool. (interview with CR occupant)*

### **Concluding remarks**

The rigour and care that were put into the research design have ensured the results of this research are valid. However, it is important to acknowledge that the existence of a number of limitations during the research design process may have prevented it from achieving more significant findings. Firstly, in terms of the qualitative nature of this research, no environmental measurement was taken to indicate temperature, air velocity, humidity and accurate energy consumption. This decision was made at the beginning of this research in

order to set a clear focus for the experiential data, at the same time to avoid causing any inconvenience to or violating the privacy of the occupants. The data collected have proved to be representative of the occupants' experiences and can be correlated to other quantitative measures (such as building parameters and energy consumption) for the purpose of drawing conclusions. However, the results may have benefitted from further comparison and analysis if environmental measures had been taken at the time of the interview.

Secondly, the significance of this study is limited by the response rate for the chosen sample. In this research, ten projects have been studied. However, the range of project types has given a good sample of the PH community and is fairly representative. It can be stated that a wider study would have enabled a broader testing or a further theoretical saturation of the codes, but would not have revealed any additional categories. While emphasising the rigorous methodological approach of this research, it is also important to acknowledge that the conclusions drawn from cross-case analysis with the interview data and a comparison of the cases remain context based. In addressing comfort issues in design, this paper confirms the risk of overheating in certain Passivhaus in line with previous studies conducted in the UK. The result from this study suggests certain connections between the design recommendations of Passivhaus and the risk of overheating, especially for south-facing houses/flats with smaller area and a more compact form. However, the study also reveals the various behavioural adaptations performed by the occupants, which, if supported by appropriate architectural design, can be exercised effectively to control overheating and to achieve comfort.

## Bridging the Theory of Regenerative Design and the Current Building Practice: Evaluation of Regenerative Design Support Tools

Aysegul Akturk<sup>1</sup>

<sup>1</sup> The Herberger Institute, Arizona State University, Tempe, Arizona, 85281, USA,  
aakturk@asu.edu

**Abstract:** Although current practices of sustainable design exhibit many improvements on conventional design, they only slow down the degradation of earth's natural systems. The emerging field of regenerative design (RD) and development extends the concept and application of sustainability by shifting the goal from a 'net-zero' to 'net positive' approach and strives to *reverse* the negative impacts. Defining RD is easier than setting measurable performance goals due to the complexity of the topic. However, several RD support tools, serve a significant role in bridging the theory and the current building practice, are emerging to guide the transition. This paper aims to explore the methods and techniques in the current RD tools and to identify their limitation and research gaps. A review of definition and key principles of RD and a conceptual framework called Holistic Regenerative Design Framework are proposed to evaluate the comprehensiveness of RD support tools—REGEN, Eco-Balance, Perkins+Will Framework, Living Building Challenge, and LENSES. The results show that none of the tools are comprehensive enough to clearly guide designers. The paper concludes by characterizing the tools; recommending an approachable way to use the tools together in order to incorporate whole system thinking; and providing directions for future research.

**Keywords:** regenerative design, sustainability, design support tools, green.

### Introduction

The emerging field of regenerative design (RD) and development redefines the goal of built environments, the process of design, and the role of designers. Although the current practices of green design exhibit many improvements on conventional design for conserving resources and reducing the damage to the environment and humans, they only slow down the degradation of earth's natural systems. RD aims to reverse the negative impacts instead of merely slowing them down.

The theory and concept of RD is complex and cannot be easily quantified. It is not easy to set measurable performance goals like the green design approach because it requires thinking of whole systems and interconnectedness of humanity and nature during design process to create living systems that are mutually beneficial and co-evolving. Several RD support tools are emerging to bridge the gap between the theory and current building practice by offering indicators and frameworks. However, there is still a need for future studies to create adequate metrics and methods to comprise whole systems thinking. In the given complexity, this study aims to examine the tools to find a clarity and a practical pathway.

## **Background and Context**

Regenerative design and development as a ‘distinct’ field emerged from an ecological worldview, and its foundation goes back to the 1880s (Mang and Reed, 2012a). The development of the concepts such as ecosystem (Tansley, 1935), living systems thinking (Mang and Reed, 2012a), biophilia (Wilson, 1984), ecological design (McHarg, 1969; Van der Ryn and Cowan, 1996), permaculture (Holmgren, 2011; Mollison, 1988), and regeneration (Lyle, 1994) in the various disciplines built a basis for the emergence of the theoretical underpinnings of RD.

John T. Lyle’s key book (1994) —*Regenerative Design for Sustainable Development*— is the first handbook that outlines RD and its principals and the first key work that extends the concept into the built environment and the field of architecture. He states that humans have replaced nature’s continual cycling system with one-way linear flows and argues that it is possible to regenerate lost ecosystems. Therefore, he defines RD as “replacing the present linear systems of throughput flows with cyclical flows at sources, consumption centers, and sinks” to change the behavior (1994, p.10). According to Lyle, “in order to be sustainable, the supply systems for energy and materials must be continually self-renewing, or regenerative, in their operation. That is, sustainability requires on-going regeneration” (1994, p.10).

After 1995, Regenesis Group studies to develop a theoretical and technological foundation for the approach. With the leadership of Mang and Haggard, the group launched a new book titled *Regenerative Development and Design: A Framework for Evolving Sustainability* in 2016. In 2012, the *Building Research & Information* published a special issue on the topic of ‘regenerative design and development’ that includes 9 key papers<sup>1</sup> covers a wide range of topics. Moreover, Hes and Du Plessis’s (2015) book, *Designing for Hope: Pathways to Regenerative Sustainability*, is one of the key resources in the literature.

## **Defining Regenerative Design and Its Key Characteristics**

There are four main reasons why regenerative approaches are gaining prominence: the need for moving beyond ‘doing less or no harm’ approaches (Pedersen Zari, 2010; Du Plessis, 2012; Cole 2012a; Pedersen Zari, 2012); the push in the industry to achieve higher performance aspirations (Cole et al., 2012; Clegg, 2012); the need for a new paradigm due to the inappropriate thinking processes of the mechanistic worldview (Du Plessis, 2012); and the call for a motivating positive discourse to address the challenges of our time.

There are an increased number of architectural practitioners that have gained experience in green design by producing buildings which achieve the highest level of performance within the Leadership in Energy and Environmental Design (LEED) and other green building programs around the world. “This maturing of green building practice has meant that leading-edge ‘green’ practitioners who have operated at this level are seeking to push much further than the performance aspirations embedded in current assessment methods” (Cole et al. 2012, p.96). Although design professionals are making advances in green building technology, the bigger problems like climate change and biodiversity loss have not been addressed yet (Haggard, 2002). RD aims to creates ‘net positive’ outcomes for ecological, social, and economic development as a whole to reverse the negative impacts.

The literature highlights the importance of moving from a mechanistic worldview — nature as a machine that humans can manage by understanding its parts and accepts that

---

<sup>1</sup> Cole, 2012a; Du Plessis, 2012; Mang and Reed, 2012b; Cole, 2012b; Pedersen Zari, 2012; Hoxie et al., 2012; Svec et al., 2012; Cole et al., 2012; and Plaut et al., 2012.

humans are independent and the master of nature— to an ecological one that accepts humans as an integral part of nature and members of the web of life. Moreover, RD manifests a positive narrative to ‘flourish’ the earth as a response to the negative narrative of sustainability that mainly discusses the limits and problems.

### ***A definition of regenerative design***

The term ‘regenerative design’ was introduced by Lyle (1994) and evolved during the last decade. The literature does not have a consensus on the definition of RD and each paper tends to represent its own definition. For example; Mang and Reed (2012a) define RD as “a system of technologies and strategies, based on an understanding of the inner working of ecosystems that generates designs to regenerate rather than deplete underlying life support systems and resources within socio-ecological wholes” (p.2). Furthermore, according to Pedersen Zari and Jenkin (2010), regenerative development “investigates how humans can participate in ecosystems through development, to create optimum health for both human communities (physically, psychologically, socially, culturally, and economically) and other living organisms and systems” (p.3). They define RD as the means of achieving desired outcomes of regenerative development.

This paper defines RD as an approach to shape and form a system (i.e. human ecosystems, communities, buildings, built environments, cities etc.) that seeks to reverse environmental degradation by creating positive impacts, rather than merely causing less damage, to increase the health and wellbeing of humans, other living beings, and ecosystems as a co-evolutionary whole. RD requires an understanding of the fundamental principles of ecosystems to explore how nature designs to regenerate rather than deplete life support systems. It sees place as a core for design and works for understanding patterns of place and ecosystems in different scales from planetary to local in order to find a way to positively participate. The overall objectives of RD are understanding how nature and ecosystems work and participating in nature as a socio-ecological partner to provide positive impacts.

### ***Key characteristics of regenerative design***

The literature was scanned and the ten key characteristics (philosophical departure points) of regenerative design and development were determined:

- Shifting the paradigm: bringing a new mind
- Seeing humans as a part of nature: co-evolution
- Seeking for positive outcomes and improving health and vitality of the co-evolutionary whole
- Offering a hope and positive direction for turning crisis into an opportunity
- Re-defining ‘design’ and the role of designer
- Establishing place as a core and unique entity
- Recognizing values to engage all stakeholders and evoke deep caring for their place
- Exploring patterns, new boundaries and scale
- Acknowledging a new time frame
- Exploring ecosystems to restore, create, and add resilience.

### **Regenerative Design Support Tools: A Bridge Between Theory and Practice**

Because of their significant role in shaping and bridging the theory and the current building practice, the selected five tools —REGEN, Eco-Balance, LENSES, Perkins+Will Framework, and Living Building Challenge— were examined and evaluated in this study. The tools aim to

simplify the theoretical underpinnings and thinking process of RD and to provide guidance and approachable goals for practitioners. The theory of RD introduces several ‘intangible’ new concepts such as whole system thinking, interconnectedness etc. Defining them verbally is easier than setting measurable performance goals due to the complexity of the topic. Therefore, it is necessary to have operational methods, guides, and metrics/indicators to understand, engage, and apply regenerative approaches. In that point, a number of RD support tools are emerging to guide the transition.

Performance assessment and rating systems such as LEED have been dominating the mainstream of green building practice. Their methods are checklist-based and depend on a list of indicators. Although the RD support tools are in their infancy, it is frequently argued that they should be substantially different from checklist-based reductive green and sustainable design assessment tools (Cole, 2012b; Svec et al, 2012; Cole et al, 2012; Plaut et al, 2012). The RD support tools strive to provide a broader framework to integrate the knowledge that comes from previous approaches. The RD support tools are summarized in Table 1 to compare and contrast (Refer to Akturk, 2016 for more information).

## Holistic Regenerative Design Framework

This paper proposes an overall framework called Holistic Regenerative Design Framework (HRDF) to visually represent RD and its key attributes (Figure 1). The HRDF highlights the importance of a new kind of understanding of success with both quantitative and qualitative indicators. It has four ‘Essence’ as a framing structure to gather all attributes together: Philosophy, Design Process, Indicators, and Emergence of Regeneration. Each Essence consists of four Categories, and there are sixteen Categories in total. Although the graphic has a linear visual representation, the process is cyclic and continual. The HRDF can be used to both design a project and to evaluate the existing design tools or case studies. In this study, the HRDF was used to evaluate the RD support tools.

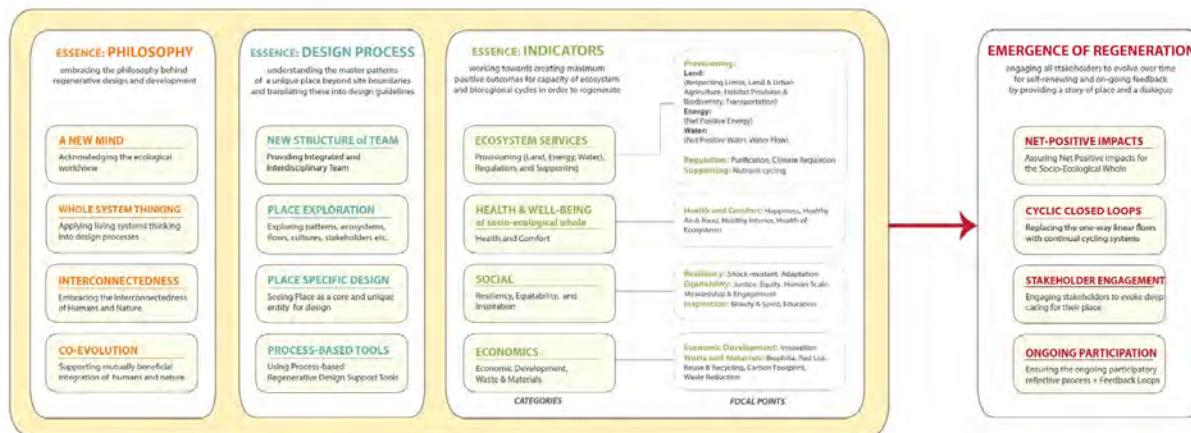

Figure 1. The holistic regenerative design framework.

## Evaluation of Regenerative Design Support Tools

### Methodology

This paper investigates how the tools apply the concepts of RD into design processes, what kind of methods and techniques they offer, and what their gaps and limitations are. The sixteen Categories of the HRDF were transformed into a table format (evaluation sheet) to analyse the tools. An evaluation sheet was filled for each tool (the last versions and original documents of the tools were gathered) as a baseline for the study (Refer to Akturk, 2016 for details of the methodology). The tool evaluation consists of two parts:

- *The Comparison of the Regenerative Design Tools: Support* aims to examine whether the tools address all of the topics mentioned in the HRDF. The overall comparison of the five RD tools was represented in two layers: Addressing and Goal Setting. The Addressing layer is represented by yellow circles while the goal setting is dark pink circles. Both layers have three options depending on their comprehensiveness (e.g. addresses, indirectly address, no explanation) (Table 2).

- *The Comparison of the Regenerative Design Tools: Theory + Practice Methods*, the second part, shows the common methods offered in the tools that strive to apply theoretical concepts of RD into practice (Table 3). The methods and techniques offered in each tool were determined separately and were metaphorically overlaid to determine common ones.

### Findings and Recommendation

The results of the tool evaluation were represented in two tables (Table 2 and 3). Overall, there are three main findings about RD tools: the shared patterns, the well explored topics, and the gaps and limitations of the tools.

First, the RD tools share three patterns. i) The tools are complex and time intensive due to their attempt to deal with complexity. ii) Although the literature of RD rejects the checklist format and element-based approaches in reductionism, the tools include a list of indicators with a different kind of representation. They provide a broader framework to engage with a holistic view and integrate this with a reductionist approach. iii) The tools provide a series of graphics to explain the issues. They emphasize the cyclic processes of RD by using circular shaped visuals. Although this attitude is understandable, it carries the risk of making the diagrams more difficult to comprehend. Second, by using the tool comparisons, the well explored concepts within the RD support tools were determined. They are (represented with black lines in Table 2): A new mind; Interconnectedness, Place exploration and Place specific

design; Building performance metrics such as energy and water. Third, the gaps and limitations of the RD tools were also determined to give a direction for future studies. These gaps are (represented with green rectangles and numbered by the order of importance in Table 2): Ecosystem services, Resiliency and social systems, Stakeholder engagement, Ongoing participation and Co-evolution.

Table 2. The Comparison of the Regenerative Design Tools: Support.

PROCESS	New Structure of Design Team Place Exploration Place Specific Design Process-based Tools	       	       	       		Well explored categories
INDICATORS and Focal Points	Ecosystem Services: Provisioning Regulation Supporting Health and Well-being: Social:	                                     <img alt="white circle" data-bbox="318 6285 338				

From a designer's standpoint, it might be difficult to use the five tools together per a project. For this case, using the combination of the LENSES and LBC is recommended. It is crucial to call attention to the gaps in the tools to acknowledge that none of the tools are sufficient to include all aspects of RD.

 Techniques explored  
In more than two tools

## Conclusion

As the concept of RD gains prominence, it is anticipated that there will be an increasing demand for more comprehensive and approachable design support tools to guide practitioners aspiring to engage with it. Observing the development and testing of RD tools will certainly lead to shifts in thinking and understanding. Although it is predictable that using the RD support tools requires many more skills and personal transformation, the new skills required to engage RD are still unclear. The other issue is considering how mechanistic and

ecological worldview work together. Moreover, it is anticipated that the concept of ecosystem services will be discussed more in the future due to its significance and lack of exploration. To better explore the concept, the design and development disciplines must coordinate research with the fields of biology and ecology on the application of ecosystem services to the built environment. The question is how will the future studies regarding ecosystem services shape and transform the practice and the tools?

## Are occupants more satisfied with indoor environmental quality in green-certified buildings?

Sergio Altomonte<sup>1</sup>, Stefano Schiavon<sup>2</sup>, Michael Kent<sup>1</sup> and Gail Brager<sup>2</sup>

<sup>1</sup> Department of Architecture and Built Environment, The University of Nottingham, UK

<sup>2</sup> Center for the Built Environment, University of California, Berkeley, USA

**Abstract:** Green building certification systems aim at improving the design and operation of buildings. However, few detailed studies have investigated whether green certification effectively leads to higher occupant satisfaction with the qualities of the indoor environment. Building on previous work, we analysed a subset of the Center for the Built Environment (CBE) Occupant Indoor Environmental Quality (IEQ) survey database – featuring 11,243 responses from 93 LEED-rated office buildings – to rigorously explore the relationships between the credits achieved by certified buildings in the IEQ category and the satisfaction expressed by occupants with their workspace and with related factors of indoor environmental quality. We found that the achievement of a specific IEQ credit did not increase occupant satisfaction. Qualitative assessments suggested that there are many reasons for this lack of relationships, many of which are outside the control of designers and beyond the scope of green building certification systems based primarily on design intent. We conclude with a summary of recommendations that design professionals, certification systems, and evaluation methods need to consider for moving us towards more comfortable, higher performing, and healthier green-certified buildings.

**Keywords:** Indoor Environmental Quality (IEQ), Occupant Satisfaction, Green Certification, Post-occupancy Evaluation, Leadership in Energy and Environmental Design (LEED)

### Introduction

Green building certification systems are assuming a prominent role to promote the sustainability agenda in the design and operation of buildings. However, their contribution towards improved satisfaction with indoor environmental quality (IEQ) is still much debated. Particularly in the workplace, the qualities of the indoor environment (heat, light, sound, air quality, etc.) can profoundly impact on occupants' comfort, performance, health, and wellbeing (Huang et al., 2012; Bluysen, 2014). However, despite the assumption that a certified building leads to improved IEQ (USGBC, 2017a), the empirical evidence has often been inconsistent, mostly due to differences in data collection and analysis techniques.

Among studies reporting positive effects of IEQ in certified buildings, MacNaughton et al. (2017) conducted cognitive tests in green-certified and in non-certified but high-performing buildings ( $n= 69$ ). While buildings had roughly equal indoor environmental conditions, cognitive performance was higher in the certified buildings (possibly also due to workplace culture and other non-measured factors). Performing meta-analysis on data from two large field studies, Leder et al. (2016) found that users of green-rated offices tended to rate all aspects of environmental satisfaction more highly than occupants of conventional buildings, although working in a certified office was not necessarily associated with higher job satisfaction. The study also suggested that users of green buildings might be more 'forgiving'

of indoor conditions, as already proposed by Leaman and Bordass (2007). Conversely, other research has emphasized that green certification criteria might not yet be informed by a complete characterization of how physical conditions drive user perception, this resulting in occupants of green buildings seldom showing consistent higher satisfaction with their workplace. For example, Tham et al. (2015) compared the IEQ perception and the prevalence of sick building syndrome (SBS) symptoms and sick leave in a platinum-certified ( $n= 31$ ) and in a conventional office building in Singapore ( $n= 33$ ). Although the certified building was perceived as cooler, and with fresher and cleaner air, it did not have different measured IEQ parameters (physical, chemical, and biological) than the conventional office, nor was any association detected between certification, lower SBS symptoms, and sick leave records.

Some limitations of previous research consist in the use of rather small sample sizes and the reliance on null-hypothesis significance testing (NHST) of differences in mean satisfaction scores, which might bias the practical relevance of conclusions (Cumming, 2014). In response, earlier work by the authors (Altomonte & Schiavon, 2013; Schiavon & Altomonte, 2014) analysed a large subset of the Center for the Built Environment (CBE) survey database featuring 21,477 responses from 144 office buildings, of which 65 were LEED-rated. The results – which were based on estimation of effect sizes, a standardized measure of the magnitude of the differences detected and not just of their statistical significance – showed equal satisfaction with the building, the workspace, and with several factors of indoor environmental quality between users of certified and non-certified offices. These findings were independent of gender, age, office type, spatial layout, distance from windows, building size, work type, and working hours. Conversely, evidence was detected for LEED buildings to be more effective in delivering satisfaction in open-spaces rather than in enclosed offices, and in small rather than in large buildings. Also, tendencies suggested that users of LEED buildings might be more satisfied with air quality and less satisfied with amount of light, and that the positive values of certification may decrease with time. Further research by the authors on BREEAM-rated buildings in UK led to similar results (Altomonte et al., 2017a).

These studies, however, did not include detailed analysis of the associations between user satisfaction and specific IEQ credits. Therefore, this new stage of research sought to assess occupant satisfaction in LEED-rated buildings considering the individual credits achieved in the indoor environmental quality (IEQ) category, the total IEQ points scored, the product and version under which certification had been attained, and the final rating level.

This paper synthesises the results obtained, focusing specifically on the comparisons between occupant satisfaction and individual and total IEQ credits achieved.

## Methods

This study was structured on a mixed-method research design, combining *quantitative* analysis of user satisfaction in LEED-rated buildings with *qualitative* assessments derived from an industry focus group with designers and researchers, our professional judgment, and a comprehensive review of the literature.

The details of the methods and analysis approach are presented in Altomonte et al. (2017b) and in Walker (2015), and we provide only a brief summary here. The dataset, which is described in Table 1, originates from the Center for the Built Environment Occupant IEQ survey database (CBE, 2017), and includes 11,243 responses from 93 LEED-rated office buildings located in US (83) and Canada (10). These buildings were selected since they all hosted office-type activities and administered the survey within two years of certification.

Table 1. Distribution of buildings and occupant responses by LEED product, rating, and version

<b>Product</b>	<b>NC</b>		<b>EB/EBOM</b>		<b>CI</b>		<b>Total</b>

2009	3	152	8	2,125	6	552	17	2,829
<b>Total</b>	<b>58</b>	<b>5,330</b>	<b>13</b>	<b>2,860</b>	<b>22</b>	<b>3,053</b>	<b>93</b>	<b>11,243</b>

LEED NC= New Constructions; LEED EB/EBOM= Existing Buildings; LEED CI = Commercial Interiors

To structure the *quantitative* analysis, we developed 72 pairings – fully described in (Altomonte et al., 2017b) – between CBE survey categories and related LEED IEQ credits. Due to page limitation, the statistical results here reported in relation to the associations between user satisfaction and individual IEQ credits focus uniquely on air quality, temperature, amount of light, and visual comfort. We calculated descriptive statistics and differences between mean and median scores of satisfaction by organizing responses in two groups: buildings that had obtained a specific IEQ credit ( $x_1$ ), and buildings that had not ( $x_0$ ). Since data were ordinal and non-normally distributed, we tested the statistical significance of differences between satisfaction scores in each group with a two-tailed non-parametric Wilcoxon rank-sum test. For all tests, the results were considered statistically significant when  $p \leq 0.05$ . Due to the large size of the samples – which may confound statistical and practical significance – we calculated the effect size by using the Spearman rho ( $\rho$ ) rank correlation coefficient in order to infer the practical relevance of the statistically significant differences detected (Field et al., 2012). Consistent with our previous research, the thresholds provided by Ferguson (2009) were used for inferring small, moderate, and large effects sizes ( $\rho \geq 0.20, 0.50$ , and  $0.80$ );  $p$ -values lower than 0.20 were considered non-substantive, i.e. negligible and non-practically relevant. For analysing the variation of occupant satisfaction based on the total IEQ points achieved, and the product and version under which certification was obtained, we performed ordinal logistic regression specifically focusing on occupant satisfaction with the workspace.

We critically evaluated the findings from the quantitative statistical analysis by *qualitative* assessments. These offered different perspectives to analyze and discuss the design features that might contribute to improved IEQ in office buildings, and frame complex design and construction processes within the dynamic nature of building operations.

## Results

We analysed a total of 72 comparisons between the IEQ categories of the CBE survey and the relative IEQ LEED credits. For a selection of these comparisons, Figure 1 and Table 2 illustrate the boxplots and the descriptive and inferential statistics of results, providing the sizes of sample groups ( $N_0$  and  $N_1$ ), the means ( $M_0$  and  $M_1$ ), medians ( $M_{dn0}$  and  $M_{dn1}$ ) and their differences ( $\Delta M$  and  $\Delta M_{dn}$ ), the two-tailed statistical significance ( $p$ -value) for the Wilcoxon tests, and the effect sizes ( $\rho$ ). Buildings were grouped based on LEED products and versions.

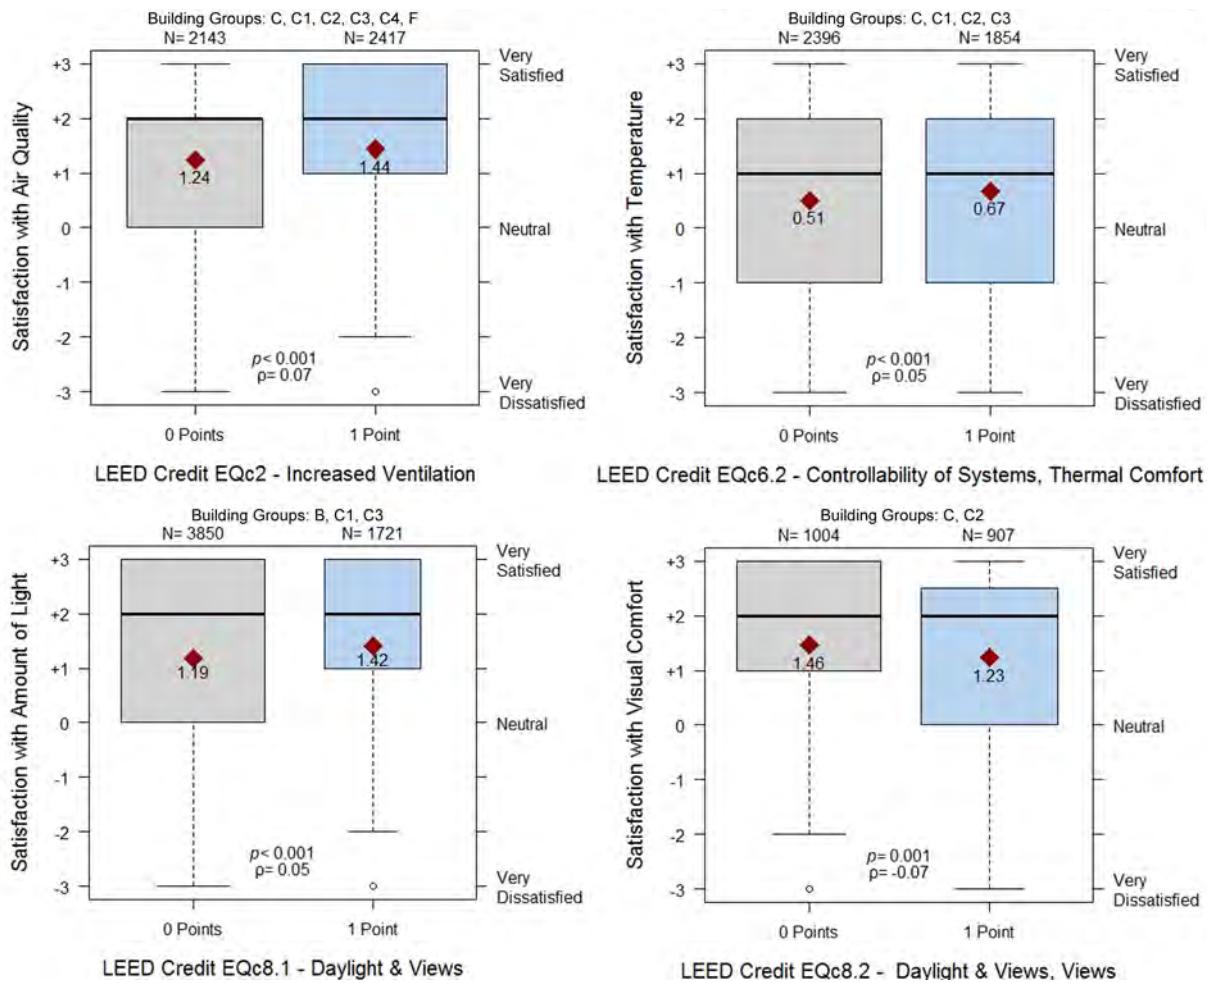

Figure 1. Boxplots for satisfaction with air quality, temperature, amount of light, and visual comfort.

Table 2. Descriptive and inferential statistics for selected comparisons between satisfaction and IEQ credits

Credit	CBE Category	N <sub>0</sub>	N <sub>1</sub>	M <sub>0</sub>	M <sub>1</sub>	M <sub>d<sub>0</sub></sub>	M <sub>d<sub>1</sub></sub>	ΔM	ΔM <sub>dn</sub>	p-value	p
EQc2	Air Quality	2,143	2,417	1.24	1.44	2.0	2.0	-0.20	0.0	<0.001	0.07
EQc6.2	Temperature	2,396	1,854	0.51	0.67	1.0	1.0	-0.16	0.0	<0.001	0.05
EQc8.1	Amount of Light	3,850	1,721	1.19	1.42	2.0	2.0	-0.23	0.0	<0.001	0.05
EQc8.2	Visual Comfort	1,004	907	1.46	1.23	2.0	2.0	0.23	0.0	<0.001	-0.07

p≤0.001= highly significant; 0.001< p ≤0.01= significant; 0.01< p ≤0.05= weakly significant; p> 0.05= not significant

p< 0.20= negligible; 0.20≤ p <0.50= small; 0.50≤ p<0.80= moderate; p≥ 0.80= large

Groups: B=NC 2.0, NC 2.1; C= NC 2.2, NC 2009; C1= CI 2.0; C2= CI 2009; C3= Canada CI 1.0; C4= CI 1.0; F= EB 2.0

The Wilcoxon tests detected statistically significant differences in 49 out of 72 total cases. However, 71 out of 72 comparisons had an effect size of negligible magnitude ( $p < 0.20$ ). The only exception was for a pairing between credit IEQc3.1 - High Performance Green Cleaning Programme and satisfaction with air quality ( $\Delta M_{dn} = -1.0$ ,  $p < 0.001$ ,  $p = 0.27$ ), although this result should be treated with caution since this comparison was based on rather uneven numbers of responses in each independent group ( $N_0 = 368$ ;  $N_1 = 1,877$ ). Graphical analysis of boxplots and inspection of the descriptive ( $\Delta M$  and  $\Delta M_{dn}$ ) and inferential data ( $p$ -value and  $p$ ), therefore, indicates that the achievement of a specific IEQ credit did not have a practically relevant influence on occupant satisfaction with the related IEQ parameter.

For the LEED buildings in the database, the number of IEQ points achieved ranged from 5 to 16. Figure 2 presents the linear regressions for occupant satisfaction with the workspace.

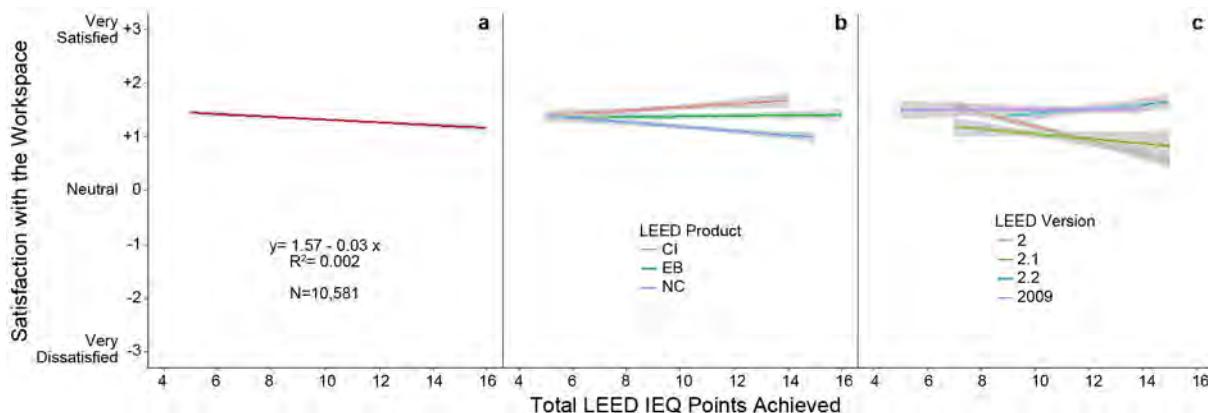

Figure 2. Linear regressions for satisfaction with the workspace based on LEED IEQ points achieved for: a) the full dataset; b) LEED product; c) LEED version. The grey lines represent the 95% confidence intervals.

Surprisingly, the graphs show a tendency for satisfaction with the workspace to decrease as the number of IEQ points increases (Fig. 2a), particularly for buildings certified by LEED NC, while for LEED CI there was a positive slope relationship (Fig. 2b). Also seen is a trend for buildings rated by newer versions of LEED (2.2 and 2009) to perform slightly better in terms of mean satisfaction as the IEQ points increase (Fig. 2c). Overall, the results suggest that the number of IEQ points achieved is not a predictor of satisfaction with the workspace.

Before discussing these results, we want to offer a couple of caveats concerning the limitations of these findings. First, even though we had a large sample, our dataset cannot be considered representative of all certified office buildings and rating systems. Second, even though a specific IEQ credit was not achieved, there may still have been other strategies implemented to address that environmental factor, hence ‘diluting’ the difference between the sets of buildings that have achieved or have not achieved a given IEQ point.

## Discussion

Using our own qualitative investigations and studies found in the literature, this discussion reflects on the many challenges occurring throughout the design, construction, and use of a building that might affect its performance in terms of occupant satisfaction.

### ***Design and certification vs. occupancy and operation***

The design intentions of a project, which is generally the basis for green certification, might be different than the operational characteristics of a building that is then assessed using a survey in a post-occupancy evaluation (in this case, within two years from certification).

Buildings are complex and dynamic, and in the time between design and occupancy many intervening factors can potentially alter the existence – or the performance – of the strategies for which the green rating was awarded. This can begin already during construction, particularly if contractors were not involved in the design phase and have to manage over-complex and inflexible building systems. Also, the operation of buildings requires fine-tuning and adjustments over time to address the performance gaps that often occur between modelled and measured energy use (de Wilde, 2014). It would not be surprising, therefore, that a similar gap might also manifest itself in occupant IEQ satisfaction, regardless of the total amount of IEQ points achieved, or whether a specific IEQ point had been scored or not at design stage. Conversely, the trends for more positive associations between satisfaction with the workspace and total IEQ points attained for newer versions of LEED may be deemed as a reassuring outcome in terms of the progress made by certification systems.

### ***The relevance of green certification metrics for IEQ***

One might question whether the current metrics used for attaining an IEQ credit are even intended to translate into improved occupant satisfaction. In fact, metrics should focus on the user as much as the building. This represents a challenge particularly due to the substantial differences that characterize the modern workplace in terms of spatial needs, task requirements (e.g., occupancy, working schedules, etc.), and user characteristics (e.g., sex, age, habits, etc.). Design criteria that address the demands of a ‘standard’ occupant might, therefore, not capture the intrinsic variability of a random user basis, especially when this is considered over the entire lifetime of a building. For example, rating tools have traditionally focused mostly on how to get the highest quantity of light across the floor area, rather than on the quality of the luminous environment. But there has been improvement. Under the recent LEED version 4 (USGBC, 2017b), in fact, the “Daylight” credit includes the need for “*manual or automatic (with manual override) glare-control devices*”, and the “Quality Views” credit features a description of the composition of external vistas.

### ***Survey measures and IEQ satisfaction***

Occupant surveys generally rely on subjective measures, although perception might at times be disjointed from actual physical conditions (Allen, et al., 2015). Also, sometimes a survey question about satisfaction with an IEQ parameter might be misinterpreted by the subject.

As an example, perceived air quality and temperature are connected and often confounded (Fang et al., 2004). The effectiveness of ventilation strategies may be considered by users as a thermal comfort issue more than a measure to dilute air pollutants. In addition, over time occupants might become ‘desensitized’ to certain stimuli (e.g., odors), or attribute the physical impacts of exposure to an environmental parameter to causes different from their sources. Finally, while meeting minimum air quality standards is a pre-requisite for most certification systems, there are many pollutants that can’t actually be perceived by people. So even if the air might be more polluted, this won’t be reflected in survey responses.

Feedback can also be biased by personal or corporate attitudes, and may vary depending on the time spent in the building and the role that the occupant has in the office hierarchy. Research has also shown that ‘green-branding’ can enhance pro-environmental perceptions (Khashe et al., 2015), and that IEQ satisfaction might be influenced by corporate concerns for energy efficiency (Tsushima et al., 2015).

### ***Acoustics and office layout***

Green rating systems treat each IEQ category independently rather than considering the integrated synergies between them. For example, one challenge is how to balance air quality, thermal, and visual performance with requirements for a satisfactory acoustic environment.

As shown in our previous research on LEED (Altomonte & Schiavon, 2013; Schiavon & Altomonte, 2014) and BREEAM-rated (Altomonte et al., 2017a) buildings, satisfaction with noise and sound privacy is often characterized by low scores. However, this is not entirely surprising considering that LEED has not featured a credit on “Acoustic Performance” until v4.

Research has also revealed a strong association between satisfaction with the workspace, noise, sound privacy, and office layout (Frontczak, et al., 2012). Open-plan layouts have commonly been assumed to promote communication and team-work effectiveness (Heerwagen, et al., 2004). However, open spaces might also be more disruptive, such that the benefits of enhanced interaction might fail to offset the penalties of increased noise and decreased privacy (Kim & De Dear, 2013).

### **Monitoring and feedback**

Some level of continuous performance monitoring and analysis of occupant feedback could be beneficial in bridging the gap between design intents and user satisfaction throughout the lifetime of a building. Although surveys are key techniques to obtain this information in a rapid, responsive, and relatively inexpensive fashion, they might lack in contextual information and continued data gathering (Deuble & De Dear, 2014). Ideally, they should be part of a broader and interdisciplinary set of measurement protocols that could exhaustively capture the functioning of a building (ASHRAE, 2012).

Green building rating systems should also systematically reward mechanisms for continuous building monitoring and occupant feedback to ensure that, following certification, the building continues to operate based on design intentions. We are starting to see this. For example, the USGBC recently launched the LEED Dynamic Plaque, a building performance monitoring and scoring platform that generates continuous benchmarking score under a set of categories, and can provide annual LEED recertification (USGBC, 2017c).

### **Conclusions**

Based on the quantitative analysis of a dataset featuring 11,243 responses from 93 LEED-certified buildings, the achievement of an IEQ credit did not substantively affect occupant IEQ satisfaction, and the total IEQ points obtained had negligible influence on satisfaction with the workspace, independent of the product under which certification was awarded.

Supported by qualitative assessments, these conclusions lead to the following recommendations. For *designers* and *facility managers*: the design phase of a project differs from the post-occupancy evaluation stage, requiring direct involvement in performance and feedback monitoring to fine-tune operating strategies and transfer best practice to the building industry. For *green certification systems*: the metrics to attain IEQ credits need to better represent reliable indicators of occupant satisfaction. For *evaluation methods and tools*: surveys rely on subjective measures assessing the perspective of the user, but are best used if supported by physical measurements and in-person interviews to holistically appraise building performance; also, satisfaction might be driven by factors other than IEQ parameters, such as time spent at the workspace, attitudes, expectations, workplace culture, etc.

There is no ‘silver-bullet’ for a satisfactory and healthy work environment. Given the dynamic nature of buildings, the complexity of the users, the diverse and evolving demands of the workplace, and the need for these factors to be effectively monitored and analysed, there are still many challenges that the green building industry needs to tackle to promote indoor environmental qualities conducive to satisfaction and wellbeing. However, if sustained by advancements in research and design practice, green rating systems can offer significant opportunities towards better, more comfortable, higher performing, and healthier buildings.

## Mind the Gap; Methodology Discussion of the Extraction and Analysis of Pilot Phase Data to Generate Multi-Configuration Household Behavioural Profiles

AbdelRahman A.I.M. Aly<sup>1</sup>, Amira ElNokaly<sup>1</sup>, Glen Mills<sup>1</sup>

<sup>1</sup>School of Architecture & Design, University of Lincoln, Lincoln, United Kingdom

**Abstract:** This paper constitutes the conclusion of a three-month pilot study, concluding March 2017, performed in a CfSH level 5 housing projects in Lincolnshire, UK. The study uses purpose designed activity and occupancy logs, climate tracking and monitoring of interior environment through the use of data loggers. The research's final output uses occupancy tracking by introducing self-observation and its translation to energy consumption by its integration into multiple occupancy calculation methodologies to investigate these results within the post-pilot study phase. The pilot study constitutes the development of these methods according to each house's occupants and the research objectives. The study aims at generating multi-configuration household behavioural profiles through extracting a comprehensive full set of data, including room functions, activities and factors that contribute to energy consumption by balancing the use of logs and participant comfort. The research undertakes a bottom-up survey, assessing consumption information of frequently used equipment in the house and calculating variable total consumption in accordance with the occupancy and activity logs. In addition, the use of an initial semi-structured interview that was undertaken to address the phenomenological causes that underline the observed behaviour, as well as account for non-quantifiable factors of behaviour. The findings of this study have shown patterns of behaviour that are atypical of usual design assumptions as well as a variety of household combinations that interact uniquely with their buildings.

**Keywords:** Behavioural Profiles; Performance Gap; Occupancy log; Code for Sustainable Homes (CfSH)

### Introduction

Agencies in the UK began with rolling out regulations to affect citizens' energy consumption. By adjusting how houses are constructed and how users interact with their building through cost manipulation (Odeyale et al, 2013; Warren, 2014) and enforcing regulations for planning and construction. After the development of Eco-Homes and its later iteration, Code for sustainable Homes in 2007, in March 2015 BRE announced the phasing out of CfSH and the use of the previously known as code level four as the base level for construction until 2016 (GOV, 2015; Department for Communities and Local Government, 2015). However measured performance post-occupation needed improvement and this caused the surfacing of PROBE studies 1995-2002 by CIBSE followed by Building Performance Evaluation funding (Tse and Colmer, 2014). As of writing this paper in 2017, housing standards are at a tipping point following the new optional building regulations which still use the previous version of SAP and the optional ability to construct houses based on any of the international or national standards such as the newly developed Home Quality Mark (HQM and BRE, 2015). During that transitional shift in regulation, the final reports for the building performance evaluation program and the performance gap studies by InnovateUK and Zero Carbon Hub (ZCH) as well as partner universities and industry specialists were published ending a phase of "proving the existence of the performance gap" and in a way, initiating the age of bridging the gap during the transitional and recommendations period (Tse and Colmer, 2014; ZCH, 2015; Digital Catapult, 2016; Pannell, 2016). This change in regulation left the

industry with a number of projects that were still under construction and ones that already exist with a set of issues that contribute to the performance gap as summarized by the ZCH end of term report (Zero Carbon Hub, 2013). Since the newly introduced Home Quality Mark has to conform to the Standard Assessment Procedures' (SAP) regulations included in Part L of the planning permissions process (HQM and BRE, 2015), it still faces the same issue of calculating user behaviour. A problem unlikely to change since the methodology implemented within SAP existed in CfSH, will exist part of building regulations post-2016 standards' review and will exist when Home Quality Mark is fully launched. Thus it remains a persistent issue for researchers, designers and assessors to work towards solving this problem.

Within the context of BREEAM building codes (CfSH and the upcoming HQM), energy calculations are accounted to achieving a reduction in emissions based on the calculations done within the SAP's technical document/ application. Said calculations, mainly within SAP's occupancy calculation (Henderson and BRE, 2008) and tables 9 within the SAP document (ref) regarding space heating which disregard personal comfort and variations in ambient space temperature (BRE and DECC, 2014), whilst serving as a benchmark in the design process, upon post-occupancy evaluation, the benefit of a probabilistic model would be needed for comparison to validate the real life trend against calculations and thus be able to decide whether the performance gap was due to short-sightedness within SAP or if users' behaviour was too unpredictable for a fixed or dynamic model to estimate (Richardson et al., 2010; Gruber and Prodanovic, 2012; Blight, 2015).

Occupant behaviour is attributed to a number of theories, following or a mixture of theories of planned behaviour Ajzen, 2011, and environmental physical probabilism (Kaiser and et al, 1996), both of which were observed through the methodologies to be discussed in the following sections. Starting at a macro scale with the choice of living in an eco-house by following an assumed theory of self-selection (Michelson, 1977). How user behaviour within their dwelling can be recognized through the models of planned behaviour; addressing the premise that behavioural beliefs, normative beliefs and perceived control over their personal comfort by being able to alter their habitat (Borden and Schettino, 1979; Ajzen, 2011; Blight, 2015). Finally, complimented by probabilism (Kaiser and et al, 1996), a midway point between environmental deterministic and possibilistic factors. The assumption that users are likely to perform actions due to a deterministic environmental factor, however their personal comfort, external criteria and free choice determines whether or not they are likely to do it (Borden and Schettino, 1979).

Examples of these factors that have been previously established are internal and external climate; predictive mean vote of personal comfort; architectural layout and spatial functions; occupancy patterns; age factors; employment and associated routine. The range of factors that operate within these theories are impractical to empirically quantify as they change depending on the conditions surrounding the subjects as well as flow with their own perception and experience of space (Parrys, Saelens and Hens, 2011; ElNokaly & ElSeragy, 2012). Thus the researcher operated on the concept that behaviour of residents of eco-houses who share the values of self-selection and planned behaviour would have similar operational norms, whilst factors such as their age, employment and occupancy patterns would vary due to probabilistic factors that could not be isolated but perhaps regressed into consumption trends that would serve as a comparative baseline for design or post-occupancy evaluation. However, a limitation to this research is to account for the variable occupant numbers per dwelling, their employment and their age would create a variation in results that cannot be considered statistically significant on a large scale without acquiring a wider sample and testing them in further research that is not constrained by time. Thus analysing it on a case-by-case basis, and allowing for the creation of a methodology and toolkit to be used would allow for expanded research and exploration of further scenarios (Pustejovsky, 2015).

### **Background to “EcoHouses” Project and Pilot study**

The pilot study was chosen as a proof of concept to the literature mentioned previously, that whilst it is agreed that user behaviour deviates from predicted SAP models, household configuration also impacts that condition (Yao and Steemers, 2005). The premise being that age and employment have a direct

impact on users' routines and thus have an impact on the total energy consumed accordingly. Hence, it was essential to recruit a set of comparable houses in terms of design and construction standards with the variable being the demographic types of users inhabiting it. In addition the research's overall aim is to streamline this process into a simple and affordable methodology that can be performed as part of a routine post-occupancy study thus within the methodology section, a number of low-tech and budget-aware solutions used to start this process and assess their viability.

To satisfy the conditions mentioned above, the researcher approached a set of privately owned houses in Lincoln, UK's Long Leys Urban Village, roughly 1.2 miles from city center. The project; composed of thirteen houses provided a fertile research opportunity due to a number of factors. The houses are built up to code level 5 standard of CfSH (November 2010) using SAP 2009, constructed and partially inhabited by the end of 2014 and, were advertised as eco-housing with low operational costs, self-sustenance and passive house design with a feed-in tariff to entice potential buyers (Elnokaly and A.J. Martin, 2014).

The housing project, located in the East Midlands, is a private development, privately owned by its current residents that were intended to be a step towards sustainable developments by its developer. Built on an area of brown land within a designated urban village within the borders of Lincoln city, the project had to satisfy a high performance rating in order to gain planning permission. The site is composed of thirteen privately owned three and four-bedroom semi-detached houses built using three various layouts and floor areas, but facing the same orientation, built up to the same standard and acquired identical SAP ratings in both design and evaluation stages. The houses studied in this research are built using two of the layouts, labelled B and D in table 1, three and four bedroom houses respectively with identical floorplans in each case. Due to constraints from the developer the exact figures for the second layout were not released, however it was assured that the released SAP rating was identical to the design specifications.

Table 1 As-Designed vs. As-Built

Dwelling type	As-Designed SAP rating	As-Built SAP rating
Layout B (three bedrooms)	99 (A)	99 (A)
Layout D (four bedrooms)	97 (A)	97 (A)

Figure 1 Site and Floor plans and participation rate

The houses were constructed to reduce reliance on mains electricity by providing a calculated 1024.5 kWh of photovoltaic generated electricity per year and 1158.8 kWh of water heating annual that feeds into a combination boiler (SAP Printout, 2015). The house utilizes two systems for heating, a combination boiler of efficiency 88-89.01% and electric underfloor heating (Compliance Report, 2015; SAP Printout, 2015; Vaillant, 2017). The first disperses its heating load through radiator panels distributed throughout the house. It is notable that these panels are ill-placed (thermostat is situated close

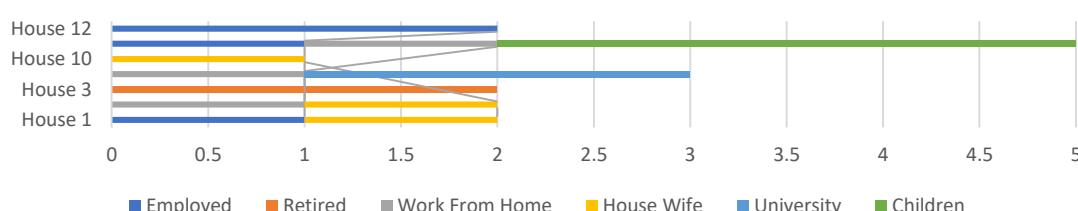

Figure 2. Occupancy and employment values within the case study, from interviews and recruitment

to the panels) causing false-feedback and disturbances within the operation and performance costs of the house. In addition, the houses are occupied by a diverse number of configurations, as shown in fig 2, varying between retired couples, working couples, parents and mixtures of the previous, with a general age range between 40 to mid-sixties. However due to confidentiality, residents' ages are grouped based on NHS age groups within the project.

## **Methodology**

To counter the aforementioned problems, the pilot study of this research project started off by identifying a number of tools, some used previously and others created for this task to generate a large amount of data that can be used within this research to draw relationships and weed out irrelevant and negligible aberrations in behaviour.

The research relies heavily on the research subjects' self-observation of their behaviour and activities through the use of: 1) Daily room occupancy logbooks, 2) Daily activity logbooks, 3) Footfall plan of movement during a typical day, the details of each tool will be further discussed in the following section. The researcher also conducted a number of interviews; based on a modified version of a Building Use Study (CIBSE, 2012) in addition to a number of transcendental phenomenological (Moustakas, 2010) questions that require the users to identify behaviours they routinely or subconsciously partake in. In addition, a bottom up survey of all electric equipment inside the house was performed and mapped on the building's floor plan.

In summary, the research will follow a mixed method research investigation (HO et al., 2006, Cohen et al., 2011). Globally the research will be conducted in the format of an investigative cross-case analysis (Simons, 1996, VanWynsberghe et al., 2008), to ultimately deduce the most prominent factors of user behaviour and how they affect buildings designed using the current UK methodology, SAP under the Code for Sustainable Homes level 5 and compared against data gathered from the Building Use Study and data gathered through this research. Individually, by using empirical data from building performance analysis reports and measurements (Digital Catapult, 2016). Qualitative data gathering through various forms of interview and usage logs (Geer, 1991, Witzel, 2000, Turner, 2010; Elnokaly & Keeling, 2016), and their conversion into comparable and analyzable quantitative values that are to be used within statistical modelling (Dixon-Woods et al., 2005).

However, in addition to gathering a large set of quantitative data, the researcher investigates using a structured interview method with open-ended questions to investigate phenomenological and perception based responses that could account for some of the observed behaviour through logbooks and an experimental procedure. The interview's structure also adopts a modified Building Use Study (BUS) Survey, to extract more perception based question. The research will validate the results obtained from the research-modified interview against the results obtained from the validated results returned by the BUS Methodology group. The BUS methodology has been developed by survey firm Building Use Studies and refined by CIBSE (CIBSE, 1997; CIBSE, 2012). It is used to extract quantitative responses regarding building quality, design and comfort (Pretlove and Kade, 2016). The logbooks are a 30-minute time step chart of activities and room occupancy designed to be filled easily by the participants, they monitor their own activities by filling in the respective time slot, that would be used by the researchers to create a time-plot of probabilistic behaviour and how it would contribute to consumption. The researcher also asked the occupants to participate in an experimental self-observation procedure (Rodríguez et al., 2002; Elnokaly & Martin, 2014)), the footfall is marked on a floor plan of their respective houses and given the intensity of lines, the researcher can compare the findings to current occupancy analysis software to identify the gap in assumed versus actual behaviour.

## **Semi-Structured Interviews**

The researcher's first task was to gather demographic, quality of life and transcendental phenomenological information regarding the users' perception of their life and actions in their current dwelling. As well as identify the possible motives behind self-selection of their current dwellings and decisions of probabilistic and planned behavior. The use of a semi-structured interview provides the

benefit of delivering a concise set of questions directed towards gathering data which are both usable for comparison within standardized quality of life surveys such as BUS surveys. Whilst allowing the researcher the freedom to gather subjective knowledge to reflect on the literature and identify limitations and possible avenues for future research. The data also provides the researcher with routine and detailed interactions that are essential to translating logbooks into tables of actions as a method of validation. In addition, recording the users' fixed routines and automated system would serve its purpose in the next phase of this project when translating system operations into energy consumption. The interviews were in the form of a 15 – 30-minute set of questions divided into 1) understanding of the house's sustainable features, 2) Lighting: behaviour and use of artificial lighting, 3) Thermal comfort: self-selection and planned behavioural data regarding their choice of residence and occupancy patterns. Followed by the same questions used within an ARUP BUS survey (CIBSE, 1997; CIBSE, 2012) however following the same grading system and by adding an open-ended response to where the participant has to elaborate in their own words as to why they chose a particular answer.

Some of the scaled data from the structured portion of the interview are shown in figure 2, validating the original claim that user experience varies between the different houses. However, the use of this data can prove to be misleading without support from transcendental phenomenological data such as the background of understanding of these systems, how they were taught to use it, who manages thermal comfort in the house and so on. Quotes from the interviews depicted in Table 2 allows the researcher to assign certain behaviour to lack of knowledge and observe how it changes throughout the study to rule it out as an aberration or a significant impact on building operation. The following excerpts from the interviews gives the research an additional dimension to allow for the analysis of socio-psychological as previously mentioned by gathering transcendental phenomenological data acquired by self-perception of their environment.

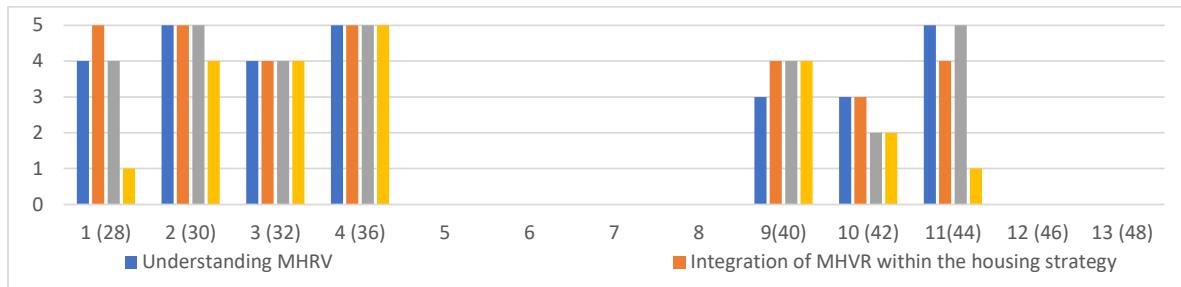

Figure 3 Summary of the house's technology and understanding section of the interview (Researcher's own work)

Table 2 Quotes that support various assumptions and validate information gathered through the logs

<i>How well do you understand the integration of MHRV in the passive strategies &amp; active heating solutions of the house?</i>
"Not well, however my husband maintains all the systems"
"We attended a course on operation of eco-houses in Grimsby so we could know the basics of the heating and heat recovery system. We are still not entirely sure how it works but we're learning"
"We have only lived here for the duration of one summer so we are not entirely sure how the building performs yet. It was quite warm so we did not need to operate any of the systems"
<i>Time of day when you start turning on the lights?</i>
All houses mentioned that they found that their lighting behaviour depends on real daylight hours, that information was validated by reviewing activity and occupancy logs.
<i>How long have you lived in this house? Is this your first high performance/ecohouse?</i>
"We used to live in a Victorian style house with 5 bedrooms that used to get quite cold and would run up quite a bill for heating. We decided to invest in a house like this hoping to cut down on bills especially now that we live alone after our children moved out"
"I used to own another property that was marketed as ecohouse, I moved here to be closer to the city and closer to work"

### Occupancy and Activity Log Books

The use of log books relies on users' ability to reflect on their activities and document them within a simple time-step/room sheet. This low-tech affordable approach combines the benefits of easily accessible resources and the need for users to recall their activities to the best of ability. Other methods such as the use of electronic trackers or using phone tracking software are a cause for privacy concerns and possible discomfort, in addition to substantial cost increase, thus they were rejected despite the possible benefits of implementation. The time constraints and man hours involved, however constrained the number of logs to two per month that would be distributed due to the busy lifestyles of the occupants as well as to prevent loss of interest. The users are required to fill two weeks per month of typical behaviour (or atypical behaviour in case of national holidays and visitors) totalling an average set of twenty-four (24) collections per log category per house per year. Upon reviewing the literature and similar research done before, the researcher observed that subjects are not likely to change their activity within one given hour, thus a high resolution profile of activities was neither feasible nor productive in this case. The researcher chose a resolution of 30-minute time-steps, with activities that occupy less than a time-step assessed on a case-by-case basis to identify their impact within the larger picture within the time frame of a single day and the accumulation within a year.

Translating that data from an analogue form to digital was done by the use of an excel sheet using the same headings, however the data was translated by identifying the maximum number of occupants in the house and inserting a corresponding digit to identify the number of occupants within a room or performing a certain task per time-step. By using the following equation, the excel sheet automatically calculates the maximum occupancy in dwelling at a certain time-step, this is required to avoid conflicts that arise due to doing multiple activities within the same interval using  $If \sum Occ_{a-e} > Max_n \text{ Then Occupancy} = Max_n, \sum Occ < Max_n \text{ Then Occupancy} = \sum Occ$  where  $\sum Occ_{a-e}$  is the total occupancy count of rooms a-e is.  $Max_n$  is the maximum number of occupants known to be available in the house at the time?

Figure 3 Data Translation procedures through excel sheet. (Researcher's own work)

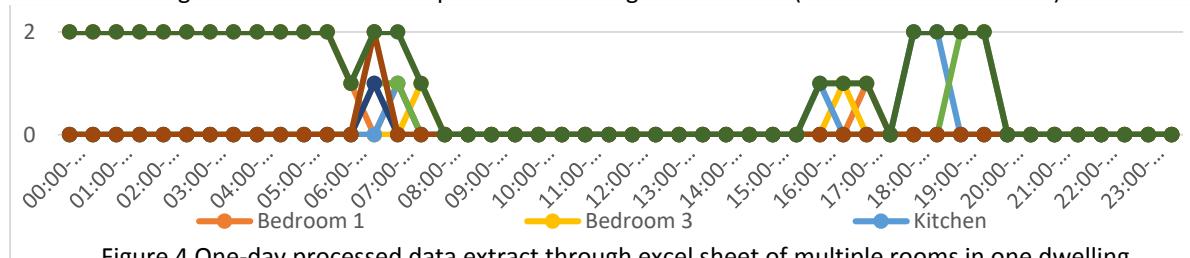

Figure 4 One-day processed data extract through excel sheet of multiple rooms in one dwelling.  
(Researcher's own work)

### Data Loggers

In order to validate the variance in control of the internal environment, the researchers used climatic data loggers placed in key areas of the house, for example, the kitchen and study, which were identified as areas of maximum occupancy. The fluctuations in temperature allow the user to identify environmental cues that influence the occupants' choice to alter internal temperature or trigger any of the automatic systems in place. Currently the research has only monitored one house due to cost and gear restraints. However this has been previously identified as a restraint and additional monitoring equipment has been ordered to continue monitoring the other households. The researcher has used

RHT10 Extech for the first portion of monitoring whilst a requisition for MX1101 (Onsetcomp, 2017) bluetooth data loggers from HOBO was placed part of the development choices after the pilot study.

### **Conclusion**

The pilot phase concluded by April 2017 laying the way for the second phase of this project and continuation of data gathering. The use of activity logs so far has been successful, given the enthusiasm and environmental awareness of occupants, and thus their eagerness to participate in this research. The research team is working on developing a digital method of inputting that data through web-based application as well as self-tracking applications that can be carried mobile for further testing. Data logging is an essential tool and proved to be the highest cost in carrying out this type of research and thus might dissuade others from participating in this kind of research. Extended results of this phase would be published in a later paper, however at this juncture previous hypotheses regarding demographic configurations and their potential impact on consumption have been supported by occupancy and data logger information. Further research is required in order to aggregate these data sets into usable information that can be refined into calculation methodologies as well as the need for expanded research and acquiring of data sets by other researchers to generate a large enough sample for computational analysis. During the handling of the interviews and logbook material, the researcher had to cast away preconceptions of behaviour, adapting Husserl's take on phenomenological research to maintain objectivity of findings (Lowes and Prowse, 2001). Due to the sheer amount of data per household, trends have started to emerge in the form of occupancy patterns, that allow the team to isolate behaviour that is not part of the norm. However, data gathering needs to continue to conclude a year in order to acquire a dataset that is inclusive of different seasonal and climatic changes. Progressing occupancy data to match with consumption data is the next stage since the passive and low-energy devices do not reflect readily with assumed SAP calculations or typical documented behaviour.

## Discrepancies between theoretical and actual heating demand in Scottish modern dwellings

Julio Bros-Williamson<sup>1</sup>, Jon Stinson<sup>1</sup>, Celine Garnier<sup>1</sup> and John Currie<sup>1</sup>

<sup>1</sup> Scottish Energy Centre, School of Engineering and Built Environment, Edinburgh Napier University, 10 Colinton Rd, Edinburgh, Scotland, UK, EH10 5DT, e-mail: {j.broswilliamson, j.stinson, c.garnier, j.currie} @napier.ac.uk

**Abstract:** The study reports on the differences between the actual heat consumption profiles of twelve dwellings monitored for four years and their predicted heat demand profiles as calculated by the UK Government's Standard Assessment Procedure (SAP). This monitoring methodology analysed the selected homes over 4 years of occupation leading to a longitudinal study. Using descriptive statistical metrics this paper considers different groupings and normalisation methods to understand differences in heat demand. It uses this methodology to compare predicted over delivered energy over longer occupation periods. The results demonstrate that the compliance SAP model, incorrectly estimates heat demand by up to one and a half times that recorded in these dwellings. It also concludes that analysing energy consumption over time should exclude early occupation years as they suffer from occupant adjustment periods. Furthermore, by applying a heat energy factor, none of the dwellings achieve equal or better consumption levels than SAP, however flats and the low consuming group dwellings achieve closest to the predicted.

**Keywords:** assumed heating calculations, actual heating demand, performance gap, Scottish housing, SAP

### Introduction

Heat consumption in domestic buildings is based on thermal comfort and personal hygiene regimes. Both depend on building envelope efficiency, occupant habits and behaviours and heating services. The heating services efficiency is dependent on the Coefficient of Performance (COP), fuel used and the degradation of the system over time, partially affected by poor maintenance patterns. Space heating is dependent on the building's envelope efficiency and the occupant's energy efficient habits. Number of occupants in the dwelling and also the patterns of use in cooking, showering/ bathing can greatly influence fuel used for water heating. Equally significant, are internal gains from latent heat sources, electrical appliances and solar gains influenced by building orientation and fenestration design. Household heat consumption from gas fuel accounts for the majority of the household energy (approx. 80%) and over half of the household's energy bill. (Kane et al., 2011).

Since the Energy Performance of Buildings Directive (EPBD) issued the 2010 guidelines (EU Parliament, 2010) for measurement and verification of energy consumption in buildings, a large focus has been on its calculation methodology, enforcement of minimum energy requirements and the certification process (Burman et al., 2014). In the UK the Standard Assessment Procedure (SAP) is the country's National Calculation Methodology (NCM), producing an Energy Efficient and Environmental Impact score from 1 to 100 (G to A) (Kelly et al., 2012). The SAP scores are based on dwellings heat consumption. The steady state

calculation reflects the predicted performance, however recent studies indicate that actual demand can differ by two and sometimes fourfold (Menezes et al., 2012).

Results from a four year energy monitoring programme categorised by twelve different building suppliers is presented and discussed in this paper. These form part of the wider research project at the Housing Innovation Showcase (HIS) in Dunfermline, Scotland. The statistical study presents initial analysis on the differences between the predicted heat consumption (as calculated by the SAP method) of the dwellings and their delivered heat energy over a four year period. Its aim is to show the importance of longitudinal energy monitoring of buildings for determining the effects of heat energy performance gap. This paper shows the findings after statistically analysing the results using alternative clustering and normalisation methods and alternative means of comparing data. A more detailed explanation of the dwellings and their construction methods can be found in research by Bros-Williamson et al. (2016).

## **Methodology**

The study of this housing development focused on a variety of system providers, all innovative in their fabrication, material use and assembly (off-site or on-site) (Bros-Williamson et al., 2016). A large focus was on comparing delivered heat energy since the dwellings handover in summer 2012 to winter 2016/17 against the predicted results using the SAP. The results are presented by calendar year; year 1 represents the occupied year of 2012 and so on until year 2015 which finalises in 2016. Comparison results have been obtained by taking in-home display (IHD) hourly energy consumption data, corroborated with yearly meter readings, focusing on delivered space and water heating predominantly using natural gas as a fuel.

The yearly delivered energy was analysed statistically to provide more insight into the energy consumption levels, patterns and behaviours of the households. The authors present the statistical data under well-established conventions however new ways of analysing and observing trends have been explored.

The analysis begins by justifying the use of typical grouping and identifier methods. Convention in this area of research selects the use of archetypes of dwellings to obtain groups within the sample. As a result of the small sample size and the varied archetype, it was intended to observe the data differently. The mean (average) delivered heat demand results over the 4 years of monitoring against the heating predicted SAP results are plotted over monitored years, first by archetype followed by consumption grouping converted into Z scores and analysing variables in a K-means cluster analysis (MacQueen, 1967), with one iteration to establish groups. The results effectively divided the sample into three groups; ‘low energy consumer’, ‘medium energy consumer’ and ‘high energy consumer’ relative to the yearly energy delivered within the group.

The paper proceeds to identify the best normalisation factor. Most energy related studies will use delivered energy over a set period, normalised by the heated floor space of the building ( $\text{kWh}/\text{m}^2/\text{yr}$ ). However, in this paper the data is compared by using other conditions such as yearly energy demand per volume ( $\text{kWh}/\text{m}^3$ ), number of people ( $\text{kWh}/\text{ppl}$ ) and predicted over actual energy consumption ( $\text{kWh}/\text{kWh}$ ) (Stinson, 2015). The Coefficient of Variation (CV), as a percentage, was used as an indicator to describe which normalisation condition was a best fit for the data. The lower the percentage CV, the closer each individual data point is to the group mean. This would suggest that the mean is a good representation of the whole data set of that sample.

Following this, the paper proceeds by statistically displaying results with a mixed-design analysis of variance (ANOVA) comparing the significant interaction between archetypes and the three groups K-means method using Z scores during the 4 years of the study.

To conclude, the paper summarises all the methods and compares the predicted against delivered heat energy demand referred to as the heat energy factor (HEF). A HEF of 0 indicates the household consumed equal to its predicted result (SAP), results >0 show higher consumption and <0 show lower consumption than the predicted SAP. The HEF is presented as archetypes (n=4) and consumption levels (n=3).

## Pre-analysis of data

### *Most appropriate identifier*

Four years energy consumption data and many of the household's characteristics have been considered to identify the most appropriate grouping for the sample (n=12).

Typically an archetype classification is used, in this sample there are (n=12), flats (n=2), Bungalow semi-detached (n=2), house semi-detached (n=7) and house mid-terrace (n=1). The flats belong to the denominated four-in-a-block configuration with a separate main entrance.

The mean delivered heat energy and its corresponding mean SAP result by each archetype is plotted per monitored year, shown in Figure 1. The mean SAP results are noticeably lower than any year of the mean delivered heat energy by each archetype ranging from the 3,000kWh/year and 4,500kWh/year. The mean results for each monitored year of consumption are closely grouped. In order to interpret the yearly spread and amount of variability relative to the mean, the CV was calculated. Flats CV = 3%; Bungalow semi-detached CV = 8%; House semi-detached CV = 4%. A CV for the House mid-terrace could not be calculated because of the small sample size. The level of variation within the archetypes is considerably low, signifying it is a good descriptor for the samples energy consumption.

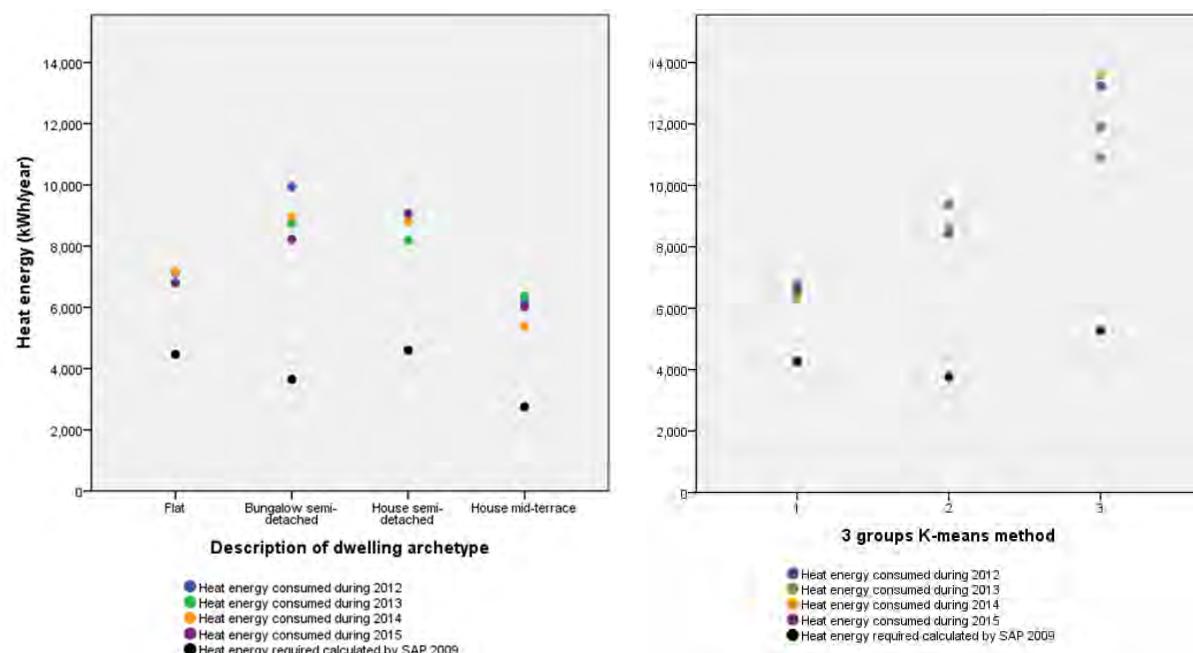

Figure 1. Heat energy by archetype

Figure 2. Heat energy by variables clustering

A second clustering method was applied which considered key variables of the household, including the dwellings floor area, volume, number of occupant adults (>16 years of age), number of occupant children (<16 years of age), the SAP results and the yearly delivered heat energy. This data was converted to Z scores and analysed as variables in a K-means cluster analysis creating the three consumer groups; 1. 'low energy consumer', 2. 'medium energy consumer' and 3. 'high energy consumer'. Figure 2 shows how these compare over the 4 years. The clustering analysis combinations are shown in Table 1 below.

Table 1. Spread of sample group by archetype and variables clustering

Archetypes (n total = 12)	Energy consumer groupings [group]		
	Low [1]	Medium [2]	High [3]
Flats (n=2)	1	1	
Bungalows semi-detached (n=2)		2	
House semi-detached (n=7)	4	1	2
House mid-terrace (n=1)	1		

Analysing the yearly delivered heat energy demand with an on-way ANOVA (analysis of variance) showed that the differences in mean heat energy demand for each archetype was not statistically significant for any of the 4 years ( $p > .05$ ). However, when the sample are split into their associated groups determined by k-means clustering the differences in mean heat energy demand are statistically significant for each individual year ( $p < .05$ ).

Similar to the observed results in Figure 1; the mean results for each monitored year of consumption are closely grouped. Low energy consumer (n=6) CV = 3%; medium energy consumer (n=4) CV = 5%; high energy consumer (n=2) CV = 10%. The level of variation within the group is also considerably low, signifying that identifying the sample by the household's variables i.e. grouping using K-Means method is also a good descriptor for the samples energy consumption. The lower energy consumers are clustered around a mean of 6,500kWh/ year, medium energy consumers mean of 9,000kWh/year whereas the high energy consumers a mean of 12,000kWh/ year.

#### **Most appropriate normalisation factor**

Other authors investigating the performance gap in buildings have conventionally used a normalisation factor of delivered energy for every meter squared of heated floor space ( $m^2$ ).

Table 2. CV values for normalisation factors applied to heat energy

	2012	2013	2014	2015	4 year average
kWh	26%	23%	33%	31%	27%
kWh/m <sup>2</sup>	26%	24%	32%	31%	27%
kWh/ppl	35%	33%	38%	35%	34%
kWh/m <sup>3</sup>	25%	23%	31%	27%	25%
kWh/kWh	33%	33%	33%	35%	32%

Results presented in Table 2 show that by normalising the heat energy consumption data by the volume of insulated space (kWh/m<sup>3</sup>) provided the lowest CV for the sample data. Normalising the heat consumption data by floor area (kWh/m<sup>2</sup>) or energy without normalisation provide the next lowest CV. Normalising the heat energy consumption by number of people (ppl) provided the highest CV, perhaps signifying that the weighting of

people on a 1 to 1 ratio is insufficient to account for the complexities of heat consumption behaviour by households with very young and/or elderly occupants. Normalising the heat energy data by the SAP result (kWh/kWh) returned a high CV value meaning it is not the best for this sample (Stinson, 2015).

## Results

### **Longitudinal comparison of energy demand**

The yearly delivered energy was analysed to provide a clearer understanding of how energy was consumed identifying trends linked to occupant behaviour.

The data in Figure 3 shows that the semi-detached houses, flats and semi-detached bungalows decreased their consumption between year 1 and 2 with a small increase in year 3. The mid-terrace house increases in year 2, then decreases in year 3. The mid-terrace houses increase demand in year 4 meeting demand of year 3 and 4. The heat energy demand profile for the flats is of similar magnitude to that of the house mid-terrace. Also, the profile of the bungalow semi-detached is similar to that of the houses semi-detached.

Results from a mixed-design ANOVA tests suggest that the delivered heat energy levels for each year are similar between the 4 archetypes. These showed that the level of heat consumed over the first 4 years of occupation are not statistically different within the 4 archetypes category  $F(9,24) = 0.608 p>.05$ . Investigating this interaction further, contrasts were performed comparing each year of heat energy consumed to year 1 across the 4 archetypes. These showed non-significant ( $p>.05$ ) differences when comparing the archetypes heat energy consumption for year 2 to year 1  $F(3,8) = 0.472$ . Year 3 to year 1  $F(3,8) = 0.265$ . Year 4 to year 1  $F(3,8) = 1.121$ .

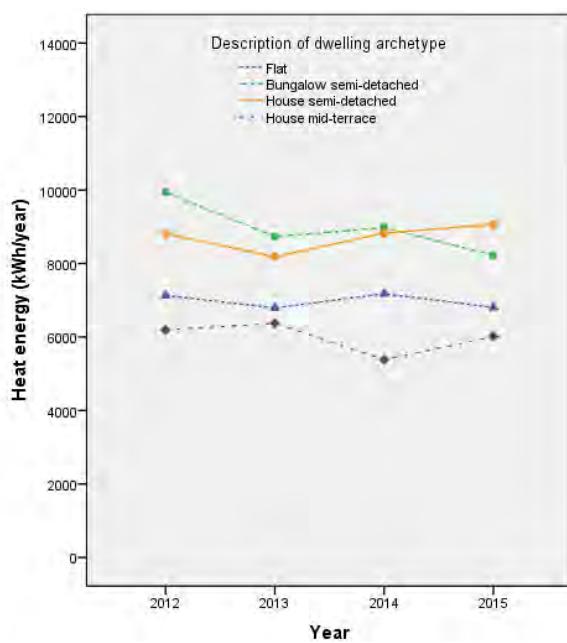

Figure 3. Delivered heat energy by archetype

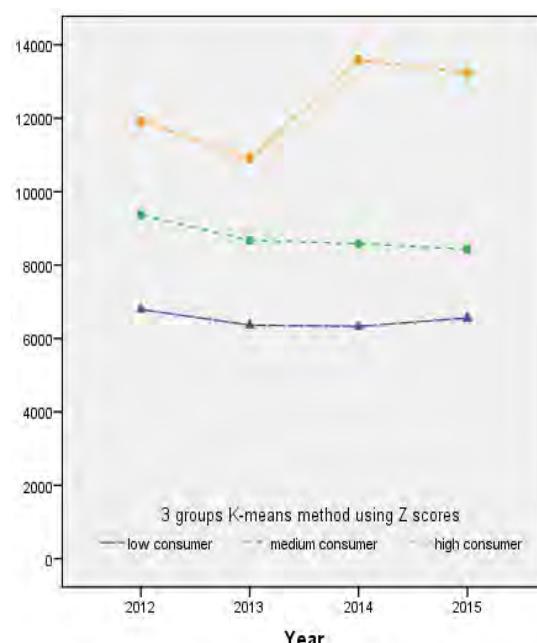

Figure 4. Delivered heat energy between the 3 groups

Figure 4 shows the heat energy demand profiles for each energy level type based on the K-means cluster analysis. The ANOVA results using the heat energy demand as grouped

by the K-means clusters shows that there is a significant ( $p<.05$ ) difference in means over the years and the grouping type,  $F(6,27) = 2.90$ .

Investigating this further, comparing each year of delivered heat energy demand to year 1 across the 3 groups revealed a non-significant ( $p>.05$ ) interaction when comparing the 3 groups delivered heat energy for year 2 to year 1  $F(2,9) = 0.258$ . Year 3 to year 1  $F(2,9) = 3.038$ . Year 4 to year 1  $F(2,9) = 2.255$ . The group of lower and medium heat energy consuming households lowered their heat energy consumption year on year after year 1.

The data presented provides evidence to support the theory that the heat energy demand for year 1 is different from the subsequent years and that yearly heat energy demand data are statistically significant from heat energy consumed in year 1. Dependent paired samples T-test shows the highest consumption was in year 1 ( $M = 8502$ ,  $SE = 634$ ) compared to any of the other of the 3 years (year 2:  $M = 7892$ ,  $SE = 534$ ), (year 3:  $M = 8289$ ,  $SE = 800$ ), (year 4:  $M = 8297$ ,  $se = 752$ ). The difference between year 1 and year 2 delivered heat energy was found to be statistically significant  $t(11)=2.23$ ,  $p<.05$ ,  $r=0.9$ . The differences between other years to the previous year were found not to be statistically significant ( $p>.05$ ).

#### ***Predicted against actual energy demand***

The heat energy factor (HEF) with the sample grouped by archetype is presented in Figure 5 and Figure 6 where the sample is grouped by consumption level. The dashed line indicates a HEF of 0 or the mean SAP score thus less of a performance gap between the groups. The results show that none of the groups align to a HEF of 0 but flats and low energy consumers are the closest. Figure 7 shows all the analysed dwellings delivered heat demand performance is compared against SAP as a percentage above the predicted annual heat energy demand.

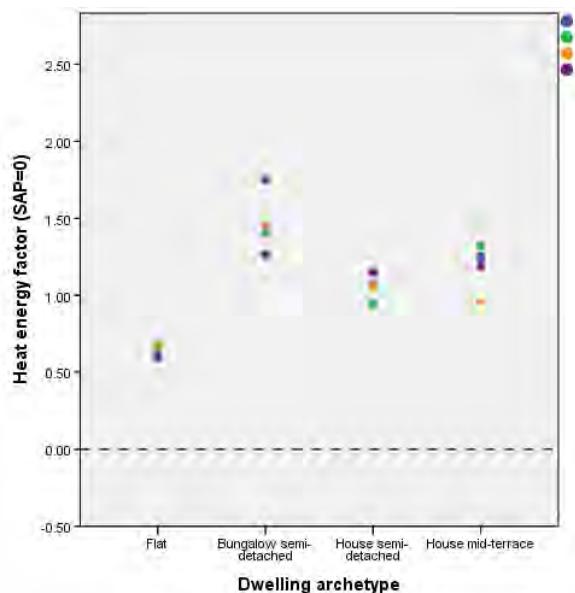

Figure 5. Energy factor by archetype

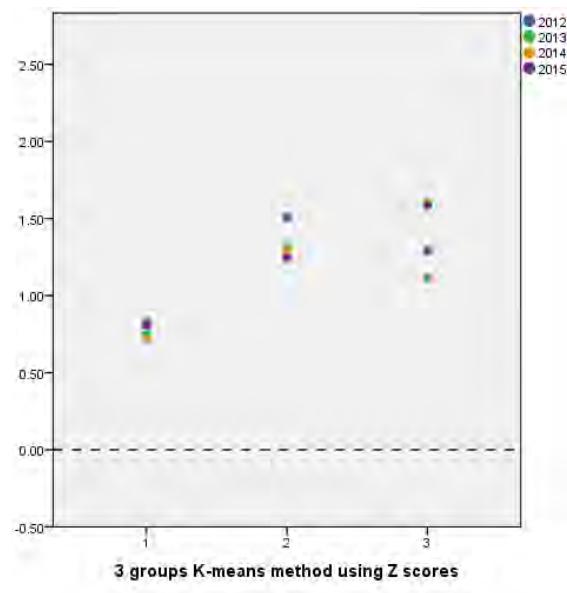

Figure 6. Energy factor by consumption groups

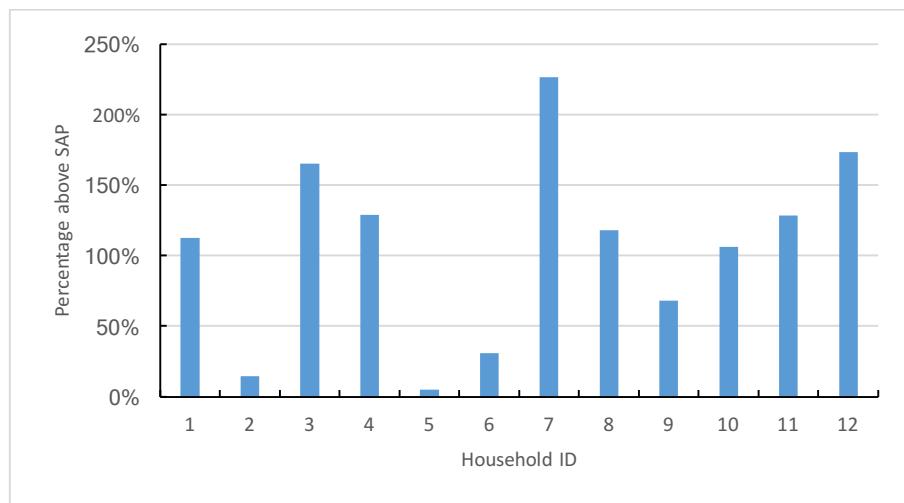

Figure 7. Average of 4 years delivered heat energy compared to SAP

## Conclusion

Using descriptive statistics, this paper investigates the use of conventional and unconventional methods for evidencing the impacts between predicted energy and actual delivered energy of a sample of twelve homes in Dunfermline, Fife.

The conventional use of clustering by archetype has been analysed, as well as proposing a different descriptor of energy demand by grouping low, medium and high energy consumer homes. Both were statistically convenient, however energy groupings evidences the gap in performance clearer over longer periods. In the same way, the normalisation methods used for analysing and benchmarking energy demand. Most will use conventional kWh/m<sup>2</sup>/yr, however this paper uses volume, people and SAP results. Lower confidence of variation (CV) results show that normalising by volume is better than conventional methods.

Finally, results comparing delivered energy over time against the predicted revealed a non-significant ( $p>.05$ ) interaction. This was evident when comparing year 1 against other years, revealing that early occupation years give little evidence of the actual energy consumption with a preference for  $\geq 3$  years of occupation. Furthermore, analysis of the individual household's delivered heat energy showed that the dwelling built with conventional methods and technology, obtained a HEF close to 0 thus performing similarly to the predicted, as shown in Figure 7 as household 5. This observation could lead to concluding that the steady-state compliance tools for predicting energy are better suited to conventional dwellings and possibly not suited to alternative construction types with new technology. It also raises concerns over alternative heating technology, not used suitably by occupants leading to increased energy.

## Sustainable building design in practice – survey among Danish DGNB consultants

Camilla Brunsgaard<sup>1</sup>, Anne Kirkegaard Bejder<sup>1</sup>

<sup>1</sup>Research group for Sustainable Architecture, Department of Architecture, Design and Media Technology, Aalborg University, Denmark, cbru@create.aau.dk

**Abstract:** Sustainability certification schemes experience growing popularity. Denmark got its own sustainability certification scheme based on the German DGNB certification scheme. Previous work based on four case studies – DGNB certified healthcare centres, suggests further research on how to improve and support the iterative design process in the initial design phases. Therefore, the objective of this paper is to investigate the design process on a more common level experienced by Danish DGNB consultants when designing sustainable buildings using the Danish DGNB certification scheme and thereby possibly verify the findings of previous work, on a more general level. To be able to cover a wide variety of projects and levels of experience with the DGNB scheme, a questionnaire is distributed to Danish DGNB consultants. The survey shows that the design teams to a smaller degree use the DGNB consultant along the design process and particularly so in the early design stages. At the same time, it shows that especially LCA, LCC and acoustical comfort are hardly implemented before the final stages of the design, questioning the holistic nature of the design. The study shows a potential in developing methods and tools to support the initial design phases.

**Keywords:** Sustainability certification, DGNB, survey, design process, decision-making.

### Introduction

Sustainability certification schemes experience growing popularity. In 2010, Green Building Council Denmark (GBC-DK) was founded and Denmark got its own sustainability certification scheme based on the German DGNB certification scheme (GBC-DK, 2016). Investigations of the design processes in four case studies – four Danish DGNB certified healthcare centres, show that the architectural design has been taken too far in the initial design phases without analysing and documenting several DGNB criteria (Brunsgaard, 2016). This questions the quality of sustainability in the overall concept, as it creates a “point of no return”, which means it is not possible to prioritise the assessment points in the certifications scheme when needed. Furthermore, it confirms the importance of multidisciplinary collaboration, including the DGNB consultant, from the early design stages. The study suggests further investigations of the decision-making and design process (DMaDP) on a more common level to possibly verify the findings on a more general level. The research presented in this paper builds upon the previous work.

Nevertheless, why is it important to study design processes? In general, knowledge about the DMaDP is important for us to constantly improve our design approaches and become more efficient. A conventional design process is already highly complex as exemplified by Bryan Lawson:

*"As well as letting in daylight and sunlight and allowing for natural ventilation, the window is also usually required to provide a view while retaining privacy. As an interruption in the external wall the window poses problems of structural stability, heat loss and noise transmission, and is thus arguably one of the most complex of building elements"* ((Lawson, 2006) page 59).

As requirements to energy use and indoor environment tighten due to the recast of the EPBD, EU Member States face new tough challenges moving toward new and retrofitted nearly zero-energy buildings by 2018 and 2020 (European commission, 2014), and due the growing demand for sustainability assessment, the complexity of design process is increasing even further. The general perception is that the "traditional design process" cannot facilitate this complex task. In response, design processes with an integrated design approach that can deal with the higher levels of complexity have been developed, with the aim of ensuring quality in the built environment both technically, functionally and aesthetically (Löhnert et al, 2003; Knudstrup, 2004). Some research shows a tendency for more integrated approaches than earlier, however there is still room for improvement, as demonstrated through case studies of the Comfort Houses (Brunsgaard et al, 2014) and the case study of the Healthcare Centres (Brunsgaard, 2016). We need to become better at handling very complex design processes, and it is important to find out how DGNB comes into play in an already highly complex design process.

The objective therefore is to investigate the DMaDP on a more common level, as Danish DGNB consultants/auditors when designing sustainable buildings using the Danish DGNB certification scheme experience it, and thereby possibly verify the findings of previous work regarding DGNB and design process, on a more general level.

## **Method**

This section will firstly describe the setup of the research design and data collection. Secondly, explain the assessment of the DMaDP. The DGNB consultants and auditors will be named DGNB consultants from here, covering both consultant and auditors as for this study it is not important to distinguish between them.

### **Research design**

The DMaDP is investigated through a questionnaire survey among Danish DGNB consultants. A questionnaire survey is a suitable approach for this research, as it is possible to investigate the topic among a large number of respondents and thereby cover a wide variety of projects and levels of experience with the DGNB assessment scheme (Bryman, 2004; Johansen & Friis, 2011). The questionnaire is distributed to 324 Danish DGNB consultants, who are considered a representative sample for this study. However, the size of the sample is too little to generalise, therefore conclusions will be indications or tendencies of the experiences with DMaDP using DGNB certification schemes. The questionnaire is prepared in the software SurveyXact (Rambøll Management Consulting, 2017) and distributed by email containing an invitation to participate in the survey and a brief introduction to the theme and aim of the questionnaire. GBC-DK provided the email addresses, and the consultants have answered the questionnaire online. The respondents are promised anonymity. A reminder was sent to consultants who have not answered to collect more answers. Following topics are covered in the questionnaire: Level of experience with DGNB in general, experience with the DMaDP in relation to stakeholders involved in different phases, documentation process and time consumption. Especially questions regarding the documentation process are important as

they indicate to what extent specific topics are considered, particularly in the early design stages where the main architectural concept is established. Not all criteria from the DGNB assessment scheme are covered in the questionnaire for these reasons: Firstly, to minimise the time consumption for answering the questionnaire. Secondly, to focus on criteria especially linked to the architectural form concept and expression. Those topics are: lifecycle assessment (LCA), lifecycle cost assessment (LCC), energy use, thermal and atmospheric comfort, visual comfort (daylight) and building integrated art. Some questions refer to phases of the design process, which are used when determining periods for documenting the selected topics in the process and when different actors are involved. The five phases are described in Table 1. When answering the questionnaire, the consultants are asked to base their answers on the latest project they have certified, again to minimise the time consumption for filling out the questionnaire.

Table 1. Description of the five phases of the design and construction phase used in the questionnaire

Idea and analysis phase	Concept and sketching phase	Synthesis phase	Project design phase	Construction phase
Analyses are carried out and design parameters are defined, i.e. decisions about the project's scope, functionality, quality, indoor environment, aesthetics, time and finances.	Developing the first ideas and concepts for the project. It will end with a clear concept and the first concrete design solutions.	The project is beginning to find its final form. The design reaches a stage where all design parameters "fall into place", as a whole.	The details in the projects are specified. The outcome will create regulatory approval of the final documents and completion of the building.	The building is constructed.

### **Assessing the DMaDP**

In order to reach high-performance and high-quality design of buildings, the complex design processes are ideally analogous to an integrated design approach. Therefore, the fundament to assess the DMaDP takes its point of departure in approaches to the Integrated Design Process (IDP) – One approach developed by International Energy Agency, Task 23 (Löhnert et al, 2003) and a similar approach developed by Mary-Ann Knudstrup, Aalborg University (Knudstrup, 2004). The key elements of the approaches, which are used when assessing the DMaDP, are iterative process, involvements of actors and documentation of important topics. The involvement of all relevant actors from the beginning of the project bringing in necessary knowledge and competences earlier than in a “traditional design process”, typically engineering knowledge, but also specialist knowledge, and in this case knowledge from the DGNB consultant. Bringing in competences timely allows additional test of constraints in the early design stages, resulting in a holistic concept and minimizing the risk of repair-work later in the design process, which usually has drawbacks for both the economy and quality of the design. Therefore, the questionnaire asks in which phases different actors are involved. By bringing together the different actors earlier, the principle is to evaluate the design continuously in loops of iterations throughout the process regarding technical, functional and aesthetic issues. The evaluation is supported by calculations/ simulations of e.g. energy use and indoor environment throughout the design process. Therefore, the questionnaire asks when selected topics are documented to clarify the level of knowledge on which the decisions are made.

## Results

The response rates of the 324 distributed questionnaires are presented in Table 2. The final response rate is 18%; therefore, the conclusions will be tentative. On the other hand, approximately 40 buildings have been certified in Denmark at the time of writing and adding up the answers regarding the amount of DGNB certified projects the consultants have completed, the numbers match. Therefore, a higher response rate will not change the result significantly, as the remaining consultants must be without experience in completing a DGNB assessment.

Table 2. Fact box of the survey

Size of sample	324
Response rate (completed the questionnaire)	58 (18%)
Response rate (partly completed the questionnaire)	21 (6 %)

### ***Level of Experience with DGNB Projects***

The level of experience is categorised in three groups, as presented in Table 3: The first group has used DGNB assessment and completed one or more certifications; the second group has used DGNB assessment without completing a certification and the third group has no experience with DGNB assessment. This paper will focus on the first group. However, it is interesting to see that the main reasons for not having completed or not having any experience in using DGNB primarily are founded in lack of DGNB assignments. Secondly, it is related to certification cost and documentation workload, which possibly have resulted in the first reason – lack of DGNB assignments. Cost and time resources are tough arguments and can become the decisive argument for the client to deselect a certified sustainable building. Another interesting discovery is that several consultants have experience with more than one project. It might show that by having experience with completing a DGNB assessment once, you are more likely to be hired to do an assessment again.

Table 3. Level of experience with DGNB projects and reasons for not using DGNB certification. The sums will not add up 100%, as respondents can be in both group 1 and 2 and are allowed to give more reasons.

Category of use	Number of respondents	Number of projects	Main reasons for not using/completing DGNB certification
<b>1) Used DGNB and completed a certification</b>	26 (45%)	14 consultants have completed more than one certification	
<b>2) Used DGNB without completing a certification</b>	24 (53%)	24 consultants have used the certification scheme more than once	<ul style="list-style-type: none"><li>- The client did not ask for DGNB certification (56%)</li><li>- Too high certification cost (31%)</li><li>- Certification was dropped (25%)</li><li>- The documentation workload was too high (19%)</li></ul>
<b>3) No experience</b>	13 (22%)		<ul style="list-style-type: none"><li>- Not yet been hired on project as consultant (54%)</li><li>- Educated consultant for other purposes than certification e.g. teaching or research (31%)</li></ul>

### ***Involvement of Actors***

The following results are based on answers from respondents in group 1. As described earlier, involving relevant stakeholders from the beginning of the project allows competences to be integrated earlier than in a conventional process. The respondents were asked to answer to

what extent each actor was involved in each phase of the design process; the outcome is shown in Table 4. Not surprisingly, the architect is highly involved throughout the whole design process, whereas the constructing architect and the contractor are mostly involved in the project design phase. The engineer has been involved in all phases parallel to the architect, only with a reduced amount of involvement. It indicates that the engineer has been involved to some extent in the early design stages, contributing with engineering competences in the decision-making – interpreted to be more than in a “traditional design process”. What should be noted is how little the DGNB consultant is involved especially in the early concept/sketching phase, where the main form concept is found and in the synthesis phase, where the project finds its final form. In those two phases, the design team will make decisions that will limit “space of solutions” for the next design phase and reach “points of no return” after which the possibility to prioritize the assessment criteria linked to the architectural form is limited. Leaving out the DGNB consultant in the early design phases requires that the rest of the design team has been well informed by the consultant, concerning where to go with the design. It is questionable if the projects have been tested well enough against DGNB requirements in the early design stages. This study cannot tell if the lesser involvement of the DGNB consultant in the early design phases has resulted in repair-work later in the design process, or if it had drawbacks for the economy and quality of the design, however that could be the outcome risk. Another interesting finding is how relatively much the DGNB consultants have been involved in the project design phase, where the building design is fixed. It may well reveal that the assessment primarily is done as a documenting step and not as an informing step in the design process.

### ***Documentation process***

The decision-making is ideally supported by evaluation and/or documentation of key topics of the assessment scheme to estimate whether the design is moving in the right direction or not. Table 5 shows how the respondents estimate the documentation of the different topics in the different phases; they can select more phases to each topic. The greener, the earlier the topic has been evaluated. LCA and LCC are only to a little extent documented in the early phases, instead more than 35% answer that LCA and LCC are documented in the construction phase, where the whole design is completed. Equally, approximately 35% also answer that LCA and LCC are documented in the project design phase, where the design is more or less fixed, however, a few elements like materials are still possible to change. This means that the concept is not fully holistic in its nature and potentials for optimisation concerning both points in DGNB assessment and the architectural qualities can be missed. Choice of materials is highly linked with the architectural qualities as regards aesthetics and perception, but also linked with the building's physical performance. Topics like energy use, thermal comfort and daylight are well documented in all phases, with a little overweight in the project design phase. Especially energy use has increasingly become a common part of the design process, as the building regulations regarding energy use have been continuously tightened every fifth year in Denmark and will be again in 2020. Compared to studies of design processes in a Danish context done a few years ago (Brunsgaard et al, 2014), the thermal comfort in these cases has been documented quite well in the earlier design stages, showing that the awareness and importance of thermal comfort has matured in the building industry. Additionally, the indoor environmental requirements have recently (July 2016) been included in the current building regulations, which means the design team now must document the indoor environment to get building permission.

Table 4. Level of involvement of each actor in each phase. The colours in the pie chart equal level of involvement and the size of the slice equals percentage of responses.

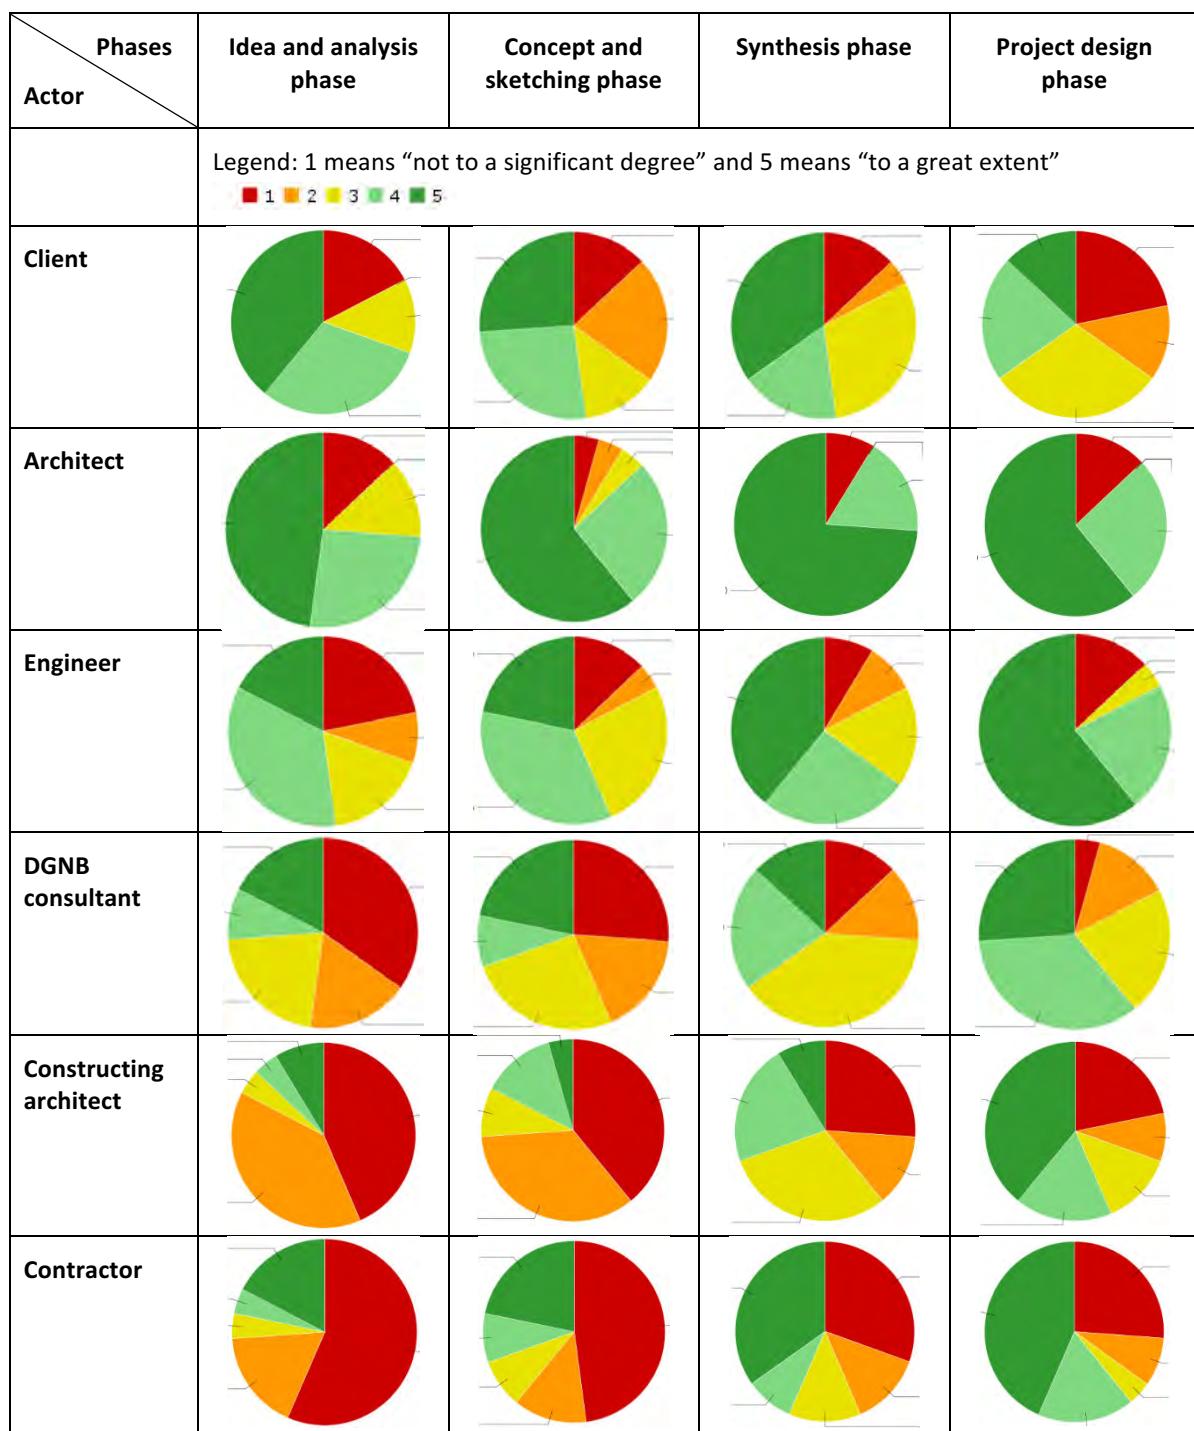

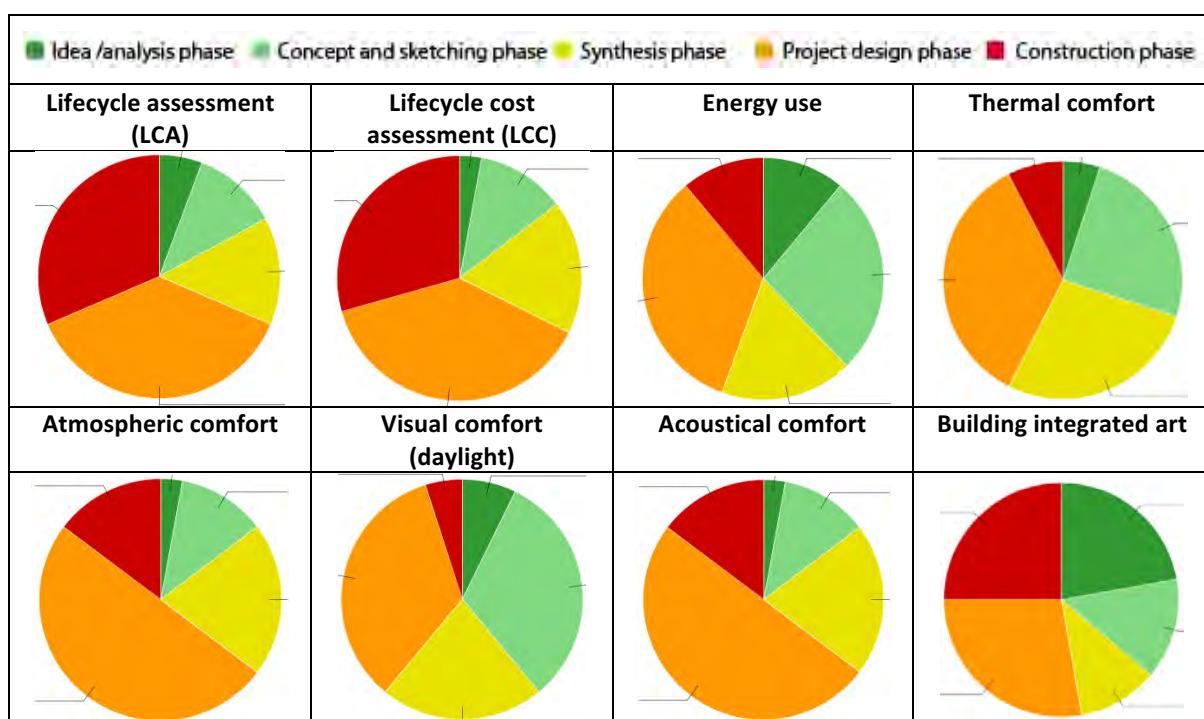

Table 5. Documentation of topics in the different phases. The colours in the pie chart equal the phases and the size of the slice show how much the topic has been documented.

To support the above findings, the consultants were asked to answer which of the topics they found the hardest and easiest to implement in the concept and sketching phase. The top three most difficult topics in prioritised order are LCA, LCC and acoustical comfort, whereas the easiest to implement are energy use, visual and thermal comfort. These answers also fit with Table 5. Concerning time consumption, 12 out of 14 consultants answer that they use "more" or "significantly more" time in a DGNB project compared to a similar project not assessed by DGNB.

#### ***Consultants' suggestions for improvement opportunities***

Nine consultants wrote suggestions to improve the DMaDP. Six of them would like to simplify the process especially in relation to LCA and to some extent LCC. Some suggested light versions of LCA and LCC tools and others suggest implementation in BIM. Another comment was that DGNB assessment is best suited for documenting the final project and difficult to handle in the initial phases informing the design process.

#### **Discussion**

Even though the DGNB consultants are considered a representative sample for this study, an inclusion of other actors of the design process, like the architect and the engineer, might have changed the outcome of the result as they could have experienced the process differently. Because the DGNB consultant evaluates his/her involvement as fairly minor in the initial phases, it is questionable if he/she can answer to what level the different actors have been involved and when different topics have been documented. Some processes might have been running between the architect and engineer without the DGNB consultant's awareness. However, it is expected that the consultants have the overview of the different criteria in the assessment scheme. They are asked to answer according to recent projects they have certified, however that limits the amount of processes covered by the questionnaire. To

compensate, they are asked whether the project represents previous process(es) or not. Their responses are equally on each side of neutral.

## Conclusion

The survey shows that to a smaller degree, the design team uses the DGNB consultant along the design process and particularly so in the early design stages. At the same time, it shows that especially LCA, LCC, acoustical and atmospheric comfort are not very implemented before the final stages of the design. This means that the concept is not fully holistic in its nature, and potentials for optimisation both regards to points in DGNB assessment and the architectural qualities can be missed. Furthermore, the consultants find those topics hard to implement in the early design stages. The study shows a potential in developing methodologies and tools to support the initial design phases securing an iterative DMaDP based on a sufficient level of knowledge, covering topics relevant to the architectural design, or at least the topics hardest to implement.

This study will be further developed as 13 respondents volunteered to be contacted afterwards for a telephone interview. It will allow the findings to be further unfolded and explained e.g. has there been any repair work to the design in later stages and why. Additionally, it would give more answers to what kind of support the design teams would like to have to improve or develop the DMaDP, in the initial stages.

## Green School Design – Key Strategies in Tropical Developing Regions

Chunya Cai

Faculty of Creative Arts and Industries, University of Auckland, Auckland, New Zealand,  
chunyacai@gmail.com;

**Abstract:** The green school movement has been developed in Western countries, such as America, England, and Australia, for decades. “whole-school sustainability” has been defined and developed as a core value and solid foundation of the green school design framework worldwide. In tropical developing regions, scarce resources and limited budget become barriers to promoting green schools and education of sustainability. Even so, there are pioneer green schools from these regions which apply technologies with low costs and simple maintenance to achieve whole-school sustainability in rural areas. These pioneer schools had awarded from international green school programs for their significant efforts. In those reward programs, schools are measured by the criteria set for developed countries. However, the contributions of these pioneer green schools go beyond the framework of the measurement. This paper introduces two green school pioneers from these regions, based on the requirements of the LEED V4 for Schools rating system, which has been used as the worldwide measurement in the award program “The Greenest School on Earth.” Beyond the basic requirements, these two schools provide solutions for environmental problems, such as water scarcity, disposing of human excreta, and waste treatment. These additional solutions represent how a green school can solve essential problems in these regions, and, most importantly, how they turn these solutions into teaching tools, to enhance environmental awareness for students, teachers, and communities. This review of the key design strategies of green schools demonstrates the most feasible solutions for tropical arid climates, to encourage authorities and educators to convert their teaching environments into green campuses.

**Keywords:** Green School, Key Design Strategies, Tropical Developing Regions

### Introduction

According to State of the Tropics (2012), by 2050, more than half of the world population will live in tropical regions, with 67% of children under 15 years old. Most tropical countries are developing countries, and will remain the same in the 21st century. Furthermore, tropical regions will play a vital role in sustainable development due to their rapidly growing economies and population (State of the Tropics, 2012). From “A World at School,” there are crucial barriers to education in developing regions, apart from critical issues of society, culture, and finance (Watt, 2014), “Lack of school buildings,” “travel distance from home,” and “poor sanitation facilities” are crucial issues in this situation (Global Citizen, 2014; Watt, 2014). In these regions, school facilities become critical and a priority for education development.

The green school movement has been developing globally over the past 40 years, since environment education (EE) was defined by UNESCO (The United Nations Educational, Scientific and Cultural Organization) in 1977 (UNESCO, 1978). However, in tropical developing regions, the green school movement is far less developed than in Western countries, despite the significant achievements of pioneer green schools from these regions, both in sustainable learning environments and education for sustainability, as well as their connection with local

communities. Two schools in this research have received a “The Greenest School on Earth” award. In this international awarding program, schools from all over the world are measured under the same criteria: LEED (Leadership in Energy and Environmental Design) V4 for Schools.

Whole-school sustainability of green schools has been highlighted by Rachel Gutter, director of the Centre for Green Schools (CGS), authority on the Greenest School on Earth program. Whole-school sustainability engages students in every aspect of sustainability, from their learning of knowledge and behaviour in daily life, through practicing in the school environment, the most important thing is to cultivate students to be global green leaders in improving the environment (Peterson, 2015). The definition of green schools follows the themes and criteria of LEED V4 for schools. Themes include: location and transportation, sustainable site, water efficiency, energy and atmosphere, materials and resources, indoor environment quality, innovation in design, and regional priority. Five major themes make up 75% of the credit in this rating system (Table 1). Each of these five themes has always required items which become the baseline for certification as a green school (LEED V4, 2016)

Table 1: Five Major Themes Basic Requirements from LEED, Data from (LEED V4, 2016)

Themes	Always Required Items
Sustainable Site	• Construction activity pollution prevention; • Environmental site assessment
Water Efficiency	• Water use reduction; • Indoor Water use reduction; • Building-level water metering
Energy and Atmosphere	• Fundamental commissioning and verification; • Minimum energy performance • Building-level Energy metering; • Fundamental refrigerant management
Materials and Resources	• Storage and collection of recyclables; • Construction and demolition waste management planning
Indoor Environment	• Minimum indoor air quality performance; • Environmental tobacco smoke control • Minimum acoustical performance

## Methodology

In this research, design strategies of two pioneer schools from tropical developing regions will be presented in five major themes from LEED V4 for Schools within the “always required” content. The rating system from LEED presents basic requirements for green schools worldwide, it also represents the most up-to-date design strategies in the Greenest School on Earth program. This research will illustrate the achievements of two green schools, and discover their effective and feasible solutions beyond LEED basic requirements.

## Cade Study

Two green schools from Asia and South Africa have received the Greenest School on Earth awards. Bali Green School was the winner in 2012, while Vele Secondary School received an honourable mention in 2014 (CGS, 2012; Cowan, 2015).

Table 2 Brief Introduction of Bali Green School and Vele Secondary School

	Bali Green School (2008 built)	Vele Secondary School (2011 built)
Location	 Figure 1: Bali Green School in Tropics' Map	 Figure 2: Vele School in Tropics' Map

<p><b>Figure 3: Climate Data of Bali-Tropical</b></p>	<p><b>Figure 4: Climate Data of Mavhuwa-Subtropical</b></p>
<p><b>Figure 5: Wind Rose of Bali</b></p>	Wind is from SSE to NNW, Stable direction at 157.50°
<p><b>Figure 6: Wind Rose of Marhuwa</b></p>	Wind is from SE to NW, Stable wind direction between 112.5° - 135°
Student Classroom Site Area Cost	400 Students 10 buildings for separated classrooms 103,142.63 m² / Building Area: 7,542 m² \$3,116,318 US in total \$375 US Per sqm
460 Students 17 classrooms in 3 buildings 51,344.16 m² / Building Area: 3,700 m² \$725,000 US in total, \$200 US Per sqm, facilities are partly donated	

Data from (Creating Schools, 2017; Meteoblue, n.d.a; Meteoblue, n.d.b; Shim, 2010)

These schools represent up-to-date strategies for green schools in tropical developing rural areas. They were chosen also because both campuses include classroom buildings, a library, sports fields, and a range of student ages, which will demonstrate more solutions.

### Sustainable Site – Construction and Eco-system protection

- Construction activity pollution prevention; • Environmental site assessment

Sustainable site requirements are related to construction activity pollution and assessment of site contamination. In both schools, the requirements are easily to achieve with the use of local materials and traditional building skills. With the contribution of school plantation gardens and green spaces, the campuses are able to avoid site contamination, both in the construction process and operation. (Table 3; Table 6)

### School Food Plantation and Gardens

In Bali Green School, school gardens are located separately and become connections between different buildings. There is a cocoa plantation, organic gardens, a medicinal garden, and peace garden; combined with green paths, the campus is filled with green learning spaces (Shim, 2010, p. 5). In Vele School, the food plantation uses rainwater for irrigation and provides organic food for the school kitchen. This effort produces a secure supply of healthy food, and plays an educational role in the organic plantation. The other achievement at Vele School is the green roof which covers walkways and part of the building's roof; this green belt provides shade for outdoor with local indigenous flora. (Table 3) (Creating Schools, 2017)

### Sanitation and Waste Treatment

The eco-toilets at Bali Green School apply a predominantly aerobic process to treat human and animal excreta. The compost station, where biomass, kitchen waste, and cow manure are collected and composted, creates organic fertilizer for the gardens and plantations. This green nitrogen mix is combined with brown carbon layers composed of wood chips, brown leaves, food scraps, and manure (Shim, 2010). In Vele School, bathrooms are surrounded by the plantation, covered with a green roof, and located in the centre of campus. The toilet uses a

waterless and on-site dry sanitation system called “Enviroloo.” The waste from the dry toilet goes to septic tanks and produces bio-gas for cooking (Creating Schools, 2012).

Food plantations and waste treatment systems in both schools act as green yards, organic food suppliers, and learning spaces for demonstrating botany, biology and cultivation knowledge. Sanitation systems use biotech approaches to transform waste into useful resources and minimize the risk of pollution. Both of their design strategies are not included in the requirements of land protection from the LEED system; however, they all play vital roles in protecting the local eco-system and community habitat.

### **Water Efficiency**

- Water use reduction; • Indoor Water use reduction; • Building-level water metering

In the LEED system, water-use reduction and metering are prior requirements for green school certification. In both schools, water-use reduction is a priority on campus. Basic metering systems have been used to monitor the use of water. Due to the scarce rainfall during the dry season in these regions, water resources are critical; however, rainwater collection and waste-water recycling are not included in the LEED system. The use of rainwater and used water could play a vital role in solving water scarcity problems.

Table 4: Water Resource and Consumption, Data from (Shim, 2010; Yong, 2010; Creating Schools, 2017)

	Bali Green School			Vele Secondary School		
Water Resources	60-meter well	River and well	River	Rainwater		Underground water
Collection	Solar energy pump from well	Pump	Pump	From classroom blocks, ground surfaces, roof, solar energy pump	From school hall roof	Solar energy pump from underground
Storage	No Storage	No Storage	No Storage	Store in 100,000-litre tanks, pump to 20,000 litre header tanks	30,000-litre tanks	10,000-litre elevated tanks
Use areas	Drinking Water	Non-potable Water	Fire hose	Irrigating food gardens	Irrigating sports field	Kitchen, drinking, and wash basins

Metering	RO filtering / metering	No	No	Yes	Yes	Yes
Water Recycle	Waste water from kitchen and bathroom are used for garden watering.			Water flows from kitchen, waterless taps, and toilet will be collected in septic tanks and be digested into bio-gas, slush will be sent into earth via French drain.		

In Bali Green School, drinking water comes from a 60-metre deep well, water for other uses is pumped from the river. Grey water is simply collected from the kitchen or bathroom and reused to water gardens. There is no evidence that a water management system has been used to control the use of water and wastewater treatments. (Yong, 2010; Shim, 2010)

The low-cost and simple maintenance rainwater management system is the most significant effort at Vele School. Except for drinking water, which is pumped from underground, all water is supplied by rainwater. Vele School has an effective rainwater harvesting and storage system. It reduces water use and recycles grey water to achieve water efficiency via its irrigation system, waterless toilet, and water-saving taps, etc. (Creating Schools, 2017)

### ***Energy and Atmosphere***

- Fundamental commissioning and verification;
- Minimum energy performance
- Building-level Energy metering;
- Fundamental refrigerant management

Due to the local climate conditions and low passive-design strategies in both campuses, no cooling or heating system has been used in either school, so refrigerant-related issues have been avoided. Energy performance has been set as a priority on both campuses. Solar panels are the main power resource, and basic metering systems are used to monitor the energy performance on both campuses. (Table 5)

Bali Green School installed a solar PV system on 2011. This system comprises 108 solar panels which have been mounted on bamboo structures for a flexible installation. A 72kWh capacity battery bank and inverter store all energy generated from solar. This system provides 21 kWp for school use (Akuo Foundation, 2013). The campus locates in riverside, and a micro-hydro vortex was built in earlier years; in 2016, it provides approximately 6 kWh. Bali Green School has become energy self-sufficient from these efforts (Green School, n.d.)

In Vele School, energy resources come from two sources: the public power grid and solar power. The solar panel installation also includes a metering system for monitoring energy consumption. However, only computers and the water pump use the power from solar energy, other electrical operations still rely on the public power grid. (Creating Schools, 2017)

Table 5 Energy Resource and Consumption, Data from (Akuo Foundation, 2013; PJCarew Consulting, 2011)

	Energy Resource	Quantity	Capacity	Use in Facilities	Monitor& Metering	Self-sufficient
Bali Green School	Solar PV	108 Panels	21 kWp	All electrical facilities in campus	Yes	Yes
	Hydro Vortex	1	6 kW			
Vele Secondary School	Solar PV	50 m <sup>2</sup>	6.4 kWp	100 Computers & Water Pumping	Yes	No (< 50%)
	Eskom public grid			Lighting / electrical		

### ***Materials and Resources***

- Storage and collection of recyclables;
- Construction and demolition waste management planning

The basic requirements of LEED emphasise the use of recyclable and waste materials, especially in storage and management. But the use of local and renewable materials which are inspired by local traditional building skills are the most significant effort on both campuses, although they are not included in the basic requirements.

In Bali School, bamboo, as a recyclable building material, has been used for structures, flooring, furniture, and most facilities; even the sawdust of bamboo has been used to boil hot water and for cooking in the kitchen. Proper treatment will enhance bamboo's resistance to humidity, insects, and mould. The life-cycle of bamboo in building is 20 years, and it only takes 4-5 years to grow to a suitable size for construction. Using traditional Balinese building skills, the roof consists of thatch, using coconut or palm tree leaves, alang alang grass, and rice straw. The ground floor uses local mud mixed with 15% cement for flooring (Shim, 2010).

In Vele School, old school buildings are retained and restored, materials were given back to the community to use. New buildings use a combination of construction with local materials such as kiln-fired clay bricks, wood, light steel, concrete, and local stone. Reduction of waste in material use has become a management priority on site. Any possible materials for construction have been specified and resulting into site works like flooring filling and retaining structure in this project. (Lafargeholcim Foundation, 2013)

Vele Secondary School (Photos copyright permitted by Architect Steve Kinsler - Creating Schools)

### **Indoor Environment**

- Minimum indoor air quality performance; • Environmental tobacco smoke control
- Minimum acoustical performance

Air quality performance is measured via the ventilation rate; in these two green schools, natural ventilation can be ensured by the semi-outdoor classroom and building orientation with openings (Figure 21; Figure 22). Bali School has a unique solution to managing acoustic performance, with the semi-outdoor classroom which has individual spaces surrounded by plants and trees which provide natural layers of insulation. In Vele School, kiln-fired clay bricks formed medium weight wall which provide effective layer of acoustic insulation.

Low passive design in both campuses has benefits beyond these requirements. In Bali School, classrooms have different shapes, skylight forms built with bamboo and canvas bring indirect light which reduces heat and glare (IBUKU, 2012). The classroom with no walls design has become a semi-outdoor space which brings fresh air for natural ventilation. In Vele School, natural light comes from north-facing windows, with a small roof overhang to reduce the heat. The chalkboard is installed on the south wall, and sunlight comes from behind the seats which reduces cross shadows on the desks. Windows and doors, open to the south corridor, also bring skylight from the corridor's metal roof (Creating Schools, 2012, p. 14)

Table 7: Typical Classroom Measurement Comparison, Data from (IBUKU, 2012; Creating Schools, 2012)

Themes	Bali Green School Classrooms	Vele Secondary School Classrooms
Shape	Ellipse floor, "turtle-shell" roof	Square with wooden roof frame
Dimensions	$\approx 18\text{m} \times 10\text{m} \times (\text{H } 4.5\text{m} \sim 7.5\text{m})$	$\approx 7\text{m} \times 7\text{m} \times (\text{H } 3.0\text{m} \sim 4.5\text{m})$
Shading	$\approx 3.5\text{m}$ (Overhanging roof)	$<0.5\text{m}$ (Shading device)
Orientation	optimal north facing	optimal north facing
Ventilation	Semi-Outdoor design brings natural ventilation, wind is from Southern South-East to Northern North-West	Windows on north and doors on south corridor provide natural ventilation, wind is from South East to North West.
Light	Canvas on roof ridge provide skylight	Indirect sunlight from shading device; skylight from metal roof.
Insulation	No	Roof Insulation

Figure 22: Classroom Section Diagram

### Discussion and Finding

Both schools have significant achievements in the five major themes of the LEED V4 for Schools rating system. With costs of construction around \$200 USD to \$375 USD per m<sup>2</sup> (Table 2), these two pioneer schools have proven their ability to achieve high performance in sustainable land, water efficiency, energy, application of local building materials, and indoor environment, which are the basic requirements of the LEED V4 for Schools rating system.

Beyond the framework of this rating system, the rainwater collection and waste water recycling system at Vele School demonstrates the most feasible water solutions for tropical arid regions. This water system has become a model for educating students and communities about water conservation in areas of water scarcity. School gardens and food plantations are more than green spaces in protection campus environment, these spaces also provide organic-plantation learning spaces. Eco-toilet systems in both campuses represent achievable solutions for sanitation problems. Moreover, these design strategies are used as educative tools, while, at the same time, making significant improvements to the school environment.

### Conclusion

From this review, pioneer green schools in tropical developing regions demonstrate a low-tech and low-cost model for achieving green school certification. Beyond the requirements, the two schools provide solutions in dealing with local resources, which make a vital contribution in local sustainability.

Design strategies summarised from these pioneer schools demonstrate the most achievable approaches in these regions; the rating system should be upgraded according to the practices to be a design guide for new schools in these regions.

## The near Zero Energy Building standard and the Passivhaus standard – a case study

Shane Colclough<sup>1#</sup>, Tomas O'Leary<sup>2</sup>, Neil Hewitt<sup>1</sup>, Philip Griffiths<sup>1</sup>

<sup>1</sup> Centre For Sustainable Technologies, Ulster University, Newtownabbey, Co Antrim, BT370QB, UK. <sup>#</sup> Correspondence email address - s.colclough@ulster.ac.uk

<sup>2</sup> MosArt, Wicklow County Campus, Clermont House, Rathnew, Co. Wicklow, A67 X566, Ireland.

**Abstract:** The EU has mandated that all buildings are built to the near Zero Energy Buildings (nZEB) standard from 2020. The Passivhaus standard has been in existence for over 25 years and potentially offers a tried and tested method of achieving nZEB. This paper explores if there is a performance gap between the PH standard and the nZEB standard. Further, analysis is carried out based on monitoring results from a real building: a 103m<sup>2</sup> three bedroom dwelling located in Ireland. The comparison of the two standards is carried out with particular focus on the assumed and recorded indoor temperature assumptions and heating periods for both standards. The analysis looks at the actual indoor climate experienced, based on the following recorded metrics which are being gathered at five-minute intervals: a) occupancy profile; b) indoor air temperature; c) indoor relative humidity; d) indoor carbon dioxide concentrations; e) outdoor temperature; f) outdoor relative humidity; g) wind speed; h) barometric pressure; i) energy consumption. Based on the above metrics a discussion takes place on the energy and IEQ performance in the context of the performance mandated by the respective standards in the quest to deliver Passive and Low Energy Architecture.

**Keywords:** Passivhaus, nZEB, Monitoring, IAQ

### Introduction

Given the planned 2020 implementation of the near Zero Energy Building (nZEB) standard in the Republic of Ireland, a comparison with the well-established Passive House (PH) standard is timely. While a number of publications have been written to investigate the potential for the Passive House standard in the Irish climate (e.g. Colclough, 2011; Clarke et al, 2012) and a number have considered net zero energy buildings, (Hernandez and Kenny, 2010, Goggins et al, 2016), none have compared the PH with the newly defined nZEB standard for the Republic of Ireland.

To comply with the Passive House standard, dwellings must consume less than 120 kWh/m<sup>2</sup>/a of primary energy, as determined by the Passive House planning package (PHPP). The nZEB standard in Ireland (to be finalised in 2019) requires that dwellings must consume less than 45 kWh/m<sup>2</sup>/a (anon, 2012), see figure 1. It therefore appears that the nZEB standard is more stringent than the Passive House standard. However, this is not a like-for-like comparison. This paper answers the question of whether a performance gap exists by comparing the derived figures for a case study of a building which has been built to the Passive House standard. In addition, initial monitoring results are presented to determine if the

dwelling is complying with the assumptions inherent in the Passive House standard and Irish building regulations.

#### Typical performance standards for nZEB for dwellings

Low Energy <sup>6</sup> Dwelling with Solar Thermal DWH	
Primary Energy (kWh/m <sup>2</sup> /yr)	45
CO <sub>2</sub> Emissions (Kg/m <sup>2</sup> /yr)	10
EPC	.302
CPC	.305

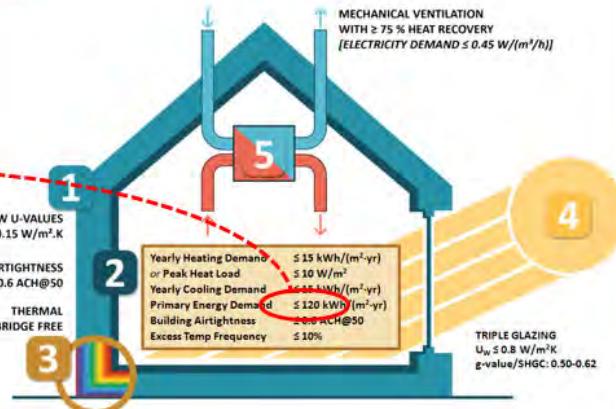

Figure 1. Comparison of nZEB and PHPP primary

#### Comparison of standards

To compare both standards correctly consideration needs to be given to the basis of the comparison, in particular with respect to the energy consumption calculations. Recognising that the calculations will vary depending on the dwelling specifics, this case study examines a house which has been designed to comply with the Passive House standard, and has been constructed by building firm Bennetts in Enniscorthy, Co Wexford, Ireland.

The house is a certified Passive House of 103 m<sup>2</sup> and is occupied by one person. It utilises an integrated HRV system which addresses the space heating and domestic hot water requirements of the dwelling, with electricity as the fuel. In addition to heating the air via a heat pump, the unit also controls two 400W electric heating elements located in the sitting room and hall.

The DEAP (Dwelling Energy Assessment Procedure) is the software used to calculate the Building Energy Rating (BER) for dwellings in Ireland and ensure compliance with the nZEB standard. The DEAP calculations were carried out on the case study dwelling, and are presented in figure 2, in addition to the calculations carried out in the Passive House Planning Package (PHPP), the software used to ensure compliance with the Passive House standard. Two figures are presented for the PHPP - "Normal PHPP", and with the PHPP modified to perform calculations on the same basis as the DEAP software ("DEAP PHPP"). Details are provided in the next section on the calculation methodology.

As can be seen, the building is compliant with the nZEB performance standards as calculated by the DEAP software, with respect to primary energy consumption, carbon dioxide emissions, Energy Performance Coefficient (EPC) and Carbon Performance Coefficient (CPC) requirements and is therefore an nZEB standard compliant dwelling.

In addition, the PHPP calculations show that the dwelling is in compliance with the Passive House standard with respect to primary energy consumption, as it consumes 91 kWh/m<sup>2</sup>/a, within the Passive House standard limit of 120 kWh/m<sup>2</sup>/a.

The case study shows that the house designed to comply with the Passive House standard, meets the nZEB requirements. However, a clear discrepancy exists between the primary energy consumption and carbon dioxide emission figures using the two methodologies. In the analysis below a comparison is made based on the specifics of the

dwelling under consideration. The analysis highlights the inherent differences in the two apparently similar primary energy consumption figures.

Table 1: Typical performance standards for NZEB for dwellings

	Low Energy <sup>6</sup> Dwelling with Solar Thermal DWH	DEAP	Normal PHPP	'DEAP' PHPP
Primary Energy (kWh/m <sup>2</sup> /yr)	45	24.37 ✓	91.1 ✗	31.2 ✓
CO <sub>2</sub> Emissions (Kg/m <sup>2</sup> /yr)	10	5.26 ✓	18.6 ✗	6.31 ✓
EPC	.302	0.159 ✓	N/R	N/R
CPC	.305	0.165 ✓	N/R	N/R

- 'DEAP' PHPP adjusted to omit plug loads, include PV production and reduce Primary Energy factor for electricity from 2.6 to 2.19
- Bennett Passive House Already NZEB

Figure 2. Comparison of nZEB calculations using DEAP, PHPP and PHPP adjusted for DEAP requirements.

#### ***Comparison of PHPP and DEAP derived specific energy consumption***

The Passive House standard calculates the primary energy required to meet all the energy needs of the dwelling (PHI, 2016) whereas the DEAP methodology bases its calculation on the building services energy load for space heating, water heating, fixed lighting and ventilation (Anon, 2012). Therefore electricity required for cooking, washing machines, clothes dryers, lighting, TV and entertainment equipment, Home Office equipment and all other plug loads are not considered. In addition, given the focus on reducing DHW and heating energy consumption in low energy dwellings to be implemented via the nZEB standard, and the significant growth in consumer electronics and electrical devices, while current building services loads in Ireland are estimated to be 50% (Anon 2015), the proportion of energy spent on building services is forecast to reduce further.

Both PHPP and the DEAP software use a primary energy conversion factor to convert the calculated energy consumed in the dwelling to the energy content of the fuel used to produce electricity in the generation stations. The PHPP calculation assumes a primary energy conversion factor of 2.6, whereas the DEAP software assumes 2.19.

When the services not included in the DEAP methodology are removed from the PHPP, and the primary enrgy conversion factor set to the DEAP version of 2.19, the PHPP primary energy demand reduces by almost 50% i.e. from 91 to 49 kWh/m<sup>2</sup>/a and when the PV contribution is subtracted, this figure drops to 31.2 kWh/m<sup>2</sup>/a.

Table 1 shows other differences in the DEAP and PHPP methodologies used. Of particular note is the floor area calculation. The PHPP works on the basis of the Treated Floor Area, TFA (PHI, 2014), which excludes areas included in the assumed DEAP calculation methodology such as the floor area associated with stairs, internal walls etc. The difference between the TFA and the DEAP floor area varies based on the geometry of the individual dwelling. In the case of the house under consideration the PHPP underestimates the house size by 10%, therefore over estimating the specific energy consumption.

Table 1. Basis of calculation methodologies for DEAP and PHPP.

	<b>DEAP Model</b>	<b>PHPP Model</b>
<b>Basis for model</b>	Benchmark house	Bespoke model for each design
<b>Validation of performance</b>	Unpublished	Scientifically validated
<b>Floor area calculation</b>	Gross	Net ("Treated Floor Area") (excludes internal walls and stairs)
<b>Heating duration</b>	8 hours per day	24 hours per day
<b>Winter Interior Temperature</b>	~ 18.5°C Average based on typical Irish dwelling layouts for 8 hrs per day	20°C throughout
<b>Summer Interior Temperature</b>	Overheating not predicted	25°C Max for 10% of year
<b>Radiant Temperature Asymmetry</b>	Not considered	Avoided
<b>Unintended air infiltration</b>	< 7 m³/m²/hr @ 50Pa	< 0.6 ach⁻¹ @ 50Pa
<b>Ventilation rate</b>	Not required	15m³ fresh air per person per hour

If the average temperature is reduced from the PHPP normal temperature of 20°C to the DEAP equivalent temperature for the reference dwelling of 18.5°C, the PHPP figure drops to 24 kWh/m<sup>2</sup>/a and when the floor area is adjusted to the DEAP assumed figure, the PHPP derived specific primary energy consumption figure drops to 19 kWh/m<sup>2</sup>/a.

Therefore without taking into consideration that the heating period in a Passive House is 24 hour compared with the DEAP assumption of 8 hours per day, the PHPP adjusted consumption figure is 19 kWh/m<sup>2</sup>/a where the DEAP software assumes 24.4 kWh/m<sup>2</sup>/a.

## Recorded Performance

The house has been monitored since August 2016.

### ***Temperature and carbon dioxide***

Figure 3 gives the temperature charts for the three month period October, November, December 2016 for the kitchen, living room and bedroom. In addition to providing an insight into the thermal comfort of the dwelling, the analysis allows a comparison of monitored internal temperatures, against those predicted by the Passive House Planning Package software and the DEAP software.

It is noted that the monitoring units deployed in the dwellings are commercially available units which are not of laboratory grade. While the units have been found to be calibrated correctly with respect to temperature, some units have been found to be outside the specified limits for relative humidity and carbon dioxide concentration. Thus, readings outside the threshold levels indicate that further investigation may be warranted.

Passive Houses are designed to have a uniform temperature of 20°C throughout. A temperature threshold has therefore been set at 20°C to aid analysis of the performance against the Passive House standard.

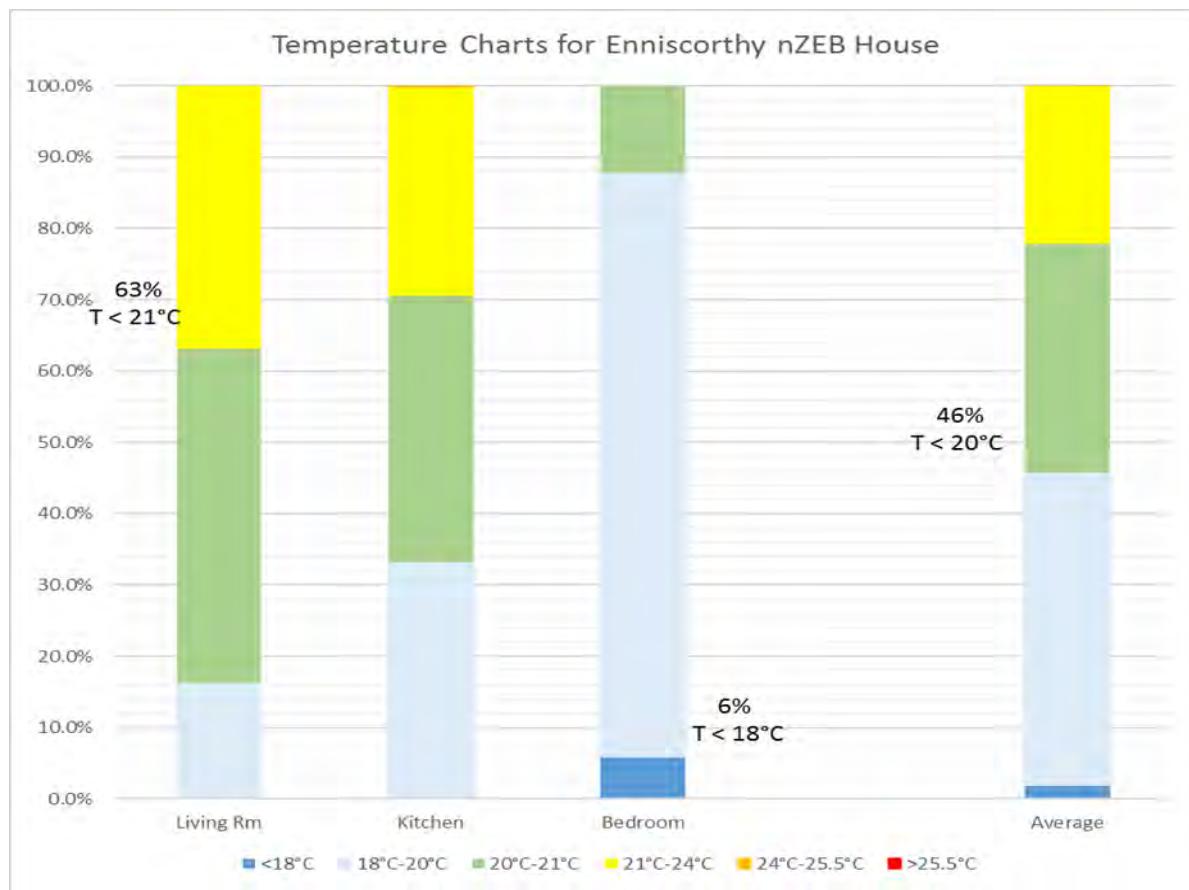

Figure 3. Temperature Chart for Enniscorthy nZEB House, October, November and December 2016.

The Republic of Ireland's Dwelling Energy Assessment Procedure (DEAP) assumes a two-hour heating period in the morning (7 AM to 9 PM), as well as six-hour heating period in the evening (5 PM to 11 PM), during which time the heating system is assumed to have a set temperature. The DEAP software assumes a set temperature of 21°C for the living room and 18°C for the "rest of dwelling" i.e. outside the living area. Thus 18°C and 21°C have been chosen as threshold temperatures in the temperature charts in Figure 3.

The temperature in the living room, kitchen and bedroom exceeds the Passive House set temperature of 20°C for 84%, 67% and 12.3% of the time respectively, leading to an overall figure of 54% of the time when the temperature is above the set temperature of 20°C. The relatively low temperatures in the bedroom are due to a personal preference by the occupant.

The temperature in the living room, kitchen and bedroom exceeds the building regulations set temperatures 37%, 100% and 94% of the time respectively. It is noted that further analysis could be carried out to determine the periods of time for which the temperatures exceed the set temperatures during the DEAP specified heating periods.

Figure 4 gives the carbon dioxide concentrations for the dwelling. Overall, the CO<sub>2</sub> concentrations are seen to be below 1000 ppm for 97% of the time, reflecting the relatively low occupancy profile.

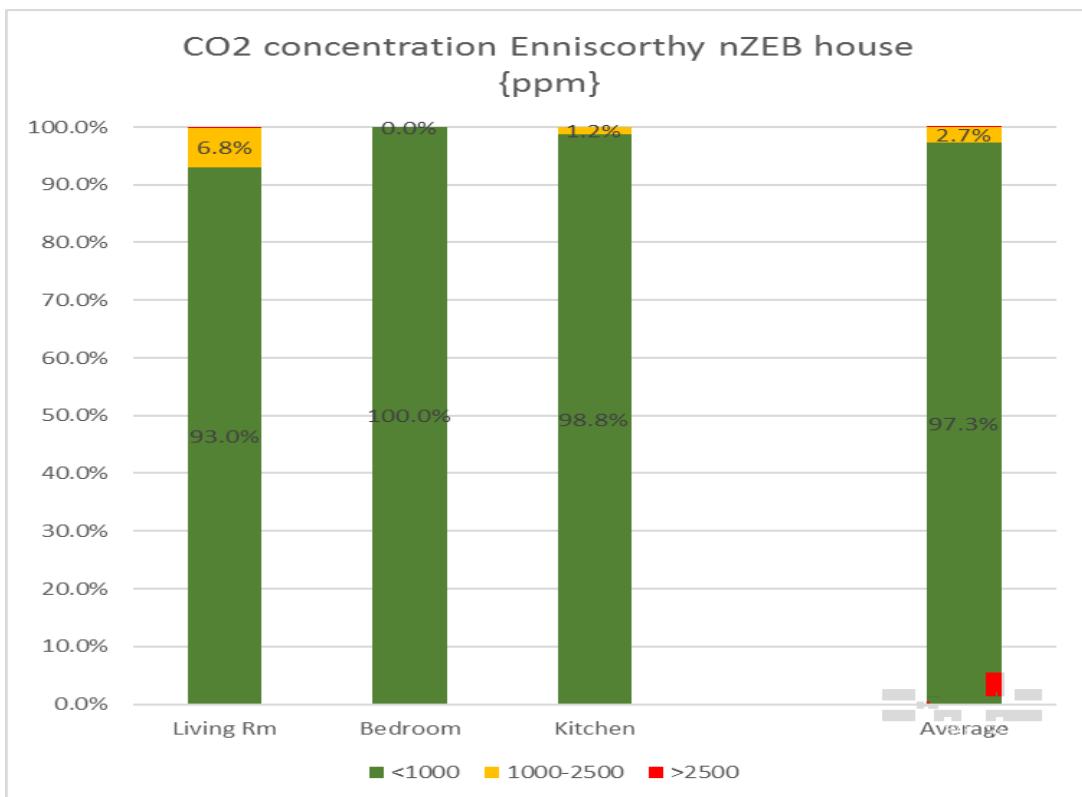

Figure 4. Carbon Dioxide Concentration Chart for Enniscorthy nZEB House.

### **Energy consumption**

Figure 5 shows the heating and ventilation energy consumption of the dwelling for six months of September 2016 to March 2017 along with the overall energy consumption. The annual consumption is therefore not available, but will be reported on in a future publication.

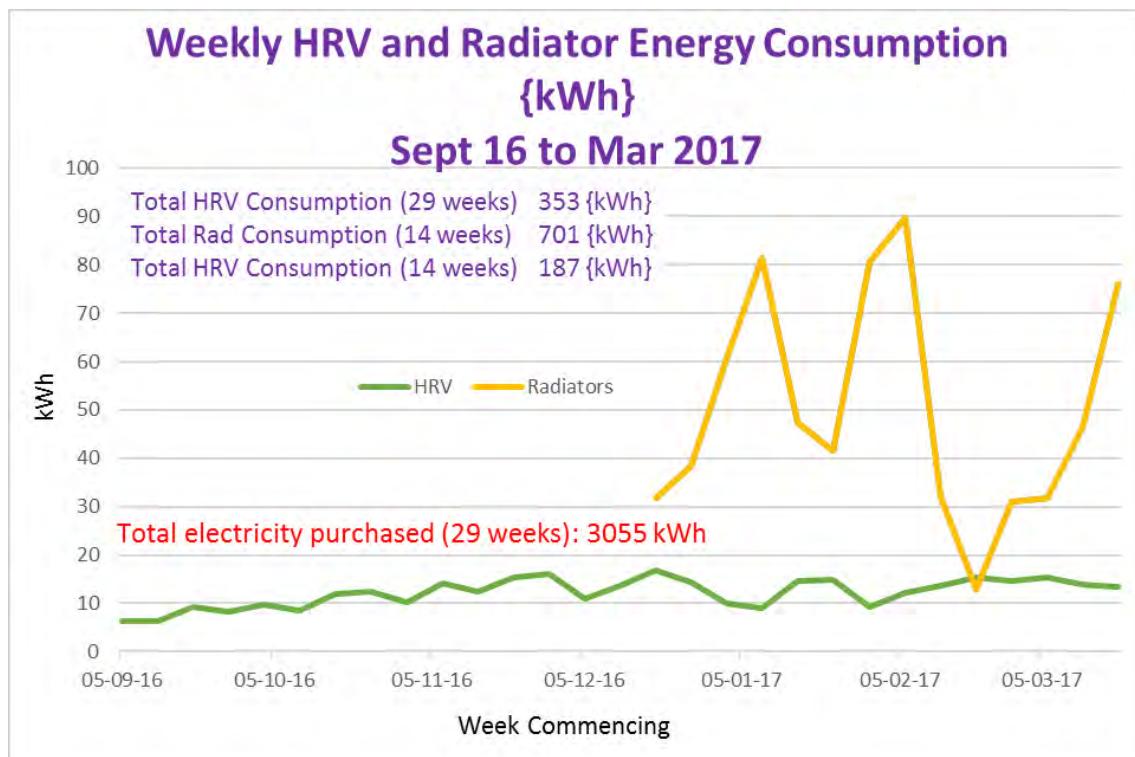

Figure 5. Energy Consumption for Enniscorthy nZEB House.

DHW and space heating energy consumption for the 14 week (w/c 19/12/2016) period was recorded at 888 kWh equivalent to 8.6kWh/m<sup>2</sup>/a (based on 103 m<sup>2</sup>), or 9.5 kWh/m<sup>2</sup>/a based on a treated floor area of 93 m<sup>2</sup>. The Passive House standard requires less than 15 kWh/m<sup>2</sup>/a for space heating alone, so even allowing for 6.6% lower than average heating degree days for the period, it appears that the certified Passive House is performing within expected parameters. The dwelling also appears to be performing within the DEAP maximum energy consumption of 45 kWh/m<sup>2</sup>/a, as 888 kWh is equivalent to 18.9 kWh/m<sup>2</sup>/a (based on 103 m<sup>2</sup> and a primary energy conversion factor of 2.19). It is noted that while this figure does not include lighting, it does include DHW, space heating and ventilation energy consumption, and covers the period which typically reflects the greatest heating demand.

Overall electricity energy purchase from the grid for the 29 week period is 353 kWh, equivalent to 65 kWh/m<sup>2</sup>/a (based on 103 m<sup>2</sup>) of primary energy (at a conversion factor of 2.19).

## Conclusion

This analysis has shown that a certified passive house designed using the Passive House Planning Package is compliant with the nZEB requirements. Using the DEAP building energy rating software, the dwelling is deemed to consume 24 kWh/m<sup>2</sup>/a, significantly below the 45 kWh/m<sup>2</sup>/a required for nZEB compliance.

The monitoring found that the house is performing within expected limits. The temperature in the living room, kitchen and bedroom exceeds the Passive House set temperature of 20°C for 84%, 67% and 12.3% of the time respectively, and exceeds the building regulations set temperatures 37%, 100% and 94% of the time respectively. The indoor air quality is also good with carbon dioxide concentrations in the living room, kitchen and bedroom staying below 1000 ppm for 93% 98% and 100% of the time respectively.

Overall DHW and space heating energy consumption for the 14 week period (w/c 19/12/2016) was recorded at 888 kWh, equivalent to 8.6kWh/m<sup>2</sup>/a, of which 187 kWh was for operation of the heat recovery ventilation unit. Monitoring is continuing to determine the annual energy performance and IEQ of the dwelling.

## Limitations of Environmental Assessment Methods for Bioclimatic Building Design

Dani Craig<sup>1</sup> and Rosa Schiano-Phan<sup>2</sup>

<sup>1</sup> Dani.Elizabeth.Craig@gmail.com;

<sup>2</sup> Faculty of Architecture and the Built Environment, University of Westminster, London, UK,  
R.Schianophan@westminster.ac.uk.

**Abstract:** The Leadership in Energy and Environmental Design (LEED) assessment standard has been successful in bringing sustainability to the mainstream of building design, and communicating a measure of environmental quality. There is a tendency in the literature as there is in the construction market to use a LEED score as a proxy for high performance construction. This proclivity obscures the processes and priorities that informed the building design, as well as differences in the performance and context of similarly rated buildings. In contrast to the LEED framework, bioclimatic design proposes to minimize environmental impact and energy demand through the implementation of passive design strategies which *cater to* site-specific conditions. Little work has been done on the ability of LEED to measure bioclimatic integration in the design approach. The aim of this paper is to understand (a) the interaction between the LEED framework and the bioclimatic design approach, and (b) how project-level and contextual dynamics influence the energy performance of buildings. This paper challenges the use of LEED as a tool to support a transition to a sustainable building industry, and suggests that environmental assessment should focus on both performance-based energy use intensity targets, and the integrative approach of the design process itself.

**Keywords:** Bioclimatic, environmental assessment, LEED, passive-design

### Introduction

Energy consumption and the resulting Greenhouse Gas (GHG) emissions from buildings comprise up to 40% of the total quantities emitted by developed countries (IPCC, 2014). The Intergovernmental Panel on Climate Change IPCC (2014) suggest that if sustainability is successfully incorporated into the building sector, it is possible to reduce GHG emissions by 6 Gt per year worldwide. Furthermore, the International Energy Agency (IEA) has identified the building sector as one of the most cost-effective industries for reducing CO<sub>2</sub> emissions associated with energy demand (Giama and Papadopoulos, 2012). Due to this potential, laws, policies and regulations requiring integration of sustainability into the built form are becoming increasingly common on a global scale (Berardi, 2012). In many cases, regional policies are incorporating environmental assessment methods (EAMs) as a strategy to encourage emissions reductions associated with the construction sector (Berardi, 2012; Hellstrom, 2007; Steurer and Hametner, 2011).

EAMs are rating systems that have been developed as a tool for the valuation of the environmental impacts of 'green' or high performance buildings. The LEED rating system was developed by the US Green Building Council (USGBC) in 1998, as a market tool 'to provide building owners and operators a concise framework for identifying and implementing

practical and measurable green building design, construction, operation and maintenance solutions,' (Azhar et al, 2011, p. 217).

Canadian Green Buildings Council (CaGBC) has administered LEED-British Columbia; a version of the assessment method which is licensed to Canada by the USGBC and apparently designed to meet the specific needs of the Vancouver market. LEED-Canada for New Construction version 1.0 is based on assessment in six categories, including (a) Sustainable Sites (14 points), (b) Water Efficiency (5 points), (c) Energy and Atmosphere (17 points), (d) Material and Resources (14 points), (e) Indoor Environmental Quality (15 points), and (f) Innovation and Design Process (5 points). Buildings can achieve performance ranging from certification (26 points), silver (33 points), gold (39 points), to platinum (52 points).

With aims to be the world's greenest city, the City of Vancouver is proposing that all new construction be carbon neutral by 2020. The City of Vancouver has identified LEED as an important part of incentivizing the transition. Although it was initially designed to be voluntary, the CaGBC LEED Strategic Direction Plan 2014-2016 explicitly describes their goal of achieving marketplace transformation through advocating and supporting the integration of LEED into building policy. City re-zoning bylaws require all new construction to meet the LEED Gold certification level (City of Vancouver, 2014).

An extensive body of research has explored the limitations of the LEED framework for assessing high performance building design. The most widespread criticisms include its inability to adapt to regional priorities, contexts, and users; all factors which have been found to significantly influence a building's energy performance (Li et al., 2015). Further, certification levels are based on the designed energy use rather than actual energy use, and thus LEED does not address the performance gap which is common to both certified and uncertified buildings (Li et al., 2015). Although LEED scores tend to be perceived as proxy for high performance construction by the public and property market, LEED certified buildings are not providing the energy savings that their certification levels indicate (Li et al., 2015). These initial findings raise serious questions about the ethics and effectiveness of using EAMs as a policy tool.

In contrast to the LEED framework, bioclimatic design proposes to minimize environmental impact and energy demand by *catering* to site-specific conditions (Tzikopoulos, 2005). Existing literature describes bioclimatic architecture as designs that consider and integrate: topography, movement of the sun, climatic conditions, environmental conditions (daylighting and shading), building massing, building code, and materiality. Structures are designed to maximize solar gains, minimize heat losses during the winter months, and limit solar exposure in order to adapt various cooling techniques during the summer (Tzikopoulos et al, 2005). Intrinsic to the design concepts are passive strategies for reducing energy demand. Understanding how bioclimatic principles can be successfully integrated into the design process is a crucial factor for reducing the GHG emissions associated with the building sector. On average, bioclimatic buildings consume 50% less energy than conventional buildings, and best-practice examples have been recorded to achieve 75% savings (Tzikopoulos, 2005).

The juxtaposition of the prolific use of LEED within the policy environment in Vancouver, against the extensive volume of research documenting the limitations of environmental assessment methods, against the effectiveness of the bioclimatic design approach, has informed the research questions on which this paper is based: (1) Are LEED-rated buildings successful in meeting a bioclimatic definition of sustainable design? (2) How do project-level differences and dynamics contribute to and limit environmental performance? (3) Are

environmental assessment methods the appropriate tool for supporting the transition to sustainable built environments? The findings of this paper are based on a multi-case study of the University of British Columbia Centre for Interactive Research on Sustainability (CIRS) LEED-rated Platinum, and the Marguerite Ford Apartments (MFA) LEED-rated Gold.

## Methods

Because there is no typical ‘bioclimatic geometry,’ or combination of technologies that would suggest a design is ‘bioclimatic,’ it is necessary for the purpose of this study to define indicators that would likely suggest successful integration of bioclimatic design. The most reliable indicator of high performance construction described in the literature is the actual energy use of the building (Li et al., 2015). As such, the post-occupancy Energy Use Index (EUI) of each case will be utilized as one of the indicators of successful bioclimatic integration. The most commonly installed energy-efficient technologies (daylighting, high-efficiency HVAC, and improved envelopes) are not statistically associated with low EUI (Li et al., 2015). Instead, it is the way that these technologies are integrated, and the relationships between technologies, occupants, and building context that is indicative of EUI. The analysis of the results will thus focus on the integrative approach of each design team, and their understanding of how these systems, technologies and passive strategies operate together, rather than focusing on the presence of energy efficient technologies.

In order to explore the research questions, this paper will examine the EUI, design approach and LEED score for each case.

### **Results: Are LEED-rated buildings successful in meeting a bioclimatic definition of sustainable design?**

#### **CIRS**

The CIRS building is a sustainability-focused research centre located on the University of British Columbia (UBC) Vancouver campus. The principal use of the building is for research, education and administration. CIRS is occupied by researchers, students, staff, and public visitors. The CIRS building is owned and operated by UBC, who have a history of pursuing operational sustainability goals and targets in its developments. On the UBC campus, all building projects must be certified to LEED Gold as of 2009. Data for this case is largely based on the Technical Manual published to UBC’s website.

#### *Energy Use and LEED Score*

In the LEED scoring system, the percent improvement over a baseline model determines the project score in the Optimize Energy Performance (OEP) sub-category within the Energy and Atmosphere category. The baseline energy use for this building type is 219.1 kWh/sq.m/yr, and the design team modelled improvements over the baseline target of 100%. The design achieved 10/10 points in the OEP sub-category (Table 1). According to the CIRS website, the current post-occupancy EUI is approximately 130 kWh/sq.m/yr, which is a 32% reduction over the baseline EUI (Table 1).

Table 1. The LEED score in the ‘Energy and Atmosphere’ category, and EUI for each case.

	CIRS	MFA
LEED Scorecard: Energy and Atmosphere (17 Possible Points)	15	12
Baseline Energy Performance (kWh/sq.m/yr)	219.1	250
Design EUI	0	95
Post-Occupancy EUI	130	123
Actual Energy Reduction Over Baseline Model (%)	32%	51%

CIRS’ score in Energy and Atmosphere is the highest of both cases, but is not reflective of its post-occupancy building performance. Rather, the score is reflective of the proposed system design, and of the incorporation of renewables. CIRS has extensive incorporation of photovoltaics, which are not providing as much energy as planned. The use and positioning of the collectors for optimized energy production is not specified in the Technical Manual.

A 3000 point monitoring system provides feedback on energy consumption; natural ventilation rates; daylighting performance; artificial illumination levels; airflow and exchange rates; and surface and air temperature. CIRS has received a credit for Measurement and Verification, and UBC plans to continue to measure building performance intensively. Although the building is not performing as intended, it is important for the owner to demonstrate that the implemented systems are able to perform. There is thus a long-term commitment to having CIRS reach its original net-zero goal; a commitment that is not acknowledged by LEED and is likely not commonplace for projects who have pursued the Measurement and Verification credit.

The case study also reports that graduate students at UBC performed a post-occupancy study which found positive feedback from the occupants, specifically concerning some of the social benefits that CIRS provides: ‘They particularly like the sense of community of the building, as well as the opportunities it creates for social interaction (facilitated by open spaces designed for that purpose)’ (CIRS Technical Manual). Such social benefits are not acknowledged by the LEED framework.

#### *Design Philosophy*

The design processes and philosophy of both the architectural firm and UBC have an obvious bioclimatic focus. The team considered how the building would perform in different seasons, explored different massing options, focused on occupant comfort, and tailored the design to site-specific conditions including climate, microclimate, users, and occupants. Architecturally, this is expressed via different responses on each building façade. Utilizing the waste heat from the neighbouring building also demonstrates the team’s focus on contextual considerations.

#### **MFA**

The MFA building is a multi-unit medium-rise social housing apartment complex. 80% of the occupants are at medium to high risk of homelessness and 20% of occupants are those who qualify for low income housing. The building is owned by BC Housing, operated by Katherine Sanford Housing Society. Data for this case is based on the survey responses and interviews with key informants.

#### *Energy Use and LEED Score*

The design EUI for MFA was 95 kWh/sq.m/yr, which is a 62% improvement over the proposed baseline energy performance of 250 kWh/sq.m/yr. They received 8/10 points for their OEP

Score. The actual EUI of the building during its first year of occupation was 123 kWh/sq.m/yr, which is a reduction of approximately 51% relative to the proposed baseline EUI.

In Energy and Atmosphere LEED category, the MFA building has achieved a lower score than CIRS. The low score is indicative of the level of renewables that were incorporated into energy system design, but does not reflect the post-occupancy energy performance. The client's commitment to energy performance is not acknowledged by LEED, as only one point is allocated for post-occupancy monitoring.

According to the survey respondents, design features that were included in the design, but not acknowledged by LEED include some of the durability features of the building, social spaces, vegetable gardens, and landscaped areas which were designed based on the micro-climate of the site. The numerous important social benefits and services provided by MFA are also not acknowledged by LEED.

### *Design Philosophy*

The requirement of BC Housing for reduced operational costs and a durable building has resulted in a strong commitment by the client, design team and building operators to improving the environmental performance of the building over the course of its lifetime. The importance of solar access and a high-performance envelope is also an important part of the architect's environmental philosophy. This commitment inherently required a level of bioclimatic integration on behalf of the design team. The design team has also utilized a user-based design approach that is built around addressing the social and health concerns of its occupants as well as optimizing livability and comfort. The building design maximized the lot size in order to achieve as many units as possible within the parameters set by the community plans. As a result, the orientation of the building was predetermined with the design focus on the performance of the building envelope in order to limit heat losses and undesirable solar gains. There was a strong understanding and consideration of the trade-off of passive strategies, and those that were selected were the best fit for the user and the client. Budgetary restraints were significant for this project, especially compared to the other case, and the importance of responding to the specific and pressing needs of the occupants of this building presented a barrier to bioclimatic integration. The landscape architect also noted that it is commonplace to prioritize views and aesthetics over context-based design and that this project was not an exception. He suggested that each façade should respond to its specific micro-climate, but this was not the case for MFA.

### **Results: How do project-level differences and dynamics contribute to and limit environmental performance?**

The following section will focus on identifying some of the project-specific factors that have been influential in determining building performance and the level of bioclimatic integration and comparing the contextual differences of each case.

### ***Modelling***

An emergent theme in the analysis of the design team-consultant-contractor relationships was the use of building information modelling. The use of BIM allows for multi-disciplinary contribution to a single building model, increased accuracy for the analysis of building performance, and can be an important tool for the integration of bioclimatic design (Motawa and Carter, 2013). The CIRS team reported the importance of BIM for engaging the general contractor early in the design process. The model helped the team to identify structural issues with the design earlier, increased coordination among consultants and between designers

and contractors, and helped the team to produce a more accurate bid (University of British Columbia, 2011). BIM was not used in the MFA design process. As Santos-Brault, environmental consultant for MFA described, the use of BIM is more challenging when every consultant is from a different company as was the case for this project. BIM also adds a significant project cost, and is only useful if building operators have enough experience to optimize the use of the model. In the case of MFA, non-profit operators required a simplified interface in order to be involved in the design process.

### ***Design Priorities***

According to the design team, BC Housing's priorities included maximizing the use of the lot, meeting the needs of the client, building durability, energy performance, and reducing operational costs. This prioritization is reflected in the post-occupancy energy performance of the building, and the numerous design features integrated for the purpose of meeting the needs of the occupant. The client was looking for more durable construction opposed to high-end architectural finishes. It is not typically what most contractors would see, as the architectural finishes are normally one of the biggest expenses. A more practical architectural design left more of the budget to allocate towards the high-performance envelope. The expression of idealized concepts in this case were limited by client's need to respond to the user and also by budgetary constraints.

As an academic institution aiming to practice what they are teaching their students, the architectural expression of CIRS is equally important as demonstrating the effectiveness and replicability of its systems. If the achievement of net-zero targets had been the only priority, this project likely had the resources, knowledge, and experience to achieve that; however, it was also important for UBC to put these systems on display, to test multiple systems, and to integrate the latest technologies throughout the lifetime of the building. Hence, the client's commitment to achieving net-zero is not reflected by the EUI.

### ***Building Operations and End-Users***

The requirements of the occupants at MFA necessitated the commissioning of a non-profit housing society to operate the building. Katherine Sanford Housing Society has experience working with tenants who are effected by mental disorders and social issues. Their feedback was required throughout design development and remains to be valuable following the completion of construction (Santos-Brault, Personal Communication, 2015). On the other hand, the individuals maintaining the building systems do not have time to effectively engage with these massively complicated systems (Bigourdin, Personal Communication, 2015). Although the society does not have experience operating a high performance building, many efforts were put in place by BC Housing to advance learning and ensure that the building can perform how it was designed to. Occupants at MFA are not aware of their energy consumption (Forsyth, Personal Communication, 2015), and have no previous experience or education regarding high performance construction. BC Housing noted that putting efforts into education for occupants has not been as effective as they had hoped. CIRS, on the other hand, has experienced building operators who have been trained in the maintenance and operations of high performance construction. Further, the users and operators of CIRS are industry experts in the fields of sustainable construction.

Understanding the nature of the dynamics that allow energy performance to become a high priority for the client and design team helps to identify some of the barriers and incentives for this prioritization. In terms of the collaborative approach of each project, some

of the incentives for designing a building with low energy demand described in this section include (a) client prioritization of low energy demand or operating costs, (b) exploring the performance of several iterations of the design through the use of BIM and other software, and (c) having an experienced building operator and educated occupants. Barriers to achieving high performance design include the high prioritization for many clients of the appearance of sustainability over post-occupancy energy performance, and the prioritization of user needs over energy performance. This analysis only scratches the surface to describe emergent themes between cases, and future studies should cover a more in depth analysis of the project dynamics of each case.

### **Conclusion: Are environmental assessment methods the appropriate tool for supporting the transition to sustainable built environments?**

The bioclimatic design approach necessitates the consideration of the building's climatic, social, economic, and cultural context. It requires a deep understanding of the ways that passive solutions are integrated in design, trade-offs between the implementation of particular strategies, and consideration of how design strategies will interact with the user after construction is completed. Although LEED acknowledges the use of passive strategies, it is unable to allocate points for how design components, systems, and strategies are interacting or how they are being integrated. The Energy and Atmosphere category is not performance based, and its requirements promote technology-based strategies for energy reduction. Instead of promoting substantial reduction in energy demand, LEED promotes relatively small improvements in energy efficiency. A design approach that perceives LEED requirements as boxes that need to be ticked only to improve the market value of the end result could potentially achieve a high level of certification by integrating efficient technologies. Conversely, user-specific, low-tech, low-energy building design may not meet sufficient LEED requirements to be certified, making it difficult for this type of approach to gain recognition in the current market.

The project level-dynamics explored in this study both contribute and limit the environmental performance of each case. The nature of the collaborative approach of a project, the design approach and priorities, and the influence of the building operator and user are some of the identified dynamics that are important for determining post-occupancy building performance. These findings exemplify that architecture is not only the work of architects, but the co-production of engineers, contractors, consultants, politicians, owners, users, and the building itself. In the cases under study, the architects are acting as mediators to manage compromises and various interests to come to a solution that aligns with the needs of all actors in the assemblage, including their own.

LEED has a dominant position in the industry and has been successful in engaging with many sectors of the building industry at multiple scales. It has become a policy tool, played a role in increasing industry and public awareness of sustainable buildings, and an increasing number of industry professionals and owners are registering their projects for certification. Whether LEED remains to be an effective tool to support a transition to a sustainable building sector is challenged in this study. Despite the dominance and influence of the LEED, the framework has a limited ability to assess environmental performance. The newest version of LEED, V4, incorporates some performance-based metrics for the assessment of indoor environmental quality and occupant comfort; however, performance based EAMs would continue to place value on an end *product*, rather than the design *process*. Understanding how to integrate an assessment of the design process itself within LEED could be an important

leverage point for triggering the necessary shift in the building sector. In order for the building sector to engage with new ways of designing, the benefits of the bioclimatic approach need to be exemplified to the industry. Policy and government incentives should play a role in supporting this demonstration by making genuine low-energy construction more affordable for both small and large companies. It is important to engage with the industry to find out what areas require innovation, research, funding, and skills, in order for small- or medium-sized developers to produce low emissions construction and engage with bioclimatic concepts.

## [Re] Measuring [LEED] Sustainability: From a Global Rating System to Tropical Specificity

Eileen Díaz-Lamboy<sup>1&2</sup>, Marisela Mendoza<sup>3</sup> and Ana Souto<sup>3</sup>

<sup>1</sup> PhD Student, Architecture, Design and Built Environment, Nottingham Trent University, Nottingham, UK

<sup>2</sup> Interior Design Faculty, University of Puerto Rico- Carolina Campus, PR,  
eileen.diaz@upr.edu

<sup>3</sup> PhD Supervisor, Architecture, Design and Built Environment, Nottingham Trent University, Nottingham, UK

**Abstract:** This paper explores the applicability of the LEED certification system through the case study of Puerto Rico (P.R.), a United States (U.S.) Commonwealth island in the Caribbean, where LEED has become widely recognized as a standard because of the geopolitical relationship with the mainland. Although LEED is used internationally, it was initially developed by the U.S. Green Building Council as a tool to measure building performance in a modern American urban environment with temperate climate, a steady economy and easy access to technology. Furthermore, regionalization strategies such as Regional Priority Credits (RPCs) and Alternate Compliance Paths (ACPs), do not address the sociocultural reality of many regions. Therefore, the focus of this research is to analyse what indicators should be added, modified or substituted to develop a revised LEED model for the specific sociocultural context of P.R.? A mixed methods research will be used to compare LEED criteria with Sustainable Assessment Systems (SAS) such as the Building Research Establishment Environmental Assessment Method, the Living Building Challenge and SB Tool. Also, SAS in tropical countries such as Singapore (BCA Green Mark), Costa Rica (RESET) and India (TERI-GRIHA) will be examined. Case studies will be analysed with a main focus in Schools.

**Keywords:** Sustainable building, School design, Socio-cultural indicators, Green building rating systems, LEED

### Green Building, Certification Systems and Regional Adaptation

#### *Introduction to green buildings and sustainability dimensions*

Several definitions of sustainability and green building since the 1970s, emphasize on energy, water and materials efficiency; the reduction of environmental impact during the construction phase; as well as the health and wellbeing of building occupants (USGBC Media, 2016; Office of the Federal Environmental Executive, n.d.:8; EPA, 2016). However, “Our Common Future”, also known as the Brundtland Report (1987), stressed the need to target **social** and **economic** aspects in addition to the **environmental** considerations required to achieve sustainable development. While environmental sustainability is concerned with the protection of nature and its resources, its social counterpart deals with the protection of basic universal human rights, such as education; equity; health; safety and security, among others (Axelsson et al., 2013:218; Energy and Resources Institute et al., 2014:59; Walker, 2014:14).

Recent models, such as the “sustainability square”, include **culture** as the fourth pillar, alongside the social, economic and ecological dimensions (Ebert 2011:21, Mateus and

Bragança 2011:1962). While the term encompasses the characteristics of a society, its norms, values, skills, knowledge and beliefs, this new approach aspires to strengthen the cultural sector; and promote its integration in policies related to education, economy and communication, among others (Axelsson et al. 2013; United Cities and Local Governments, 2010:4). The socio-cultural dimensions of sustainability will be further explored throughout this investigation, to demonstrate its application to current certification systems.

### ***Certification systems in Puerto Rico as case study***

Worldwide, certification or ‘sustainable assessment’ systems (SAS) such as the Leadership in Energy and Environmental Design (LEED) and the Building Research Establishment Environmental Assessment Method (BREEAM), among others have provided a framework of reference by including criteria and objectives of what a sustainable building should be.

These systems have been used worldwide to rate buildings beyond their country of origin. This is also the case of Puerto Rico, an island located in the Caribbean, which holds the largest amount of certified projects in the region (USGBC, 2016). Being a United States Commonwealth, the LEED SAS has become the most widely recognized standard because of the geopolitical relationship with the mainland. While P.R. shares a common Hispanic background with nearby countries, green building is subject to U.S. laws, building codes and regulations even though its culture, climate, construction systems and native language are different.

### ***School Sustainable Assessment Systems (SAS)***

Sustainable Assessment Systems such as LEED and BREEAM, among others, are mostly based on weighting building performance and environmental impact mitigation through resource consumption, mechanical systems efficiency and overall site planning. However, these criteria might overlook critical social components when assessing educational institutions. Schools, which influence the students’ views toward society and the environment and in addition to being the learning centre for more than 75% of the K-12<sup>1</sup> student population in Puerto Rico (Instituto de Estadísticas de P.R., 2014:13), makes the focus of this investigation to assess the applicability of LEED for Schools under the *Schools for the 21st Century* program. This federally funded<sup>2</sup> program included the “modernization, renovation, or repair of public school facilities”, which had to be certified, verified or consistent with LEED or other equivalent program (U.S. Department of Education, 2009; U.S. Senate, 2008:22099). This project was extended to all 78 municipalities and promoted Puerto Rico’s largest public school improvement program in decades (Fielding Nair, n.d.: 3)

The present study analyses and questions the validity of U.S. LEED as a reliable tool to evaluate buildings in the tropical Caribbean region with distinctly different environmental, economic, and socio-cultural conditions, to revise current and propose new sustainability indicators that could contextualize this system in P.R., for the particular case of Schools. Also, to assess USGBC’s regionalization strategies such as Regional Priority Credits (RPCs), used as part of the LEED for Schools certification process in P.R. to attempt to adapt the system to the local context. Other strategies for climatic adaptation, Alternate Compliance Paths (ACPs) and Innovation in Design credits, will be analysed to determine their applicability.

<sup>1</sup> Based on the U.S. and P.R. Educational system, which names school levels prior to college as kindergarten (K) through the 12th grade (12).

<sup>2</sup> The American Recovery and Reinvestment Act (ARRA) signed in 2009 by U.S. President Barack Obama, was developed to stimulate the economy of the U.S. and its Territories, including P.R. (“ARRA- Puerto Rico,” 2012).

This paper will discuss and demonstrate the gaps in current LEED indicators in regard to socio cultural factors as part of a larger body of work going on a PhD research project focused on the following objectives:

1. To inform how and determine if the U.S. LEED certification program addresses social and cultural elements as sustainability indicators.
2. To analyse why and propose how LEED indicators and regionalization initiatives by the USGBC could be modified to respond effectively to the tropical context of P.R.
3. To identify what aspects of sustainability<sup>3</sup> in the tropical Caribbean P.R. region are excluded from LEED but could be incorporated as indicators.

### ***Methodology and organization***

To address the above-mentioned objectives, this research is divided into two main sections, the first includes an overview of the LEED system, as well as an in-depth analysis of its current regionalization strategies. Also, an implementation strategy for recommendations resulting from this investigation will be discussed.

This research will reference widely used **international SAS** such as **BREEAM**, **Sustainable Building (SB) Tool** and the **Living Building Challenge (LBC)**, its categories, indicators and weightings. A comparison between LEED and most recent versions of these SAS will inform what indicators may be added, modified or substituted to develop a revised LEED model for its specific socio-cultural context. Also, **localized** systems such as **Requirements for Sustainable Buildings in the Tropics (RESET)** in Costa Rica, **Green Mark** in Singapore and the **Green Rating for Integrated Habitat Assessment (GRIHA)** in India, that have emerged as a specific solution to the problems of a country or region within the tropics, will be discussed.

To analyse and compare the sustainability dimensions considered in the selected SAS, the second section includes a re-categorization of indicators that was developed as part of this investigation. Finally, contains a summary of social and cultural components deemed relevant for schools.

### **Leadership in Energy and Environmental Design (LEED)**

#### ***LEED overview and its implementation in Puerto Rico***

The US Green Building Council (USGBC) was established in 1993 by Rick Fedrizzi, David Gottfried and Mike Italiano (USGBC, 2016). LEED version 4 comprises a family of rating systems that address several building types in different stages of development (USGBC, 2016; Todd et al., 2013), that include Building Design and Construction, Operations and Maintenance, Interior Design and Construction, Neighbourhood Development and Homes.

Although LEED was designed in the United States and primarily reflects US market conditions, it has been used extensively around the world. As of July 2016, there are more than 161 countries and territories with LEED projects and over 33,500 certified commercial projects. Currently there are nearly 1,800 K-12 schools certified and over 2,000 registered (USGBC, 2016). Puerto Rico has the largest amount of LEED projects in the Caribbean region with a total of 47, out of which 9 are schools (19%). Additionally, 78 projects are labelled as “registered”, out of which 3 are schools (3.8%).

While most Green Building Councils in Latin America and Caribbean countries promote LEED as their main SAS, countries including Brazil (Selo Azul de Caixa), Mexico (PCES), Costa

---

<sup>3</sup> Sustainability includes environmental, economic, social and cultural dimensions.

Rica (RESET) and US Virgin Islands (Green Building Certification) have developed their own SAS that incorporate socio cultural indicators in an attempt to address local needs.

### ***LEED section weightings, categories and credits***

LEED contains prerequisites and credits in nine (9) categories: Integrative Process, Location and Transportation, Sustainable Sites, Water Efficiency, Energy and Atmosphere, Materials and Resources, Indoor Environmental Quality, Innovation and Regional Priority (USGBC, 2016). To determine the LEED score, the total obtained in each criterion is added up, the maximum being 110 points. The number of credits achieved determines the project certification level as Certified, Silver, Gold or Platinum (the highest ranking) (USGBC, 2016).

The process to determine LEED v4 priorities and credit weightings, in order to target “social, environmental and economic goals”, was dedicated to answering this question: “**What should a LEED project accomplish?**” (Owens et.al., 2013:2,6). Hence, the LEED Steering Committee developed seven (7) weighted goals, namely: Climate change (35%), Health and well-being (20%), Water resources (15%), Material resources (10%), and Biodiversity (10%), while Economy (5%) and Social equity, environmental justice, and community quality of life (5%) were given the least percentage.

### ***LEED's Regionalization Strategies***

In order to improve global reach, several **regionalization strategies** such as Regional Priority Credits (RPCs), Alternate Compliance Paths (ACPs) and Pilot Credits, have been implemented.

#### ***Regional Priority Credits (RPCs)***

The **Regional Priority Credit** category, introduced in LEED 2009 allows project teams to earn bonus points by demonstrating compliance with the priority credits identified for a specific location. These credits, selected by the LEED International Roundtable and volunteers from green building chapters around the world, target environmental issues that affect their particular region or country (USGBC, 2016). Social, cultural and economic dimensions could not be considered because RPCs only recognize compliance of existing credits, and these are currently not included in LEED.

#### ***Alternative Compliance Paths***

In addition to RPC's **Alternative Compliance Paths (ACPs)**, attempt to adapt LEED to the local context and recognize differences in climatic conditions, codes, standards and laws applicable to projects outside the US (Horst, 2014). Even though projects in Puerto Rico can use some of these Global-ACP's (USGBC-FAQ), these would not be an effective strategy to locally adapt LEED considering that P.R. references U.S. standards and building codes. While overall consistency would be achieved, the recognition of local social, cultural and economic conditions in LEED indicators would need to be strengthened.

#### ***Pilot Credits and Innovation in Design Category***

Projects may pursue **Pilot Credits (PC)** within the **Innovation in Design Category**. This strategy allows teams to test criteria in the PC Library developed by others or submit new credits (USGBC, 2016). All proposals are then evaluated by the Pilot Credit Committee (PCC) and approved by the LEED Steering Committee (USGBC 2016).

An analysis of existing PC can give valuable insight about trends and new criteria proposed by project teams. For instance, most of the PC for LEED BD+C are related to the Materials and Resources category (33%), however a smaller percentage of credits (15%) belong to the Innovation category. It is relevant to acknowledge that within this category,

project teams proposed criteria that target social issues such as: (a) Social equity within the community and the project team, (b) Green training for contractors, trades and workers, (c) Integrative Process for Health Promotion, and (d) Prevention through Design.

The above-mentioned PC suggest an interest and need for LEED to target social aspects, however, there is no mention of any cultural aspects. As result, the USGBC's LEED Steering Committee created a Social Equity Working Group to improve the practical implementation of the above-mentioned Social Equity PC (USGBC 2016). Considering that the social and cultural sustainability dimension should be strengthened, the PC Library may be a valuable tool to propose new LEED criteria and test its effectiveness.

### **Proposed Implementation of Research Findings**

LEED regionalization strategies were analysed to determine the best approach to adapt the system for countries in tropical regions. In P.R., the USGBC local chapter, determined RPCs based solely on climatic and environmental conditions in the Island. Since Regional Priority credits were selected from existing indicators, no social or cultural factors were considered.

Out of the LEED Regionalization strategies, the innovation category could be a starting point to test the proposed indicators product from this research. Once approved by the USGBC and tested as PC, a Socio-cultural Working Group, under the LEED Steering Committee, could be developed by the USGBC to further develop these indicators, as it happened with Social Equity credits. Proposed PC could be used by other project teams within the Innovation in Design Category or could be incorporated into LEED as part of a new Socio-cultural Category. Green Building Chapters could then recognize social and cultural credits as critical and select them as Regional Priorities (see Figure 2).

### **International Comparison of School Sustainable Assessment Systems (SAS)**

This section will examine criteria in international and tropical SAS worldwide (BREEAM, Green Mark, GRIHA Prakriti, TERI GRIHA, LEED, LBC, RESET, SB Tool), to determine possible aspects missing in LEED and indicators that could be added into the system. The sustainability square, which includes the environmental, economic, social and cultural dimensions, was used as an initial reference for this analysis. A total of 8 certification systems and 779 indicators were added to a matrix, labelled according to the main issues identified; and regrouped into the following categories and subcategories, as shown in Figure 3 (Ebert 2011:21, Mateus and Bragança 2011:1962).

- **Building Technology and Environmental Impact:** Includes building and site considerations such as Infrastructure; Quality; Management; Efficiency; Material and Resource Availability (Sources); Consumption and Economic issues.
- **Design Criteria:** Includes indicators related to planning and spatial quality in buildings.
- **Social Needs and Integration:** Includes user related social and cultural aspects.

To further determine relevant sustainability cultural and social aspects that should be included in school SAS, a qualitative literature review analysis was developed. The study references work by several authors such as Walker (2014) and Axelsson, et al. (2013), that have developed cultural and social sustainability indicators and metrics to support design strategies and planning. Selected SAS manuals; documentation from the United Nations Education, Scientific and Cultural Organization's (UNESCO) proposal for Culture as the 4th Pillar of Sustainable Development in the Process of the Rio+20 Summit (Culture 21, 2011) and Culture for Development Indicators (United Nations, 2014) were also used as reference.

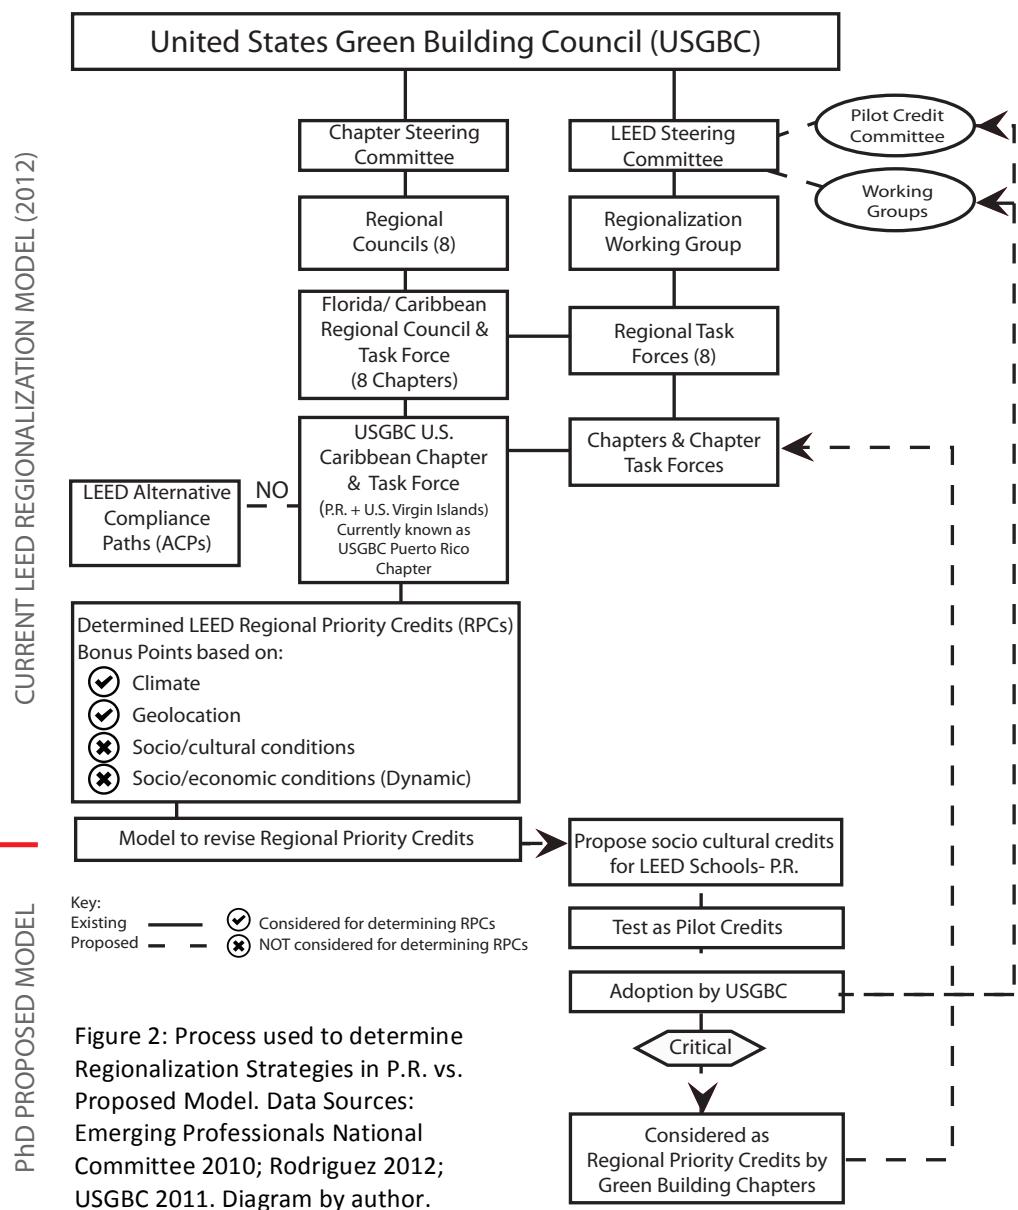

Figure 2: Process used to determine Regionalization Strategies in P.R. vs. Proposed Model. Data Sources: Emerging Professionals National Committee 2010; Rodriguez 2012; USGBC 2011. Diagram by author.

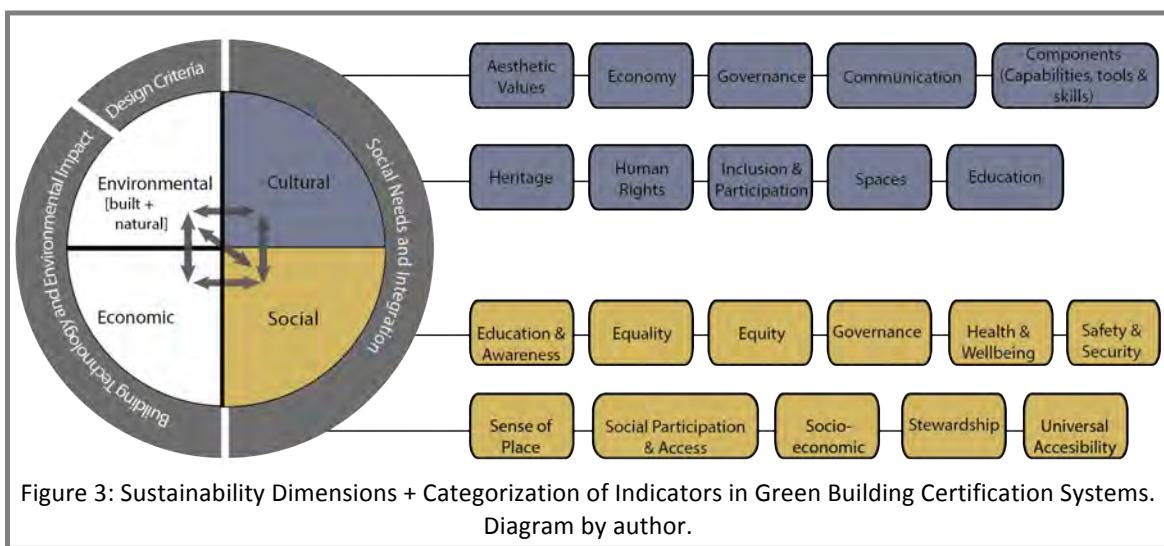

Figure 3: Sustainability Dimensions + Categorization of Indicators in Green Building Certification Systems. Diagram by author.

An analysis of previous studies suggest that cultural sustainability can be defined by the following components: Aesthetic values; Economy, Governance, Communication; Capabilities, tools and skills; Heritage; Human rights, Inclusion and participation; Cultural spaces; as well as Education, as shown in Figure 3 (Axelsson, R. et.al., 2013: 217; Culture 21 2011:1; Intl. Living Future Institute 2014: 59–60; UNESCO, 2014, 1989, 1972; UN, 2014:12; Walker, 2014:12).

While the term **culture** relates to the characteristics of a society or group of people, **social** relates to the “individual, family, or individuals in a society” and their interaction (Axelsson et al., 2013:215; Merriam-Webster, n.d.). Based on the literature review, **social sustainability** can be defined as a combination of the following components: Education and awareness; Equality; Equity; Governance; Health and well-being; Safety and security; Sense of place; Social participation and access; Socioeconomic; Stewardship, as well as Universal accessibility, as shown in Figure 3 (Aguilera et.al., 2006; Axelsson, R., et.al., 2013: 217-218; Diaz-Chavez, 2014:5, Gibberd, n.d.; GBC South Africa, 2014; “Sustainable socioeconomic development,” 2015; Government of Canada, 2010; Intl. Living Future Institute, 2014; Owens 2013:16; Energy and Resources Institute et al., 2014: 57-60; United Nations, 2014; Walker 2014:14; Wynhoven, n.d.).

Even though social and cultural indicators are included in the selected SAS (schools and others), not all components identified on the literature review and outlined on Figure 3 are considered by the certification systems analysed. Table 1 shows the components that are contemplated, the majority being socially related.

LEED's indicators, classified under the Social Needs & Integration category, for the purpose of this research, are mainly focused on Governance, Social participation and access, as well as the provision of Cultural Spaces. Other relevant indicators can be found under the PC library, as previously discussed, and are focused on Social equity, Education and awareness, Health, as well as Safety and security.

Table 1: Cultural and social components and indicators included in the selected SAS- Schools

Social and Cultural Sustainability Components in SAS					
Cultural Sustainability Components	Other systems	LEED Schools	Social Sustainability Components	Other systems	LEED Schools
Aesthetic values			Education and awareness		*
Cultural economy			Equality		
Cultural governance			Equity		*
Cultural communication			Governance		
Cultural components			Health & well-being		*
Cultural heritage			Safety & security		*
Culture and human rights			Sense of place		
Cultural inclusion & participation			Social participation & access		
Cultural spaces			Socioeconomic		
Cultural education			Stewardship		
			Universal accessibility		

**Key** The SAS includes all indicators identified in the literature review; \* Indicator included in LEED PC  
 Other Systems (Schools): BREEAM International In Use & NC 2016; Green Mark Existing Schools & New non-residential buildings 2015; GRIHA Prakriti Existing Schools; TERI GRIHA; LBC V3.0; RESET; SBTool 2015-16.  
 LEED for Schools: LEED V4 BD+C & O+M Schools

## Conclusions and future research

The discussion and findings of this paper will inform the overall objectives of the PhD. The sociocultural components identified will be further researched by developing a questionnaire to be administered to green design professionals and school directors. Results from this investigation could benefit LEED and SAS worldwide.

*Design to Thrive*

## Zero-Energy Me - The Struggle for Individual Energy Neutrality

Andy van den Dobbelaer<sup>1</sup>, Craig Lee Martin<sup>1</sup> and Greg Keeffe<sup>2</sup>

<sup>1</sup> Faculty of Architecture and the Built Environment, Delft University of Technology, the Netherlands, correspondence: a.a.j.f.vandendobbelaer@tudelft.nl

<sup>2</sup> School of Natural and Built Environment, Queen's University Belfast, United Kingdom

**Abstract:** The strife for zero-energy buildings and carbon-neutral developments is – however noble and benevolent – mostly aimed at an abstract target, such as a design in architecture school, a house still to be built, an urban plan under development. It is mostly dealing with there, then and them, rather than here, now and us. A sustainable, climate-, carbon- or energy-neutral society implies that each individual needs to be sustainable, climate- or carbon-neutral. Acknowledging this, the main author started to keep track of his performance in energy use, travel and food habits, and during lectures he presented about this openly to his students. Over a period of 7 years, the detailed tracking of energy, travel and food, and, more so, consecutive actions taken, have led to a lower energy consumption and hence carbon footprint. In the author's private life, we should say, because in the meantime his professional international career took off and so had many flights across the globe. They once more demonstrated that we, even when living low-carbon consciously, often are penny-wise, pound-foolish. This individual research clarified the greatest challenges and most effective strategies of living in a modern, dense city, with abundant access to unsustainable food and with easy opportunities to travel unsustainably for little money. As it held a mirror to the author, it will do too to a greater audience.

**Keywords:** net zero-energy, carbon neutrality, accommodation, transportation, food

### Introduction

If we want to stay beneath a 2-degrees temperature increase – widely considered a maximum level to avoid runaway climate change with unpredictable outcome - the world needs to reduce its carbon emissions by 80% in the year 2050 [IPCC 2014]. For a sustainable situation on the longer term, climate neutrality or carbon neutrality is essential, creating a balance between the greenhouse gases emitted on the one hand and chemically binding or sequestering of these gases on the other.

### Society's great energy challenge

The predominant part of achieving this goal, as agreed upon in the Paris treaty of 2015, is to be achieved by becoming independent from fossil fuels, the greatest contributor to greenhouse gases as methane, CO<sub>2</sub> and NOx. Therefore, the term 'fossil free' was introduced in various European projects already since 2006 [e.g. Roggema et al. 2011], after Al Gore's 'An Inconvenient Truth' came out [Gore 2006]. Fossil free simply means that no fossil fuels (coal, mineral oil and natural gas) are used anywhere in the system considered. With our fossil society this is an ambitious goal to achieve, and it may take a lot of time to get there. In the meantime, becoming 'net zero-energy' already is a big step. This ambition, often also described as 'energy-neutral', means that in a year's time one is not to use more energy than one can generate oneself. It implies acceptance of fossil fuels as long as this quantity of energy

is compensated for by self-generated renewable energy. In its Energy Performance for Buildings Decree (EPBD), the EU prescribes that as of 2020 all new buildings need to be ‘nearly zero-energy’. The word ‘nearly’ of course leaves space for interpretation, but it is clear that designing fully zero-energy buildings will put architects on the safe side for a building permit.

### ***Individual energy-neutrality***

The strife for zero-energy buildings and carbon-neutral development is noble and benevolent for future generations to follow. However, it is usually aimed at an abstract target, such as the design of a building in architecture school, a house still to be built, an urban plan under development. It is mostly dealing with there, then and them, rather than here, now and us. A sustainable, energy- or carbon-neutral society will not be possible if people themselves on average are not sustainable, climate-adaptive, carbon-neutral in their own way of living. It is easy to point at others and not achieving these goals oneself. People who understand the importance of striving for a sustainable world, must set the example by becoming net zero-energy in their habits. Acknowledging this, the main author started to keep track of his performance in energy use, and during lectures he presented about this openly to his students. This paper gives an account for the measurements and calculations done in the period of 2010-2016.

### **Boundary conditions and starting-points**

#### ***Sources of energy use considered and unconsidered***

Energy neutrality may be considered for many parts of our lives.

Perhaps most trivial is the energy used at home, including building-related energy (for lighting, heating, ventilation, pumps etc.), user-related energy (for use of equipment, devices, lifts etc.), and also the ‘embodied energy’ of building materials (for winning, transport, production etc.). The latter we usually do not consider because we usually do not have data thereof.

Other forms of energy use are related to our own living: mobility (private travel, commuter travel etc.), water (energy needed for producing drinking water, for pumps, for the purification of waste water, etc.), food (energy needed for growth, transport, storage and production of food), clothes (energy needed for the resources, transport and production of clothes), stuff (energy needed for the resources, transport and production of stuff), and again, the embodied energy of packaging and materials of previous products.

Least obvious, yet an essential part of everyone’s life is the (embodied) energy use of everything we use outside ourselves: infrastructure (roads, bridges, piping, wiring, sewage, etc.), utilities and facilities (for electricity, drinking water, waste water treatment, etc.), public objects (public buildings, street furniture, etc.), commercial objects (factories, offices, retail, etc.), and so on.

For practical reasons this research was limited to the building-related and user-related energy at home, mobility and food. Based on estimates that around 30-40% of carbon emissions result from the built environment (buildings) and 20-30% from transportation, the authors assume that thereby they have covered over half the energy individuals use, at least a part they can influence.

## **Method**

Over a period of 7 years the main author's energy use and travel was tracked in detail, linked to annual energy bills. Since the main author moved house in December 2009, with a baseline measurement done, account was made on the 1<sup>st</sup> of January every year. 2010 was the reference year, with little to no adjustments made to the house, after which various consecutive measures were taken and their effect measured.

Next to this private part of life, a professional career defines the use of energy; also with the individual considered. Working in an office most of the time, the energy consumed at the office is important but has to be divided by all who use it. Business travel can be an even more decisive factor. In the case of the authors this is certainly true, reason for which to keep track of business trips, both by car, train and plane.

## **Basics of energy**

Repetition of some figures is useful before we present energy data in the section to come. For conversion to a general energy value only two conversion factors are relevant (actually only one): 1 kWh = 3.6 MJ; and 1 MJ = 0.278 kWh. Besides, the energy content of common energy sources is important. Table 1 gives an overview of this. Notice that all fossil fuels as well as biotic oil and fat have an energy content of around 36 MJ i.e. 10 kWh per unit.

Table 1. Energy sources and energy content per unit

<b>Energy source</b>	<b>Unit</b>	<b>Energy content</b>	
Natural gas	1 m <sup>3</sup> nge (natural gas equivalent)	35.2 MJ	9.8 kWh
Petrol	1 l (litre)	32.4 MJ	9.0 kWh
Diesel	1 l	35.8 MJ	10.0 kWh
Kerosine	1 l	37.4 MJ	10.4 kWh
Oil and fat	1 kg vegetable/animal	37.0 MJ	10.3 kWh
LPG	1 m <sup>3</sup>	26.0 MJ	7.2 kWh
Coal	1 kg	24.0 MJ	6.7 kWh

Related to the energy mix of electricity the Netherlands has an average efficiency of around 45%, which implies – unless one uses electricity from renewable sources – we have to multiply the use of electricity by 2.2, in order to get to the amount of primary energy.

Furthermore, note that one flame (either a flame of a candle, oil lamp or gas burner) has a heat power of around 100 W [Hermans 2011]. Gas boilers and geysers often used to have ten rows of ten gas flames, giving them a heat power of 10 kW. One flame burning one hour long has produced  $100 \times 1 = 100$  Wh (watt-hour). Someone taking a shower for 15 minutes has used  $10,000 \times 0.25 = 2,500$  Wh or 2.5 kWh. Taking an efficiency of 100%, this is the equivalent of 0.25 m<sup>3</sup> of gas, or 250 ml ('a longdrink glass') of petrol.

## **Local energy habits**

In the Netherlands, the main author's home country, inhabitants typically have access to electricity, natural gas, drinking water, sewage, and other utilities that are centrally provided by public or private service companies. Recently, there is a shift towards dwellings free of natural gas, but the large majority of the building stock still relies on it (for both heating and hot water). Cars mostly use petrol or diesel, and airplanes kerosene. Electricity comes from centralised, regional power plants, which run on natural gas, coal or a small share of biomass. In North-Western Europe electricity is not bound to country borders and some of the energy produced in the Netherlands is exported while a small amount of nuclear power is imported from Belgium or France. The Netherlands are positioned second to last on the European table

of renewable energy (a share of around 5%) [Eurostat 2016]. So the energy mix is diverse, with dominance of natural gas.

### ***Energy use of Dutch households***

For their house, Dutch households on average use 1,400 m<sup>3</sup> of gas (13.6 MWh thermal) and 3,500 kWh (7.7 MWh of primary energy). In total this is 21.3 MWh<sub>prim</sub> (76.7 GJ). Ignoring public transport and bikes, for their mobility the Dutch drive on average 13,300 km per year. With 8 l/100 km this is around a thousand litre of diesel or petrol, or 36 GJ or 10 MWh<sub>prim</sub>. Hence, for living and private travel the total energy demand of a Dutch household is 31.3 MWh<sub>prim</sub>. Households on average contain 2.2 persons [CBS], so the individual energy use is 14.2 MWh<sub>prim</sub>. This is nearly 30% of the total energy the Netherlands used in the year 2015: 49.9 MWh per inhabitant [PBL 2017]. The private use of energy requires a continuous power of 3.56 kW, of which 2.43 kW for the house.

## **Domestic energy consumption**

### ***Energy system of the house***

The terraced house under scrutiny is positioned in the inner-city of Delft, the Netherlands. Officially it is an apartment, squeezed in between two neighbours and a cinema at the back, with shops underneath and a parking garage below these. It therefore has an uncommon wide and shallow floor plan, with one open façade. Total gross floor area is 165 m<sup>2</sup>, with approximately 460 m<sup>3</sup> of space. The house is inhabited by a family of four: two parents and two teenage children.

The multifunctional urban complex the house is part of was delivered in 2005. Compliant with the energy codes of that time it has HR+/HR++ windows ( $U = 1.0\text{-}1.3 \text{ W/m}^2\text{K}$ ) and, compared to the Dutch average, good thermal insulation ( $R_c = 3.0 \text{ m}^2\text{K/W}$ ). For energy-efficient ventilation the house has so-called balanced ventilation with heat recovery, which can be switched to three speeds; filters for incoming and outgoing air need to be regularly replaced by the house owner. The complex has a shared heat-pump system that is connected to a collector of tubes that exchange heat with the underground. The heat extracted from the soil pre-heats warm water used for floor heating and hot water. For hot water (used in the bathroom) it needs to be electrically after-heated in a boiler tank. The house's kitchen contains small electric close-in boilers, one for boiling water, one for normal hot water from the tap.

### ***Energy use in 2010, the reference year***

After a year of use and only minor adjustments (replacing broke lightbulbs with more energy-efficient ones, the energy use measured was:

- Electricity 5,622 kWh
- Heat 36 GJ heat (from the heat-pump system)
- Total 56 GJ or 15.6 MWh

The total energy use come down to 1.77 kW of permanent power (in this case fully electric). This is already 27% less than the Dutch average house. So although the consumption of electricity is higher than average, the use of heat from a heat pump is so much lower than the usual use of gas, that the house could be called energy-efficient already.

### ***Measures taken since 2010***

Since 2010, all lighting has been replaced by LED and energy-saving fluorescent lighting. Based on calculation of sufficient levels of fresh air for a family of four, standard ventilation rates were brought down from 50 to 20% of full power, which also reduced noise levels indoors. The boiler temperature was reduced from 65 to 55°C, a level that safe enough against Legionella bacteria with short piping circuits. In August 2011, 5 m<sup>2</sup> of mono-crystalline PV was installed on the small flat roof of the house (15%, 550 W<sub>peak</sub> ~ 600 kWh/a). As a measure of effective flexible thermal insulation during winter evenings and nights, in November 2011 thick curtains were hung behind the large windows of the second floor. As a technical measure to fix the floor heating system, a much more energy-efficient water pump (from hundreds of Watts to 10 W on average) was installed in early 2013. Finally, and not unimportantly, the residents switched off boilers and electrical equipment when they were away for at least two days.

### ***Energy use since 2010***

Table 2 gives values for energy use figures, measured between 2010 and 2016. All values have been converted to 365 days, and heat values were calibrated according to degree days.

Table 2. Energy sources and energy content per unit

Date	Electricity	Savings	Heat	Savings	Total	Permanent	Savings
02-10-2011	4,676 kWh	17%	36.0 GJ		56 GJ / 15.6 MWh	1.77 kW	
31-10-2012	4,338 kWh	23%	25.6 GJ	29%	42 GJ / 11.8 MWh	1.35 kW	24%
16-11-2013	3,946 kWh	30%	74.7 GJ*	-108%	89 GJ / 24.7 MWh	1.82 kW	-56%
08-11-2014	3,822 kWh	32%	28.9 GJ	20%	43 GJ / 11.9 MWh	1.36 kW	24%
07-11-2015	3,739 kWh	33%	24.3 GJ	21%	38 GJ / 10.5 MWh	1.20 kW	26%

\* In 2013 a very odd measurement was done by an official of the energy company. Although no fraud by the official could be proven, the energy company returned the extra costs of 2013 in the years after, when the dwellers had proved the falseness. So this measurement can be ignored.

Converting the results of Table 2 to the main author only, taking the two kids as one adult, the personal use after these years of savings turns out to be 12.6 GJ or 3.5 MWh, 400 W permanent. This is 55% less than the average Dutch person. For this use of electric energy renewable power is purchased off an organic farmer with PV on his stables, via energy company Vandebron (literally ‘from the source’). So the house considered is not energy-neutral – it does not produce all of its own energy – but it is carbon neutral – all energy it uses is from renewable sources.

### ***Further savings***

Following the New Stepped Strategy [Dobbelsteen 2008], further reuse of waste heat (step 2) is difficult since heat from exhaust air is already recovered and installing heat recovery systems on waste water from the shower and bath is practically impossible.

That leaves the following measures for reducing the energy demand (step 1) still to be taken: achieving better airtightness by foam strips (executed in the winter of 2016), applying curtains in all rooms (still to be done), and using external sun-shading (see next).

A greater production of renewables (step 3) could be achieved by a solar collector, but in combination with the heat pump system already installed, the added value is very limited, and extra expenses disproportional. Adding more PV is only possible on the facades, for which approval is necessary of the house owners' society and municipal architectural committee. More interesting would be to combine external sun-shading with PV strips (louvres) on the south façade next to the roof terrace (a big source of undesired heat in summer). This is currently explored. Adding a small wind turbine next to the PV on the upper roof (for instance the Windleaf, by Windchallenge) is spatially possible but with a projected annual yield of around 800 kWh and an investment of more than 3000 euro, return on investment still takes about 20 years. It is however considered seriously.

It appears, as with many dwellings in dense inner-city locations, possibilities for personal production of renewable energy (and hence, becoming net-zero energy) is limited, leaving the sustainable procurement as a good option.

### **Personal transportation and commuter travel**

#### ***Situation before and after 1 January 2010***

In December 2009 the main author, following his appointment as full professor at TU Delft, moved from Amsterdam to Delft, changing his modal split from riding the train and cycling to and from stations to cycling directly to his faculty building. Regardless of this commuter transport there of course also is personal transport, which will be elaborated shortly here.

#### ***Cycling and walking***

Cycling costs approximately 60 kJ/km (per person). Energy for this comes from food. Before 2010, the main author cycled 5 days a week, 10 km a day, which comes down to 2,300 km a year. In energy this equals 138 MJ. After 2010 the cycling distance halved to a maximum of 5 km a day, 5 days a week, entailing an energy use of 79 MJ.

#### ***Public transport: train rides***

Trains use 80 Wh/p.km of electricity, based on average occupancies in Dutch trains. Before 2010 for his commuter transport the main author travelled 5 days a week over a distance of 72 km, a total annual distance of 33,000 km. The electric energy needed for this was 2600 kWh (9.36 GJ). After 2010 this dropped to an average of train business trips of 80 km a week, a total annual distance of 3,700 km. This implies an energy use of 294 kWh (1.06 GJ), 90% saved.

#### ***Private car use***

The main author has a private car, a Volkswagen Transporter T4 camper van with Transfalia infill. It has a 2.4-litre diesel engine, and it uses one litre for 11 kilometres on average. Hardly energy-efficient but seldomly used and a sustainable means of combining travelling with holidays on campsites in summer. The car is used for the whole family, two adults and two teens, which we count as 3 persons, so the individual share for the main author is one third.

Before 2010 the main author used the car for 12,000 km a year, using 1,090 l of diesel, which equals 36,3 GJ. Divided by three this means a personal use of 12.1 GJ. After 2010 care use dropped to 9,000 km a year, implying a use of 750 l of diesel with the energetic equivalent of 27,3 GJ. The main author's personal use therefore is 9.1 GJ.

### **Conclusion**

Seeing the figures for transportation one noticed the big difference of energy used for cycling, riding trains and driving cars. The car, even with a smaller distance covered than the train uses by far the most energy per person. For the main author's private travel the total energy use went from 21.6 GJ in 2010, to 10.2 GJ (2.8 MWh) after that year, an energy saving of 53%.

Since 2017 the Dutch railways ride on 100% of renewable energy (wind power) after one year of 50% of renewables. So the only real problem to become carbon neutral is the main-author's diesel-fuelled car, with a share of 41% of his total energy use, including the house.

### **Other factors of individual energy**

#### ***Business travel and the energy of flying***

Based on energy data of air travel the main author has kept track of his business trips since 2011, consisting of train rides in the Netherlands and neighbouring countries (Belgium, Germany, UK), some distances covered by car and flights. The energy use of airplanes strongly relies on the distance covered, the airplane itself and the occupancy.

Based on the distance and mode of transport, 2011 showed a relatively modest energy use of 3.2 MWh (11.5 GJ), 90% of the personal use of energy for the house. 2012 saw 3 intercontinental flights and 3 continental flights, which led to a total energy use of 47.6 MWh (171 GJ), seven times more than the energy used for house and personal travel. In 2013 business travel reduced to 42.7 MWh (154 GJ), in 2014 to 32.6 MWh (115 GJ), but thanks to the success of European research projects and international collaboration the energy consumed for business trips in 2015 and 2016 was greater than 50 MWh.

#### ***The energy of food***

As already introduced, food is an important factor for energy consumption. The term of 'food miles' indicates the distance that food has to travel to arrive in the supermarket; also the means of transport and necessity of frozen or chilled storage plays an important factor. Not to forget the production of food in greenhouses, under optimised conditions, requiring heating in winter, to mention one aspect. Meat and fish cost more energy than other foods; meat is the killer when considering greenhouse gas emissions [[www.landshare.org](http://www.landshare.org)]. So becoming energy-efficient and low-carbon requires a conscious lifestyle that includes wise selection of food. The authors made a calculation of average eating patterns and compared these to vegetarians or vegans, which made a big difference when taking an American lifestyle as the basis [US Department of Agriculture] and less so when looking at a continental European [RIVM]. In general, eating seasonally fitting food avoids a lot of energy for transport and storage. Most effective is eating less meat.

#### ***Other sources of individual energy use, not assessed***

There are many more elements of life that cost energy and that have not been assessed for this paper. For instance, pumping out rainwater, producing drinking water and processing wastewater all cost energy. Furthermore, the extraction, transport and processing of resources requires energy that can be considered as 'embodied energy' of materials and

products. A particular kind of products are clothes and what we may call stuff. Almost impossible to assess all of these, they form a part of everyone's life and choices, hence have an important influence on the environment.

## Conclusion

In total, in the year 2015, the individual considered used 22,8 GJ or 6,3 MWh for his house and personal travel. This is 41% less than the reference year and 49% less than the average Dutchman. The actions taken by the main author clearly led to a lower footprint. Of the energy used, 60% is carbon-neutral, the diesel van being the main problem to be solved. Net-zero energy living is possible but difficult when considering dense urban circumstances, but everyone can be carbon neutral when energy is procured from renewable sources. For mobility, unless one can fully use human-powered or public transport, becoming energy- and carbon-neutral is more of a challenge, and this particularly holds true for flying. The calculation of energy for flying goes to show that painstaking efforts to reduce the energy used at home to carbon-neutral and nearly zero-energy are terrifically over-compensated when flying for business (or for private goals).

If all energy used at work were to be accounted to employees, we would have to include many more sources of energy use: the office, ancillary company utilities, the conference for which this paper was written... Perhaps all of these factors should be included. After all, in the near future we will all have a carbon budget that cannot be exceeded, produced at home or at work does not matter then. Therefore, one of the next steps is to convert all energy use related to the university to all of its employees and students. Including these factors will increase the individual influence one can have on the national energy use from 30 to at least 50%.

This individual research clarified the greatest challenges and most effective strategies of living in a modern, dense city, with abundant access to unsustainable food and with easy opportunities to travel unsustainably for little money. As it held a mirror before the author, it will hopefully do as well before a greater audience.

## Cognitive mapping as a link between the urban designer and space user

**Dr. Marwa Adel Elsayed<sup>1</sup>, Dr. Walaa S.E. Ismaeel<sup>2</sup>**

<sup>1</sup>The British University in Egypt, Marwa.Adel@bue.edu.eg

<sup>2</sup>The British University in Egypt, Walaa.Salah@bue.edu.eg

**Abstract:** The Visual Identity of open spaces results from our cognitive image. This can be the result of both physical and non-physical ties to the landscape change. It affects users' perception and provokes their senses. Recent researchers revealed there is a gap between the intended design developed by the urban designer and the users' cognitive map of the space. The research aims to determine the most important factors that the urban designer should keep into consideration to reduce this gap. The research used semi-structured interviews & mapping tool to analyse the landscape change over the past 10 years for open space food courts in three new residential communities in Egypt. The result presents a comparison between the three perspectives for landscape change; 1) theoretical guidelines for designing urban space elements, 2) urban designer's design approach and 3) users' cognitive map for open spaces. This method can be used to convey, share and exchange information for landscape designers, urban planners and decision makers.

**Keywords:** Cognitive map, Cognition, Landscape Change, open Space.

### Introduction

Human cognition is a reflection of what is processed in memory as a result of the perception of featured elements and experiences. This is developed into knowledge and understanding of the surrounding context and includes processes of reasoning and judgment (Adams & Aizawa, 2010; Lewandowsky et al., 2012). It depends on a set of physical and psychological factors. The former constitute factors related to the design of space elements, while the later constitute factors related to users' age, sex, metabolic activity, culture and occupation (Berto, 2005). Yet, few studies have provided an empirical basis to consider the use of cognitive maps in designing open spaces in Egypt (Marwa Adel El Sayed and Ayman Mahmoud Hassan, 2015). This contradicts with the poor knowledge that urban designers and landscapers have about users' cognitive map (Marwa Adel El Sayed and Ayman Mahmoud Hassan, 2015)

The study is divided into two parts with ten years apart. It aims at comparing the principles of landscape design change through the main cognitive factors indicated in the first part of the study for open space food courts. According to Oxford dictionary, Food court is defined as the area in a shopping mall where fast-food outlets are located. The study uses analytical methods and techniques to structure and display the case study data. It also uses structured interviews to characterise users' cognition towards open space design.

### Literature review

Previous studies have attempted to understand the relationships between landscape characters and how this affects visual perception. Some studies used statistical analysis such

as multivariate analysis, cluster analysis (Hagerhall, 2000; Hoffmann-Kroll et al., 2003; Ruiz & Domon, 2009), photographs and interviews (Polat & Akay, 2015; Nitavská, 2011).

### **Landscape features as a Communication language**

Brown & Brabyn (2012) stated that understanding and managing landscape values require investigating a common set of terminology for landscape interpretation (Brown & Brabyn, 2012). Some studies have pointed the need to have a classification of landscape characters to develop a common language of visual vocabulary and act as a reference for communication at the most basic structural, perceptual and aesthetic levels (Atik et al., 2016; Brabyn, 1996). This includes cultural features, aesthetic features and value features and elements. This develops the distinct and recognisable character of landscape design based on common vocabulary and language of particular features and values (Swanson, 2002; Turner, 2006; Jessel, 2006). Hence, characterization is developed into communication through conceptual grounds of objective, subjective and interpretive cluster analysis (Caspersen, 2009).

### ***Space change, interaction & multi-functionality; Forces of change and interaction***

Quinn & Bhatt (2012) stated pinpointed that our perception of our environmental is influenced by both temporal and spatial factors (Quinn & Bhatt, 2012). According to Palang et al, (2000), understanding landscape change can be used to draw prediction scenarios for the visible, material changes. Such scenarios should create the transitional link between the past and future trends in landscape design (Palang et al., 2000). Landscape component and value is composed of both individual elements and landscapes as a whole, and that the former is only meaningful when perceived within the whole landscape context (Antrop, 1997; Naveh, 2000). This requires methods of exploring the divergent methods of understanding, evaluation and goals which caused the change, and motives of different stakeholders which could affect their role in managing landscape change (Marcucci, 2000). It also requires methods of monitoring, evaluating and managing change through both quantitative and qualitative analysis such as the landscape impact analysis method (Emmelin, 1996).

### **Methodology**

This study targets outdoor food court spaces as recently introduced amenity areas in the Egyptian context. The paper adopts an analytical comparative approach that uses both the tools of data collection and data analysis. These tools allow an approach that is structured based on cognition science. Both qualitative and quantitative data have been compromised in the research. The tools of the qualitative data are built on literature review and collecting deferent methods of thematic cognition. The tools of quantitative data are mainly built on site observations, structured interviews, and structured questionnaires. Ten percent of the space peek daily users have been interviewed. Hence a number of 210 users were interviewed in Rehab food court, 250 users were interviewed in Safari food court, and finally 200 users were interviewed in the district food court. The users have been divided according to the gender (male, and female) and each are divided into three age groups. The first age group ranges from 18 to 40, the second ranges from 40 to 60, and finally the third over 60. Through the designed questionnaire and the structured interviews three main aspects were measured. It starts by investigating the elements that enhance users' perception through internal and external factors. The former is based on the users' grounding experience and the latter is related to material of the surrounding space. Then it is followed by studying the elements that enhance the users' cognition processes. Those elements are divided into age, sex, culture,

and previous experience for the users. Finally it considers the demands for both the outdoor environment and outdoor activities that support forming an identical cognitive map.

The study aims at investigating the effect of time on landscape design principles and how this affect users' cognitive map in outdoor food court areas. It is divided into two parts carried with 10 years difference. Ten main criteria were deducted from part one of the study as a result of a comparison between urban design theories state, users' perception, and urban designer's intended design. Part two of the study tests the effect of time on landscape change in terms of these criteria.

### **Part one (March 2007)**

This part aimed at investigating users' perception which is developed into individual preferences. The study used structured questionnaires, structured interviews, and site observations. The practical field study was completed for two food courts; Safari Zone food court and El Rehab food court. The former covered a wide service area due to its location lying along the main spine of Cairo-Alexandria within a business, commercial, craft context. Its unique location is considered an attracting destination for Cairo citizens; the food court size was one (100 meters \* 10 meters). The later was located along Cairo El-Suez road surrounded by a residential compound, which mainly serves Rehab, Nasr city, and Heliopolis residents. The food court size was one hundred and (80 meters \* 50 meters) as shown in Figure 1.

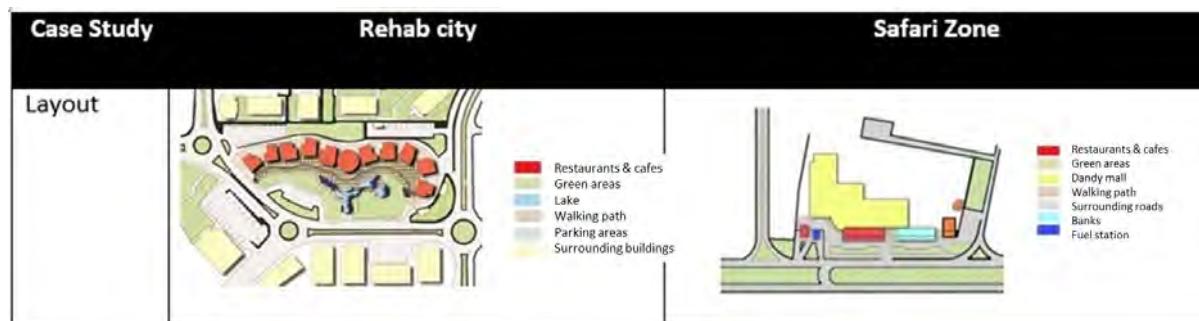

Figure 1. The layout of the two food courts

The study highlighted seven principles for urban and landscape design, those are; size, enclosure, entrances, boundaries, furnishing, Morphology of surrounding building and pedestrian safety. This is in addition to three factors that aid to provoke cognitive image using senses, those are; landmark, paths and unobstructed view.

Conferring to different urban concepts and theories, Lynch (1960) has recommended that the optimal size of an urban space varies from 24m to 137m, and Gehl (2011) proposed that it should not go beyond 100 m (Lynch 1960; Gehl 2011). Users' sense of enclosure is enhanced when the ratio between the vertical and horizontal planes is 1:2 or 1:3 respectively. If the ratio goes down to one-fourth or less, the users start to lack the enclosure sense of the space. The urban space entrance should be visible and welcoming to users and exposed to public right of ways. As for space furnishing, the open-air sitting is divided into two categories, the first category is sitting benches that are preferred to be placed one m linear of seating for each nine square meters, and the second category considers walls with height forty-five meters that may be with or without a handrail. According to the law of Gestalt of simplicity continuity and similarity of form, Morphology of surrounding building can be perceived more easily than other complex buildings (Jäkel et al., 2016). Pedestrian safety is improved through elimination or reduction of vehicle and pedestrian conflicts throughout separation of space,

either vertical or horizontal, or via time separation. Additionally, provoking cognitive image using senses should be achieved using more identifiable landmarks with a clear form and contrast with the background. The placement bed of the path should be finished from one type, to provide a sense of continuity to the observer. The path width should follow the following equation Path width = V (M) / S. Unobstructed forward view for pedestrians for walking is 10.6 m plus (Huang et al., 2014).

Table 1 presents the results of the comparison and the researchers' observations. The green colour indicates the matching of views and the red colour indicates a conflict of views.

Table 1. Shows the results of part 1 of the study

Urban Space	Theory	Reality	Users	Researchers' observations
<b>Space size</b>				
Rehab				Not only is the space size that gives the users a sense of relief and content, but it related to the surrounding urban morphology. This includes the height and arrangement of surrounding buildings inside the space. Space size may be the same but users' perception may change depending on urban morphology. This may consequently reflect on their feeling of safety, containment and relief inside the space.
Safari			Red	
<b>Space Enclosure</b>				
Rehab				Users' feeling of safety in urban spaces is enhanced by reduction or elimination of vehicle circulation crossing with users' circulation. This can be done physically through horizontal and/or vertical separation, and it can be done through time separation as well. It is important to note that the larger the street width, the more separation is required.
Safari			Red	
<b>Entrances</b>				
Rehab		Red		The food courts' entrances provide a welcoming approach for many users. This is the case in the Rehab food court, the entrance is facing the stairs path of the parking lot, and the entrance of Safari is located along the path of the parking lot.
Safari		Red		
<b>Space boundaries</b>				
Rehab	Red			Space definition enhances users' visual perception of the urban space. Bounding the spaces by at least one main street increases the accessibility to open spaces.
Safari	Green			
<b>Space Furnishing</b>				
Rehab		Red		Proper space Furniture reflects on users' perception of the space and forms a strong cognitive map. This creates a social relationship among users and enhances their sense of the urban space
Safari	Green	Red		
<b>Morphology of surrounding building</b>				
Rehab				Easier urban space morphology and functionality enhances users' perception of the space.
Safari				
<b>Pedestrian safety</b>				
Rehab	Red			Vertical separation positively effects forming identical cognitive map than the horizontal separation.
Safari	Red			
<b>Landmark</b>				
Rehab				Landmarks may have a positive or negative effect on forming users' cognitive image of the space.
Safari	Green			
<b>Paths</b>				
Rehab		Red		Path stresses users' cognitive map, particularly through walking activity.
Safari	Green	Red		
<b>Unobstructed view</b>				
Rehab				Unobstructed view enhances forming an effective cognitive map.
Safari	Green			

## **Part two (March 2017)**

The past ten years have witnessed wide spreading of open spaces food courts users. Hence, this part of the study is going to investigate the District food court which has been developed recently. The results of this part of the study apply the previously highlighted factors to deduct landscape change that has been developed over the past ten years and its effect on users' cognitive map.

### ***The District Sheraton***

The food court lies alongside the ring road between two main residential contexts. It mainly serves the resident of Heliopolis and Nasr city. The size of the food court is 180m\*120m. The food court is surrounded by Wadi Degla club from the north, the ring road from the east, the kids' area from the west, and the furniture Complex from the south as shown in Figure 2. The buildings surrounding the urban space have almost the same shape, finishing and colour. The space is mainly divided by one main path leading from the entrance and divided into two paths to embrace the lake which is considered the space landmark. The influence of and experience and age is perceived to be the maintenance and development of cognitive illustrations for surrounding environments.

Figure 2. Shows the layout of The District Sheraton

## **Results and Discussion**

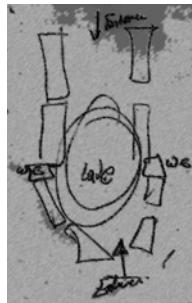

The results are divided into two sections

### ***Analysing cognitive maps***

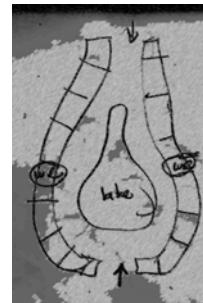

Through analysing the users' cognitive maps for the district open space as shown in figure 3, it has been found that most users' cognitive maps indicate mutual elements (Lake, Restaurant and café, toilets, Parking lots, and Stairs entrance) and also misses other mutual elements (Green areas, and Walking path). Hence, the researcher granted Singh's idea that discussed the relation between the age of the user and the precision of cognitive map which is well-thought-out as a directly proportional relation (Al-ghamdi & Al-Harigi, 2015).

Lynch (1960) indicated that paths and Landmarks serve as primary route-finding clues in urban spaces (Lynch, 1960). On the contrary, it has been found that the lake as the main landmark has drawn users' responsiveness, but only 33% of them have sketched the main path. Similarly, the researcher approved Downs and Stea idea (1973 & 1977) that stated missing any of the buildings in users' maps means that this building had not drawn the users' attention. Additionally, Gehl (2011) addressed the importance of drawing users' senses of

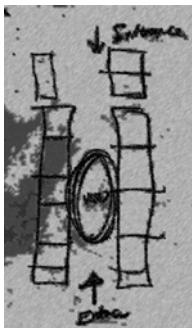

vision, hearing and smelling to develop an identical cognitive map (Gehl, 2011). Investigating the urban elements, the urban designer was able to attract the sight sense of the users, and this was noticeable in their maps, but he was not able to appeal the hearing and smelling senses of the users.

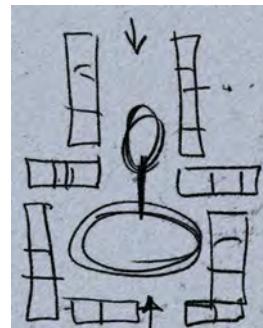

Male, age 18- 40, undergraduate student

Female, age 40 - 60, engineer

Female, age 18- 40, undergraduate student

Male, age over 60, police man

Figure 3. Users' cognitive maps

#### *Interviewing users*

The researcher has interviewed a number of users, as the questions aimed to show the users' desires and opinions. These questions are divided into three main sections. The first section aimed to detect the main function the users target the space for. The resulting percentages were indicated; 60 % eating, 20% reading, 10% walking and 10% watching shows. It is noted that users from age twenty to over fifty have grumbled about the far away distance of the children play area.

The second section mainly aimed to show the main activities that users implement in the space. These activities are; sitting, walking, and standing. Sitting at the space centre is chosen to be a preferable choice for users than sitting at the edges. Most of the users complained about the lack of the sitting places, and they showed their desire in preferring movable benches facing the view than fixed ones. Hence, siting uncomfortably affects negatively the users' cognitive map

The users agreed that the paving material of the path is really suitable for walking, except for the narrowness of the path that is not suitable for free walking. This caused manoeuvring or pushing or disturbance. Handicapped and mothers with baby stroller added that they do not prefer the presence of steps in the path. Which may be a clear cause for not illustrating the path in the users' cognitive maps as they are not able to perform free walking.

As for the standing activity, users have been distributed into two classes. Around 57% of them chose to stand under shelter, and 43% chose to stand in open space, but all the users chose to stand at space edge rather than standing at the centre.

The third section presents the results of the one to one interview with space users. Almost all the users have granted that urban space is utilised positively except for the remoteness of kids' area, and lack of places for sitting. As they can spend there from three to five hours inside the space, enjoying relief and containment. The space is vertically separated with lower steps, so users are rarely affected by the noise or the crowd of the surrounding streets. Through the researchers' daily observation, It has been found that eating, reading, and using laptops take place during breakfast time, walking activity during lunch time, and finally sitting activity during dinner time. Males preferred to spend their dinner time in the space, while females preferred to spend their breakfast and lunch time inside the space. Most of the users stated that the seasons affect the urban space's image. This can be observed in the changing image of the space during Christmas times and Ramadan. Nearly most of the users established that they got tangled among the morphology of the surrounding restaurants as the designs were almost alike. This fact explains Gestalt law (Jäkel et al., 2016) as the modest building are easily recalled and illustrated in users' maps, but also morphology repetition may lead to misperception.

## Conclusion

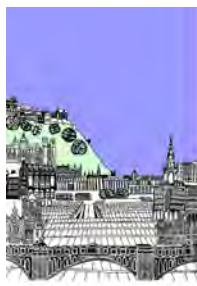

Very few studies attempt to evaluate open space design. Hence, this study attempts to fill this gap. It investigates the use of cognitive maps as a catalyst to develop open urban space design. Table 3 presents researchers' observation for the landscape change for the two parts of the study. A colour code has been used to signpost its effect on the ten previously defined criteria for the two parts of the study. The green colour indicates no change, while the red and green colour indicates a change process.

Urban Factors	Part one	Part two	Researchers' observations
Space size			Space size complied with theories recommendations
Space Enclosure			Space enclosure was better reflected in the later design, integrating both linear and circular space enclosure.
Entrances			Better accessibility is pronounced in the later design through providing two entrances
Space boundaries			Recommendations for space boundaries are achieved in the two parts of the study
Space Furnishing			No change furnishing was provided in the two parts of the study. Hence, recommendations of previous studies should be taken into considerations for providing space furnishing.
Morphology of surrounding building			Both parts followed Gestalt law, users feelings of redundancy and confusion are reflected in users' cognitive maps.
Pedestrian safety			The vertical separation promoted users' feeling of safety.
Landmark			Both parts followed Lynch's theory (1960).
Paths			Both parts show that case studies did not consider users' needs.
Unobstructed view			Both parts show compliance with the theoretical recommendations.

## **Indoor Environmental Quality Design for Advanced Occupant's Comfort – A Pre-post Occupancy Evaluation of a Green-Certified Office Building**

**Ihab Elzeyadi<sup>1</sup> and Stanley Gatland II<sup>2</sup>**

<sup>1</sup> Professor of Architecture, School of Architecture + Environment, University of Oregon, Eugene, Oregon, USA, email: ihab@uoregon.edu

<sup>2</sup> Manager, Building Sciences and Comfort, CertainTeed Corporation, Malvern, Pennsylvania, USA, email: stanley.d.gatland@saint-gobain.com

**Abstract:** The aesthetic and functional appeal of high performance green-certified building is daunting. It creates a hyped expectation of better energy and indoor environmental quality (IEQ) performance that is usually hypothesized to improve occupant's health and productivity. Despite the favourability of this hypothesis, most recent studies have failed to prove these linkages leading to non-conclusive evidence of green building performance. Most previous limitations point to methodological deficiencies in quantifying occupant's experience, as well as the comprehensive measurements of physical and behavioural environmental factors of place in an integrated and comparative approach. The specific question of this project is whether a well-planned evaluation study with pre-post occupancy analysis of a retrofitted green-certified building could lead to more conclusive findings related to the impacts of green buildings, in general, and those with specific high IEQ on occupant's well-being, health, and productivity. This paper reports on a longitudinal assessment of a commercial high performance LEED™ double platinum retrofitted building. The building houses 800 employees working within 270,000 sq.ft. (18,000 sq.m.) of open-concept office space. The buildings were monitored for IEQ parameters of visual, thermal, acoustical, indoor air, and spatial comfort over a period of one year before occupancy and retrofit as well as a year after occupation. Continuous and intermittent measurements were performed and pre- /post-occupancy evaluation surveys were conducted. Results show strong correlations between improved visual, acoustical, and indoor air qualities of the retrofitted green environment that is well correlated with improved employee's productivity and satisfaction. Implications and spatial visualization are discussed as well as a continuous commissioning approach to improve the thermal environment through additional retrofits and occupant's behaviour. Proving that, for high performance buildings both the occupants and the buildings require on-going dialogue to ensure the occupants are able to adjust to the building systems and achieve its desired levels of performance.

### **Introduction – The quest for high-performance buildings**

If you build it will they come? How would they feel when they occupy it? And in what ways does a high-performance office environment impact occupant's productivity, health and well-being? These questions summarize important, yet under studied, objectives of high performance and LEED™ certified green buildings. Not only do green buildings propose to combat the building industry's energy addiction, but they also promise the market a reduction in greenhouse gas emission, better indoor environmental quality, and more recently a value proposition that they provide better health and well-being for their occupants.

Employers, building owners, designers, developers, and investors throughout the world are persuaded, in response to an increasing marketing campaign by the building industry, that office design affects the health and wellbeing of occupants in many ways and so it is a smart business move to create green buildings that are healthy (Elzeyadi, 2016). With staff accounting for 90% of business operating costs, a 1% improvement in productivity can have a major impact on the bottom line and competitiveness of any business (Kats, 2003). Building developers, owners, and investors are also discovering the business value of delivering to their markets healthy and green buildings. In a survey of 200 Canadian building owners, for example, 38% of those who reported increased value said healthy buildings were worth at least 7% more than normal ones, 46% said they were easier to lease, and 28% said they commanded premium rents (WGBC, 2016).

Despite the favourability of this hypothesis, most recent studies have failed to prove these linkages leading to non-conclusive evidence of green building performance. Most previous limitations point to methodological deficiencies in quantifying occupant's experience as well as comprehensive measurements of physical and behavioural environmental factors in an integrated and comparative approach. The specific question of this paper is whether a well-planned evaluation study with pre-post occupancy analysis of a retrofitted green-certified building could lead to more conclusive findings related to the impacts of green buildings, in general, and those with specific high IEQ on occupant's well-being, health, and productivity. The paper builds on a previous interpretation framework of sustainable design as a place experience (Elzeyadi, 2015), thus acknowledging the complex systems of interactions between people and their indoor/outdoor environment on multiple layers relating to multi-comfort parameters, occupant's productivity, and symbolic perceptions of their building as a facilitator or inhibitor of performance.

### **Conceptualizing indoor environmental quality as a sustainable place experience**

Building on early definitions of place experience (Canter, 1991; Rapoport, 1989) this paper defined indoor environmental quality (IEQ) as all the qualities of the place that are collectively perceived and evaluated by its occupants as affecting their needs, wants, and the tasks they perform, without impacting the global environment in both products and process. Following a systems perspective, qualities of a sustainable place experience can be grouped in intellectual taxonomies according to their levels of meaning to occupants. These are: (1) sustainable attributes, which groups all the utilitarian qualities of the environment, (2) sustainable aesthetics, reflecting middle-level latent meanings, which represent value function qualities of the environment, and (3) sustainable ambience, higher-level symbolic meanings that are related to symbolic qualities of the environment (Elzeyadi, in press). Each level of meaning will group a number of qualities that form a profile. Each of these qualities can be perceived as a "negative" or "positive" attribute of the environment depending on whether it facilitates or inhibits the occupants' experience, as well as how well it satisfies their wants and needs. The paper adopts a systems interactions framework between occupants (people), their settings (buildings), and place (environment) following the triple bottom-line approach epistemology that defines sustainable place experience.

### **The Study Context – A double Platinum LEED™ Office Building**

To validate the proposed IEQ model, different spatial configurations and IEQ design strategies were assessed and measured for a double platinum-rated LEED™ building (USGBC LEED v3 Core and Shell and Commercial Interiors) over an extensive 18 months renovation. The

existing building was stripped down to the steel and concrete structure and enclosed with a high performance building envelope and glass façade. The interior open-plan office space was designed to maximize occupant comfort, as well as improve the health and well-being of the employees. The four-story 25,734 sq.m. headquarters is located on a 263,046 sq.m. mature landscaped site, 40 kilometres west of Philadelphia in Malvern, Pennsylvania, USA. The corporate site includes 18,000 sq.m. of open-plan office area, 116 collaborative spaces, a cafeteria, pantry areas, a fitness centre, a pond, outdoor workspaces by a rainwater fountain and 2.1 km of walking trails to further enhance the employee experience (Figure 1).

The state-of-the-art facility was designed to promote cross-collaboration, as well as attract and retain talent. Sweeping views of nature that provide an abundance of natural light are possible from 92% of the interior space. Continuous fresh air ventilation and no- or low emitting materials were employed to create excellent indoor air quality. Acoustic comfort at the 800 plus workstations was created through the thoughtful placement of sound absorbing surfaces, noise reducing interior partitions and an active sound masking system.

Figure 1: The building complex before (right) and after retrofit (left)

### **Indoor Environmental Quality and Multi-Comfort Analysis – Multi-method Approach**

Multi-Comfort parameters and metrics with the thermal, visual, acoustical, and air quality environment were assessed and analysed for both before and after green retrofitting the building. Both instantaneous and long-term field measurements data of the physical

environment and multi-comfort parameters were collected at the level of the building as well as the scale of the occupant work setting. Environmental sensors and data loggers measuring temperature, relative humidity, air velocity, and air movement stratified across the different floor levels of the buildings, were deployed over the winter, spring, and summer seasons respectively. In addition, infra-red (IR) and high dynamic range images (HDRI) were taken over the course of sampled seasonal days for the occupants workstations and from their direct view sheds employing wide angle and fish-eye lenses to simulate their perspective and field of vision. The different imaging techniques were employed to document surface temperature, mean radiant temperature, and glare indices over the study period. In addition, acoustical attenuation, sound levels, and speech intelligibility measurements were recorded for typical office simulated conditions in the field at different times before and after the retrofit. To evaluate indoor air quality, approximately 15 litres of air was sampled for high performance liquid chromatography (HPLC) and mass spectrometry analyses as well as volatile organic compounds (VOCs) concentrations (see Figure 2). Airborne particulate concentrations were measured using a light-scattering laser photometer in the near-infrared light range.

Occupant's perspective and satisfaction was collected by employing a series of structured and open-ended focus groups. Each focus group included 10-15 employees representing different job-levels and workstation locations. This was followed on by administering an occupant survey to the entire employee population before and one-year after the move into the green-retrofitted office building. Response to the survey was very high with 289 employees completing the questionnaire before the move and 320 completing it following the move. Data tabulation and coding were performed on both the physical and human-response data sets. Physical measurements and survey responses were spatially tagged and statistically analysed using SPSS software. In addition, data visualizations and multi-comfort parameters were computed using a suite of software that spatially analysed the occupant's visual, thermal, acoustical and indoor air quality (IAQ) across various locations of the building.

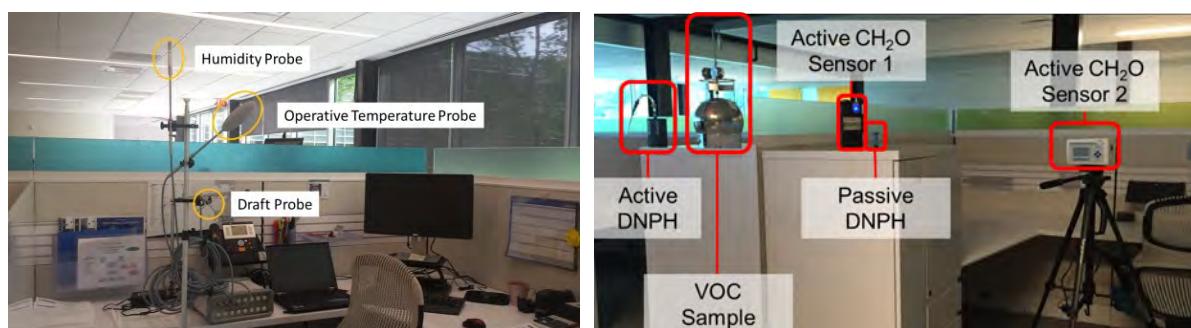

Figure 2: Research Methods and Instruments Used

### **Visual Comfort Analysis**

To evaluate visual comfort inside multiple LEED™ certified work environments, we measured lighting distribution metrics; useful daylight autonomy (uDA100-1000), visual asymmetry, and glare in the field of vision using five glare analysis metrics (DGP, DGI, UGR, VCP & CGI). A comparative analysis reveals how different spatial configurations and proportions between the two phases of the buildings impact both daylight level distribution and glare. With improved envelope performance (Tvis & SHGC) of the glazing as well as higher light reflectance values of space finishes, the green retrofitted building shows more than 70% improvement in daylight distribution. Furniture layout and the provision of flexible working

spaces around the perimeter without cubicles and partitions show substantial impacts on daylighting performance and glare management of the green retrofitted space. This green-retrofit provided better daylighting distribution ( $uDA = 74\%$  and  $DGP = 10\%$ ) over the pre-retrofit condition ( $uDA = 27\%$  and  $DGP = 40\%$ ) in this sampled location (Figure 3).

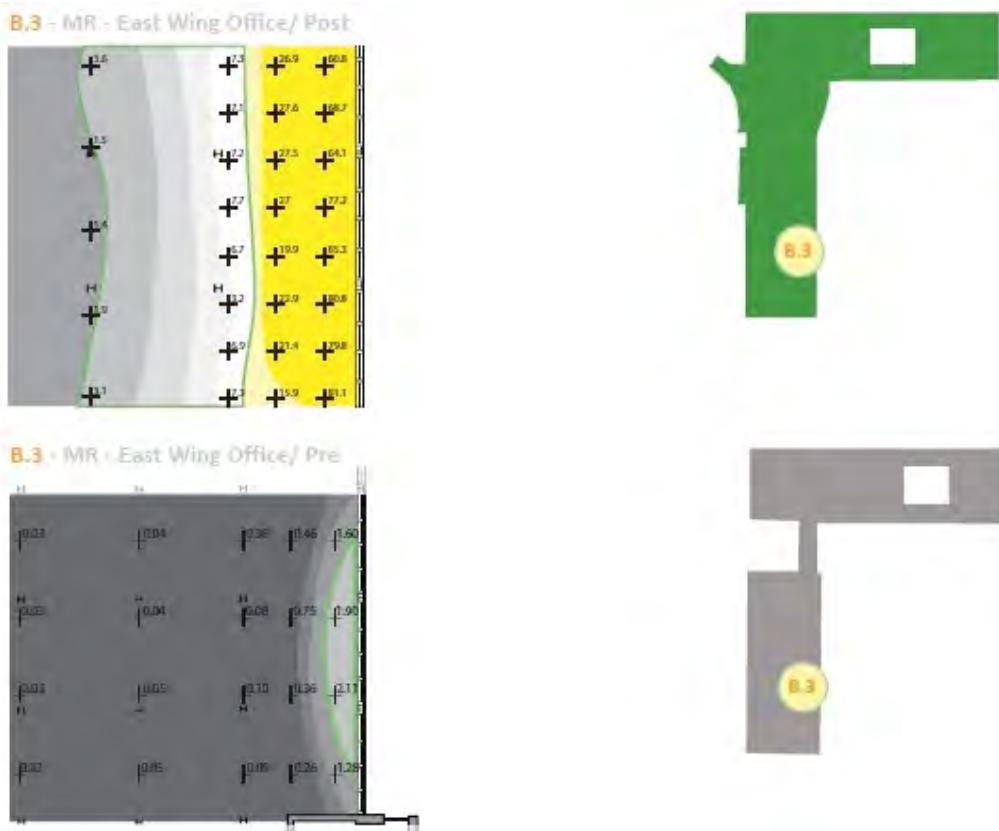

Figure 3: Comparative Analysis of Visual Comfort Metrics for a Typical Floor Area of the building (after retrofit, top and before retrofit, bottom)

### ***Thermal Comfort Analysis***

Thermal comfort metrics were calculated using the measured data and equations described in ANSI/ASHRAE Standard 55-2013. Thermal comfort is visualized for sampled locations using the a Thermal Comfort Plot on the psychrometric chart for both the pre- and post-green building retrofit conditions while acknowledging the occupant's presumed metabolic rate (met) and clothing level (clo).

Figure 4 provides a comparative plot of occupied hours for a typical workstation in the spring season for both phases of the building. Each dot in the psychrometric chart represents the thermal conditions for one occupied hour during a typical spring work day. Pre-retrofit, thermal conditions ranged from completely outside the comfort zone for perimeter workstations (orange dots) to partially within the comfort zones or in-between the comfort and adaptive zone for internal work zones. In contrast, most of the thermal conditions after retrofit fit nicely within the thermal comfort area yet provide enough variation to avoid falling in thermal boredom conditions and still reflect diversity in thermal conditions suitable for occupants' different clothing and metabolic levels within the space in different times of the day.

Figure 4: Comparative Analysis of Thermal Comfort Psychrometric Charts during Spring Season of both Building Phases (green post-move/retrofit, red pre-retrofit, orange pre-move and black outdoor)

### ***Indoor Air Quality***

Formaldehyde concentration was evaluated in conformance with EPA Method TO-11 (US EPA 1999). Approximately 15 litres of air was sampled using collection pumps with flow rates operating at 0.125 l/min. The samples were transported to an accredited laboratory for extraction and analysis using high performance liquid chromatography (HPLC). Air testing for volatile organic compounds (VOCs) was conducted by EPA Method TO-15. The procedure includes analysis by HPLC combined with mass spectrometry. Results of the indoor air quality evaluation are graphically displayed in Figure 5. Values were normalized to exposure limits for each parameter and scaled to 100 percent. Indoor environmental conditions for comfort and gas concentrations were all well below exposure limits for each category.

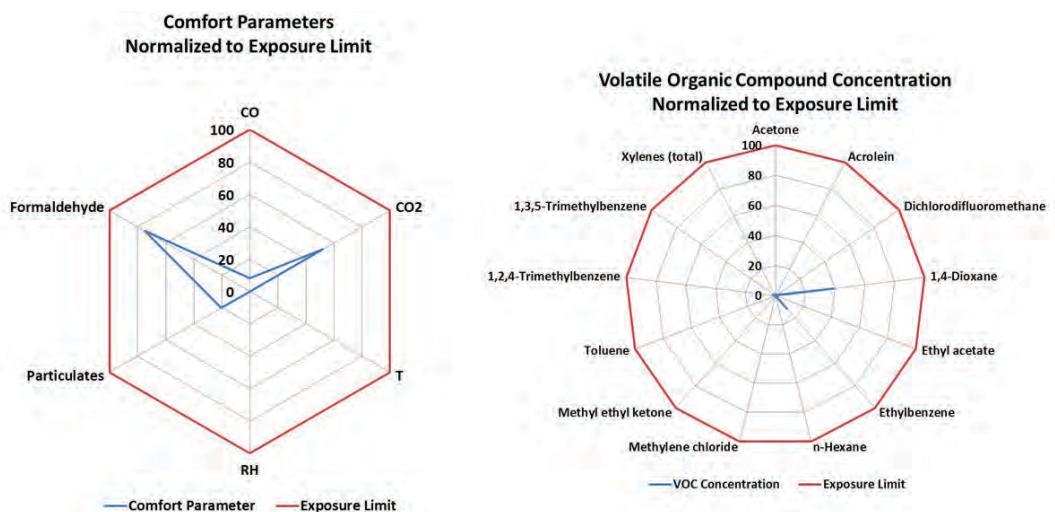

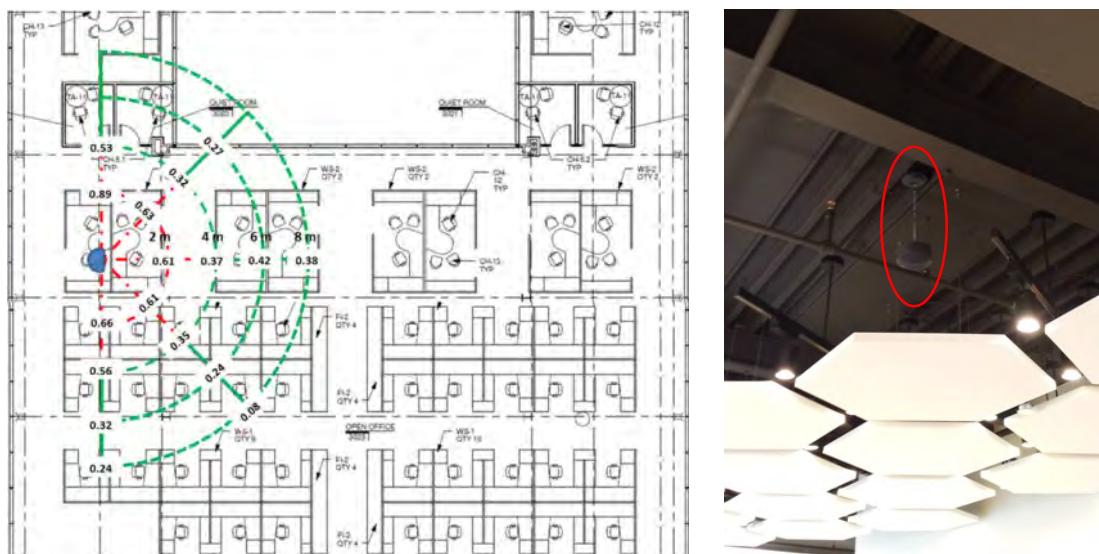

Figure 5: Comfort Parameters and Gas Concentrations Normalized to Exposure Limits

### **Acoustic Comfort Analysis**

The challenge of acoustic design in open concept office spaces is to limit sound reflections and noise levels in large spaces, while creating acoustical privacy at individual workstations. Acoustic comfort can be achieved through the use of sound absorbing surfaces, high performance noise reducing interior partitions and exterior facades, as well as sound masking systems. Managing speech intelligibility between workstations is the goal, so that employees are not distracted by their office conversations. Sound masking systems were employed to generate white noise in the space. The recommended noise criteria (NC) curve limit for open plan office spaces with forced air distribution systems is NC-40 or less. Several workstations were evaluated for spatial sound distribution of the speech transmission index to assess the distraction distance from the speaker where the speech transmission index falls below 0.50. Acoustic comfort mapping for spatial decay and distraction distance with STI is illustrated in Figure 6. Results highlighted by the green lines indicate that the desired distraction distance is achieved within 2 to 4 meters for most locations.

### **Indoor Environmental Quality - Occupants Perspective Analysis**

In addition to physical assessments and visualization of the multi-comfort metrics of the environment, an occupant questionnaire was administered to solicit employees' satisfaction of both buildings. Questions were added to address specific issues such as Thermal and Visual comfort of the various spaces. An average of 32% of the employees for pre-retrofit in and 32% of the employees for post-retrofit completed the questionnaire. Preliminary results of the survey show strong occupants satisfaction with the environmental agenda and green/LEED™ certification of the building. More than 75% of occupants in the retrofitted building agree about the importance to work in a building that is environmentally conscious (Figure 7).

### **Conclusions**

The main objective of this paper is to provide detailed as well as context specific information to assess IEQ inside green buildings from a comprehensive approach. By establishing a comparative approach between a traditional building pre-retrofit and its green retrofitted LEED™ certified platinum phase, the study provides an evidence-based guide of green

building design strategies that impact IEQ parameters. It is important to note that green strategies should not be perceived as “one size fits all” in general and might not be suitable in all design situations. Designers will need to balance pros and cons of green systems as they manage the value proposition of the impact of green buildings on IEQ and occupant’s comfort with actual performance of spaces and the design of a quality environment. This paper provides an overview of a comprehensive study that will be reported-on further with more details in future publications and analyses. The hope is to spur future research to apply the proposed model and contribute to a better understanding of the nature of IEQ in buildings beyond our over fascination of their promised performance and marketing hype. Results show strong correlations between improved visual, acoustical, and indoor air qualities of the retrofitted green environment that is well correlated with improved employee’s productivity and satisfaction. Proving that, for high performance buildings both the occupants and the buildings require an on-going dialogue to ensure the occupants are able to manage the building to achieve its desired levels of performance.

## Active House Label – tool to empower house owners and developers to design sustainable buildings

Kurt Emil Eriksen<sup>1</sup>, Rory Bergin<sup>2</sup>, Amdi Worm<sup>3</sup>

<sup>1</sup> Head of Policy Workgroup, Active House Alliance, kurt.emil.eriksen@activehouse.info

<sup>2</sup> Arch MSc, Partner, Sustainable Futures, HTA Architects, England

<sup>3</sup> Senior Consultant, Sustainability, Arkitema Architects, Aarhus, Denmark

**Abstract:** Active House is a vision of buildings that combines energy efficiency with specific attention to users health and comfort. It include design guidelines, specifications and evaluation tools, and focus on parameters that has relevance and direct influence on the qualities for the homeowner. In order to empower house-owners, architects and professional house builders to design sustainable buildings; the Active House alliance has developed a label, that can be given to projects that meet the Active House requirement and focus on combining requirement to building design with people's concerns regarding comfort, health, energy, safety and environment. It is the holistic view on buildings and the combination of quantitative and qualitative parameters that makes the Active House label unique and it is the focus on affordability and human aspects that makes it valuable for homeowners. A building being labeled must be calculated and evaluated on 9 parameters within comfort, energy efficiency and environment and the calculation must be validated by an independent body.

**Keywords:** Sustainable buildings, Active House, Indoor comfort, Energy efficiency, Label

### Active House

Active House is a vision of buildings that combines energy efficiency with specific attention to user health and comfort, indoor climate and the environment. Active House focus on Comfort, Energy and Environment, and require a holistic view.

An Active House is evaluated on the combination and integration of the three main principles of Comfort, Energy and Environment. The evaluation has to be done in accordance with the Active House specifications and the performance are described through the Active House Radar (Fig 1) showing the level of ambition of each of the three main Active House principles and their nine sub-parameters.

The integration of each parameter describes the level of ambition of the building. For a building to be considered as an Active House, the level of ambition can be quantified into four levels, with 1 as the highest and 4 the lowest.

The building must be evaluated and benchmarked on the nine sub parameters, (Daylight, Thermal Comfort, Air quality, Energy demand, Energy supply, Primary Energy, Environmental load, Freshwater, Sustainability) where each of them is evaluated in accordance with international standards, like EN15251, ISO14040 as well as national standards and methodologies for i.e. energy demand. Some of the parameters are included in building legislation and in this sense, the methodology used on national level can be reference.

Figure 1. Active House Radar

Figure 2. Active House Label

### Active House Label

The Active House label (Fig 2) is a quality stamp for comfortable and sustainable buildings. It is based on elements that are important to humans life and living in their homes. It can be given to projects that have been evaluated in accordance with the Active House specification and has been verified by an independent body.

The label is a sign to homeowners that this building is designed with focus on human needs and a home fit for the future. In order to obtain the Active House label, a project must be benchmarked on the nine sub parameters mentioned above. As some of the parameters are topics that are not yet a legislative requirement to buildings, the label can only be given to buildings that exceed the legislative requirement and focus on more qualities to buildings, like health, comfort and environment.

The evaluation of a project must be carried out by use of the Active House calculation methodology and can be carried out by the architect or a consultant. The calculation is verified by an independent body approved by the Active House Alliance. The independent body carry out a screening of the project and make a sample evaluation on two or more parameters in order to verify the calculation. Based on the outcome of the verification a project can be given the label.

The Active House label was introduced during 2016 and the first five projects has already been labelled. The following projects has been labeled in 2016 and show some of the qualities by an Active House approach to building design.

### Active House Centennial Park – use passive solutions to create good indoor comfort

Great Gulf's Centennial Park Residence is the first labelled Active House. The Active House evaluation (Fig 3) shows how the comfort parameters has been a main focus area, with high score on air quality, thermal comfort and daylight. The home is designed to improve human comfort and well-being. The design is the result of highly process-driven approach to building an energy-efficient home with the use of the Active House vision as guidance. It is developed through the collaborative expertise of a team of Building Science professionals, award-winning architects and Great Gulf, a Canadian home builder committed to evolving the Active House concept in Canada.

Figure 3. Centennial Park Radar

Picture 1: Active House Centennial park

The project includes a clean modernist architectural aesthetic design with energy-saving and environmentally conscious features such as interior and exterior LED lighting systems, low-flow water fixtures and finishes that are easy to maintain. But what ultimately makes this home so appealing is an approach to design that maximizes opportunities for natural daylight and natural ventilation.

Picture 2: Well daylit ground floor due to windows with different orientation and C shaped courtyard

The quality of the design is shown by the strategic use of natural daylighting that defines the true character of the Great Gulf Active House where little to no artificial lighting is required during the day. Visitors immediately notice the light-filled double-height C-shaped courtyard which forms an architectural “anchor” for the entire home. The ground-floor is laid out in an open plan with no barriers to obstruct daylight. And double-height spaces vertically connect upstairs spaces.

To reduce the energy required for air conditioning, Active House Centennial Park contains features that boost air quality while reducing energy for ventilation. Large operable windows and roof windows facilitate natural ventilation and ventilative cooling to keep the house cool during warmer months while ensuring effective ventilation throughout the year. Fully programmable windows feature an intuitively designed intelligent interface to maintain their automatic functioning for natural ventilation purposes.

Picture 3: Double high rooms create good daylight and is optimal for natural ventilation

### **RenovActive – comfortable and affordable renovation for replication**

Renovactive is the first renovation project that has received the Active House label. It is designed with focus on affordability , replication, as well as healthy and comfortable indoor comfort. These were the main criteria set up for the RenovActive project, a single family house of the social housing company Foyer Anderlechtois, located in Anderlecht, Belgium. The aim of the renovation project was to test the Active House principles in social housing and single-family homes.

Figure 4. RenovActive Radar

Picture4. New attic and facade *insulation k*

The project aim to become a guide for how to renovate houses with focus on excellent indoor climate with a good energy performance, therefor several renovation scenarios were considered and their performance was analysed according to the Active House specifications.

The final project is an example of affordable and replicable renovation techniques that not only improves the energy efficiency of the dwelling but perhaps more importantly, focuses on providing the best possible indoor environment (fig 4).

The design targets for indoor climate, energy and environmental impact are based on the Active House Specification. As there is a clear financial frame for the house, the approach in the design process was to evaluate different scenarios that combined different technical solutions. Each scenario was evaluated according to the Active House radar diagram (fig 5).

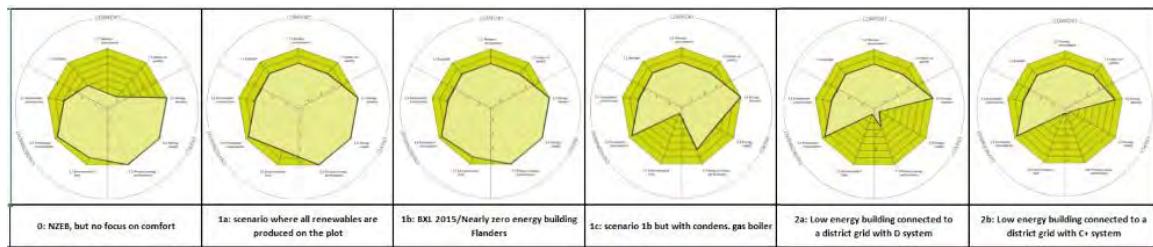

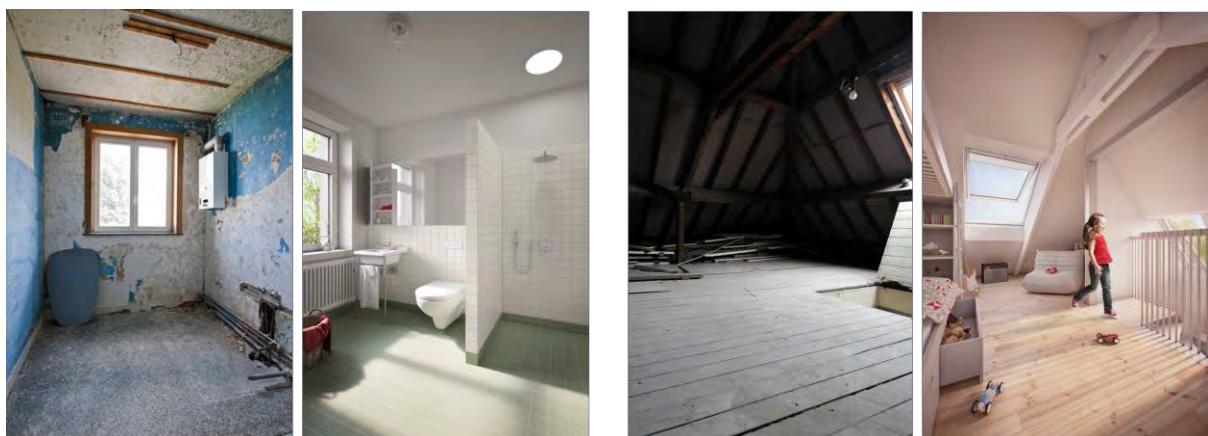

Figure 5 Six out of nine different scenarios based on Active House

The RenovActive House includes a number of replicable elements that constitute the RenovActive concept. All of the elements are implemented as separate units of products and solutions, and optimise essential home performance parameters in relation to energy, comfort and indoor environment – the three pillars of the Active House concept. This flexibility and inherent scalability makes it possible to replicate the project to other buildings in the neighbourhood and match their respective budget.

Picture 5: Before and after renovation of the bathroom and the attic

The RenovActive project focuses on providing maximum daylight. A Daylight Visualizer was used to simulate daylight levels in the building, revealing excellent levels of natural light after renovation. The new roof windows in the new attic will be a good source of natural light and give the inhabitants indoor comfort all year round.

In view of the glazed surfaces, which guarantee levels of natural light and passive solar gains in winter, it is important to control excess heat using fully automated solar protection. The opening and closing of the exterior blinds will depend on the hours of sunshine and the outdoor temperature. The windows will also be fitted with interior blinds that will control the light as desired.

To ensure a healthy indoor atmosphere and a maximum of fresh air in the house, a natural ventilation system is fitted. When the outside temperature is over 14°C, an automatic window-opening system will be used. Natural ventilation will be controlled via intelligent window systems, which makes it possible to easily open or close windows. Sensors (humidity, temperature, CO<sub>2</sub> etc.) integrated into the ventilation unit control the opening of the windows, guaranteeing excellent indoor air quality. In winter, air is let in by ventilation flaps integrated into the windows. This ensures maximum air quality and comfort: the ventilation levels adapt to user needs in real time. This system also saves energy, as it avoids excessive ventilation.

A proposal was made to place solar panels on the roof of the garden shed to heat water but the additional cost generated by the solar collector does not meet the social housing budget for a project like RenovActive and therefore the amount of renewable energy installed on the building is low. However the main issue was to reduce the energy demand and this has been reached by reduction to 60 kWh/m<sup>2</sup> for all the energy need in the building, including heating, domestic hot water, ventilation, technique and lighting. In order to reduce use of water, rainwater will be collected in a 5,000 litre tank and reused for flushing toilets, the washing machine, use in the garden, etc.

### Green Solution House

Green Solution House is the first labelled conference and hotel centre, and it is the winner of the Active House Award 2016. The main target with the project is to inspire visitors by offering a comfortable stay in a healthy and creative environment. The building and landscape show a holistic approach to sustainable design, emphasising regenerative solutions including healthy indoor climate, renewable energy sources, active materials and recyclability. The design of the building itself is based on several parameters to show a holistic approach to sustainability. The building is based on the criteria of the Active House vision (fig 6).

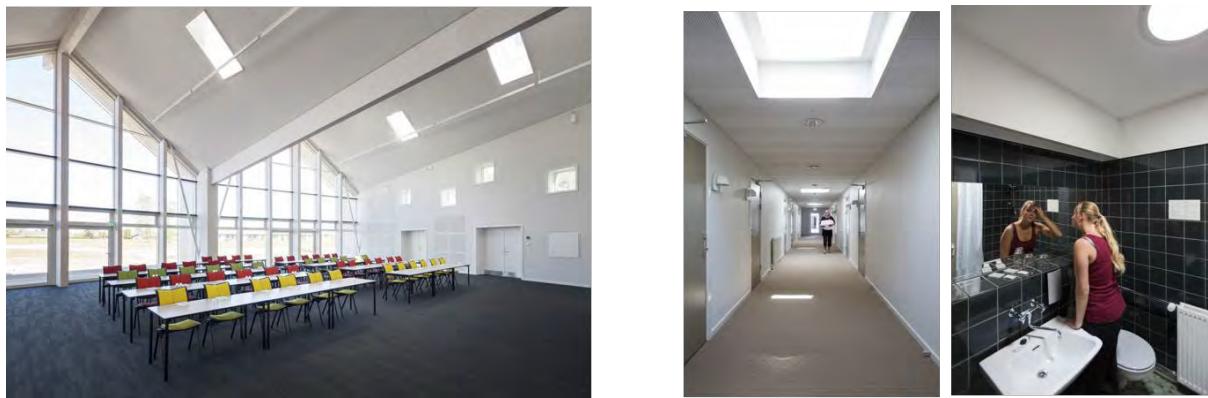

Figure 6. Green Solution House Radar

Picture 6 Garden view - Green solution House

The cycle of natural light is fundamental to humans wellbeing and ability to maintain a healthy circadian rhythm, as well as daylight improves humans productivity and ability to focus.

Therefore the conference rooms at Green Solution House are designed to accommodate meetings in broad daylight, utilizing diffused light from the north. Inside the hotel rooms, daylight conditions have also been optimised with retrofitted glass balconies. Sun Tunnels and light cables redirect daylight to every nook and corner, where natural light is limited, like in bathrooms. In all common areas and hallways, skylights are utilised to create a comfortable indoor climate with generous daylight levels. Altogether, a strong focus on daylight driven design has helped to create well-lit spaces, resulting in better user experience and less energy consumption.

Picture 7: Daylight conditions - optimized in dark rooms like conference rooms, hallways and bathrooms

Clean air is essential to optimising the quality of indoor environments. Green Solution House have created a variety of solutions that contribute to keeping the air fresh and pollutant free. The carpets on the floor absorb dust particles, the plasterboard on the walls take care of formaldehyde, and the roof membrane captures and neutralises pollution particles from traffic. The Green Wall in the Third Climate Zone naturally purifies the air with plants and balances humidity levels.

Picture 8: Supply of clean air is created by use of green wall, permeable ceilings and natural ventilation

The architect has focused on balancing the thermal environment for optimal indoor comfort, by balancing natural ventilation, mechanical ventilation with a heating strategy that response to the seasons. This strategy has resulted in the highest score possible in the Active House analysis of comfort in the building (fig 6). The diffuse ventilation strategy supplies fresh air through permeable acoustic panels in the conference center and restaurant ceiling and has two major advantages in terms of indoor climate. First, the even distribution cools the air without causing discomfort and drafts, and thus reduces supply air requirements and duct sizing.

### **Looking forward**

The three cases shown before have all been developed on the basis of a sustainable guideline that include a higher focus on sustainability than just energy savings. It is shown that by use of such tools the building design is balanced between indoor comfort issues and energy efficiency. All the buildings have been designed with an Active House philosophy in focus.

It is already proven that environmental schemes like BREAM, LEED, DGNB has moved the focus from purely focus on energy use to a more holistic view on sustainability, which include parameters like indoor climate, sustainability, sourcing and energy efficiency.

However many existing programs for environmental benchmarks of buildings are developed for larger scale buildings and have – due to complexity and costs - limited relevance for single family homes and small buildings. By implementation of a simple systems which cover the main sustainable parameters, like Active House and other similar systems, the awareness and utilization of sustainability for small and medium size buildings grow.

The existing labelling of small buildings are based on the compulsory energy labelling schemes and similar schemes that focus on energy efficiency and heating demand. Those schemes do very seldom cover other parameters like sustainability, daylight and indoor comfort. Thereby the focus on human needs in the building have a risk of becoming a second priority.

By use of the Active House principles and its nine parameters there are now a simple scheme available for single family homes and smaller buildings, that can drive the development of a more holistic view on sustainability in this segment

## Soft Landings Driven Design Management process: Achieving sustainability in a school building in the UK

Victoria Gana<sup>1</sup> and Giridharan Renganathan<sup>2</sup>

<sup>1</sup> Kent School of Architecture, University of Kent, Canterbury, United Kingdom.

email: vg77@kent.ac.uk

<sup>2</sup> Kent School of Architecture, University of Kent, Canterbury, United Kingdom.

email: G.Renganathan@kent.ac.uk

**Summary:** One of the challenges facing the industry is closing the energy performance gap in non-residential buildings. Despite various recommendations and introduction of new technology, the problem remains widespread. Debate on how designers and architects can contribute to finding solutions to this problem continues. Soft Landings has been on the forefront of encouraging the delivery of buildings where estimated energy targets align with actual targets. This paper investigates the working processes of a Soft Landings design team; using Interviews, walk-throughs and contract documentation of the project. The paper explores the design management side in a Soft Landings process. How end users and sub-contractors were involved during the design stage of the project and how decisions taken affected the outcome of the project. The study discovers that learning from past projects plays an important role for new projects in achieving their goals with respect to energy efficiency and sustainability. Participation of the end users need to be coordinated to maximise their advantage without sacrificing time and cost. Additionally, practical implications are presented for architects about the involvement of end users in a Soft Landings project.

**Keywords:** Soft Landings, Design Management, Energy performance gap, Sustainability, Non-residential buildings

### Introduction

The link between energy performance of buildings and its design has been established (Bordass and Leaman, 2005). Proving that complex and complicated designs often make it difficult for building managers to correctly operate Building Management Systems. This affects the energy performance of buildings with the estimated energy usage higher than actual usage. This difference is known as a ‘performance gap’ (Gupta and Gregg, 2016) and negatively affects building owners and end users. This is most prevalent in non-residential buildings (Axon et al, 2012) and leads to missing energy, sustainability, and overall carbon emission targets (Fedoruk et al, 2015). The concept of sustainability in design and construction covers a wide spectrum of interconnected elements (Burnett, 2007). From Burnett’s definition, of the 3 scopes of sustainability (social, environmental, and economic), this paper looks at sustainability from the environmental definition which means that building targets go beyond CO<sup>2</sup> reduction to consider the building lifecycle.

In 2004, the aspiration for schools to be ‘models of sustainable development’ was a result of the 1997-2010 labour government policy (Moncaster and Simmons, 2015). This brought sustainability to the forefront of school building projects. The government called on construction companies to act to make school buildings more sustainable and required individual designs to achieve a ‘Very Good’ rating in BREEAM assessment tool. In response

to this, construction companies intensified their focus on environmental sustainability targets in schools (Moncaster and Simmons, 2015). A report by the government (DfES, 2006) outlined six themes for sustainable schools. They were ‘stakeholder engagement’, ‘getting the basics right’, ‘low energy design’, ‘renewable energy systems’, ‘managing energy and ICT’ and ‘the building as a learning tool’. The fact that stakeholder engagement was the first on the list underscores the importance of the design team’s relationship with the client and end-users.

Soft Landings aims to achieve project targets of energy efficiency and environmental sustainability by closing the performance gap (Way and Bordass, 2005; SLF<sup>1</sup>, 2014). It calls for greater collaboration between all stakeholders of a project from the inception to handover, aftercare and extended aftercare. Until recently, designers did not consider how the end user was going to operate a building (SLF, 2014). The introduction of complex building systems (heating, cooling, ventilation, lighting) has presented an opportunity for the design team to involve not only the construction team but building managers and end users. This collaboration, therefore, will be in the form of high-level multi-layered information exchange (SLCP<sup>2</sup>, 2014; Gana et al, 2017). This will involve regular reality checks and feedback throughout the project. Usually by a Soft Landings Champion who is a member of the team but has the extra role of ensuring the realisation of project targets.

This paper looks at a primary school in London which used Soft Landings at various stages during the construction of an extension block. The main research question is ‘how were the principles of Soft Landings applied to the project during the design stage?’ The paper will provide a working insight into the design process of a Soft Landings project. Using interviews with the design team, it will look specifically at the interactions between the design team and the end users and how feedback was collected and incorporated into the design. The paper will also discover how the use of information from an earlier school project helped to inform the design and the lessons learnt in the process.

## **Methodology**

### ***Case Study***

The method for investigation in this research was case study. This allowed the investigation of the complex interaction between the design team, end users and other professionals within the natural setting of the ‘case’ (Yin, 2003). Case study also allowed the research to get a multidimensional insight into the Soft Landings design process and probe deeper into specific situations. This paper investigated a single school project to discover the interaction of the design team with end users and other professionals during the design stage. According to Flyvbjerg (2006), generation of theory from a single case is possible depending on the selection process of the case. Leaman, Stevenson and Bordass (2010) agree; stating that a single case can shed light on new issues and processes and create hypothesis that can be tested. The study was carried out after completion to give the occupants a chance to experience the building and find out any issues discovered during the post occupancy evaluations. The focus of the case study, however, was the design stage of the project. The building is a school in the south-west of London procured via a framework agreement

---

<sup>1</sup> SLF: Soft Landings Framework; this literature was originally developed by BSRIA in 2008

<sup>2</sup> SLCP: Soft Landings Core Principles; this literature was developed by BSRIA and the Soft Landings User Group

with the local council, the main contractor and property consultants. The client held a mini competition with the winning design team engaged by the main contractor. The brief called for an extension of a classroom block consisting of 8 new classrooms, a library and ICT suite, deputy head's office, and a separate kitchen and dining room. The contract was awarded in 2010 with the contract sum of £2,530,000 and obtained a BREEAM 'excellent' rating for design.

### **Data Collection and Analysis**

The researcher carried out a walk through the designed spaces to see how the occupants interacted in the building. Notes on the public consultation and the 'visioning workshop' were also used to find out how the user feedback was collated. Data was collected using semi-structured interview with the project Architect, Project Manager, and the M&E subcontractor (Mechanical Engineer). The questions were open-ended to allow each respondent to give their own unique view of the project. The questions were based on the literature review which highlighted certain factors as barriers to achieving sustainability; and a report on the post occupancy evaluation of the building from the building data exchange (BDE, 2014). Specific questions were designed around these factors to allow investigations. The questions were divided into 2 sections with the first section establishing profession, level of experience and level of knowledge in Soft Landings. The second set of questions were about the design process with respect to Soft Landings and end user participation.

Each professional was interviewed for about 1 hour. The ethics review board from the University of Kent approved the interview questions and format. Information on the research and consent forms were distributed prior to the interviews. The information was anonymised as stated on the information forms. The interviews were transcribed and copies sent back to the respondents for approval before analysis. Nvivo software was used to store the information and generate codes. A combination of descriptive and analytic codes were generated. The emerging themes were compared to those from the literature review to develop the final codes.

### **Findings and Discussion**

The interview revealed how the design team interacted with the end users and other professionals to achieve the project sustainability goals. These are discussed under the themes generated by coding.

#### ***Soft Landings at the design stage***

The client wanted this project to showcase its new sustainability policy, as such the brief reflected its demands.

**Interviewer:** '*how were the project objectives included in the design?*'

**Architect:** '*We worked within the brief and wanted sustainability to be a core objective of the project. I suppose the client was quite keen on promoting sustainable and energy efficient buildings.*'

**Project Manager:** '*the objective of the project was to have the new buildings achieve BREEAM excellent standard and everyone was clear that the project was going to give attention to sustainability. The team was aware of the objectives and the client understood that we were going to do something radical to achieve the project goals.*'

**Interviewer:** '*what did you find was the difference between this project and other conventional projects?*'

**Architect:** ‘For me, the design took longer on average I would say, with all the meetings and consultations. Trying to make sure that we listened to every idea and suggestion added about 2 extra weeks in design.’

**Project Manager:** ‘Time is valuable once any project gets underway, one extra day can add all sorts of complications. I would say we had an awful lot of meetings and emails back and forth.’

The case of the design stage lasting longer than a conventional project seems to be prevalent (Gana et al, 2017). However, the extra time spent on this stage allows all the stakeholders apply better knowledge about the building when completed.

**Interviewer:** ‘was there any research into past projects?’

**Architect:** ‘I remember we looked at different structural systems, we looked at timber frame, we looked at masonry.’

Table 1: Comparison of predicted against actual targets

Targets	Predicted	Actual
Air Permeability ( $\text{m}^3/\text{m}^2\text{h}$ )	10	Classroom: 8.48 Dining Block: 11.85
Delivered energy (Gas) $\text{kWh}/\text{m}^2$	Classroom: 47 Dining Block: 60	Classroom: 95.4 Dinning Block: 215.8
Electricity consumption ( $\text{kWh}/\text{m}^2$ )	Classroom: 34 Dining Block: 91	Classroom: 28 Dinning Block: 73.8

*The timber frame was too expensive. I think the wall build-ups were made a bit cheaper than originally designed quite a few school constructions were going on so I had a meeting with one of our partners on the project.’*

**Interviewer:** ‘Is there anything you would have done differently on the project?’

**Project Manager:** ‘The location of some of the services could have been positioned better. The conical roof was a nightmare, we did another school for the same authority two months down the road, it was curved but it was infilled with rectangle wedges, it made it so much easier. If I hadn’t been on Castle Hill we would have had the same problems.’

This is in line with the Soft Landings framework, which emphasises on the need to learn from similar past projects. The design team could look at past school and glean valuable information for the current project including the cost implication of the use of steel frames.

### ***Introduction of the end users***

The design team engaged extensively with the end users and project stakeholders. There were 12 recorded meetings between them. There was a public exhibition which attracted all groups of stakeholders. They held several consultations periodically to inform and update the end users.

**Interviewer:** ‘When were the end users introduced to the design stage?’

**Architect:** ‘we had the end users around during the briefing stage. The head teacher was at the first meeting and we had the discussion to invite the school for a brainstorming workshop.’

The engagement of the design team with the end users yielded valuable information for the team. They could go back and assess the information given to them and use that in

the design. A major example of was the agreement to shift the entrance of the site, the end users had years of experience using the school so they could provide the team with valuable information. The Architect:

*'We took feedback from the local residents and we fed it into the design. The access to the site rather than the buildings themselves. I remember there an entrance side, the railway station side and a small fire escape on the other side of the fields. We had to change that slightly to reflect feedback but the buildings didn't really change.'*

**Interviewer:** *'How did you deal with end user concerns for the project?'*

**Project Manager:** *'For this project, the end users were very involved. Some of our projects we are not fortunate to speak to actual end users. The head teacher of the school was very involved, he had a clear vision on his expectations. We spoke to teachers, students, parent representative and every meeting helped us gain new perspectives into the project.'*

*As a Project Manager, I treated the end users as team members. Their input contributed to the success of the project.'*

The words of the Project Manager indicated that the team engaged the end users and treated them as part of the design team. This according to Altomonte, et al (2015) is a formula for successful sustainable construction. The inclusion of the end users during the design stage sets the scene for collaborative working. This inclusion mentally prepares the end users and gives them a sense of ownership with the finished design (Jenson, 2011). This was true of the project because the occupants gave the highest rating to the design during the building user survey (figure 3).

The lack of a dedicated Soft Landings Champion prevented the team from profiting from a better streamlined system of meeting with the end users. The Engineer remembers a lot of unscheduled feedback from the end-users which can be a problem when assessing the comments for use. A dedicated Soft Landings Champion would have been able to specifically work on the structure of consultations and make sure that feedback did not stray to topics not needed. Although there was a lot of feedback, the Project Manager admitted that the end users had little to do with any design changes.

**Interviewer:** *'How much input did the end users have in the project?'*

**PM:** *'Well, they had little input in the building designs apart from telling us how the classrooms and playrooms were going to be used. They were particularly helpful when deciding the entrance of the site.. During the design team meetings, we discussed the points and had to decide which ones we wanted to adopt. Of course, we had to research them first.'*

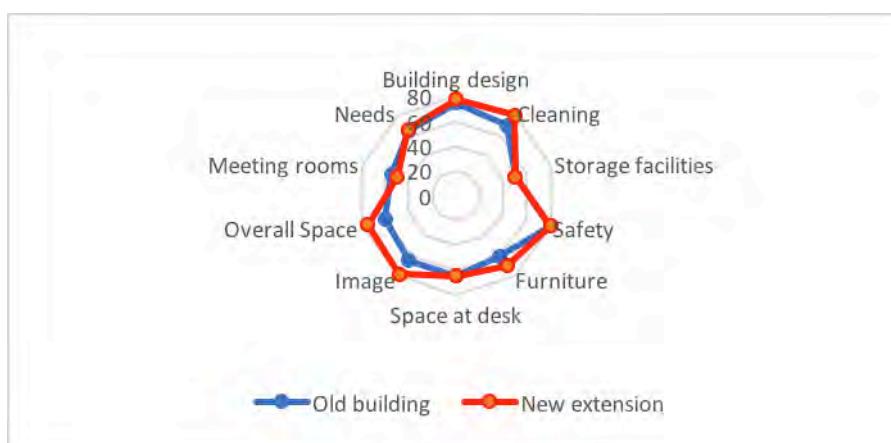

Figure 1: Percentage of user satisfaction

**Interviewer:** 'No major changes occurred because of end user participation?

**Architect:** 'None, in the building design, well just in the location of classes. The buildings were very popular with everybody we spoke to... we got really good feedback. Partly because of the curved shape of the classrooms and partly because of the barn. So it was a very popular design, there was no problem.'

Although there were no major changes because of end user participation, the workshops were classified as a success. There were suggestions from the end users that helped and informed the design. Minutes from meetings showed that the client contributed to the design by referring to equipment like extractor fans in existing buildings that were difficult to maintain and source new parts. This was noted and relayed to the M&E engineers for action. All these contributed to producing a design that was both popular and practical. Client and end user participation did present some problems as the Project Manager recalls

*'... we had some conflicting requirements during the consultations, the School wanted to have a single storey building because they were easier and cheaper to maintain. As they had some problems with replacing equipment in higher floors. While some parents and the school body preferred a storeyed building to save some space in the compound for other facilities'.*

The presence of a Soft Landings Champion would have afforded the team focus on more important aspects of the project target rather than having numerous meetings with the end users. Goldsmith and Flanagan (2017) discovered this situation as the norm with design teams actively seeking end user feedback but they are unable to convert this information into significant changes. This situation has opened an opportunity to developing a framework for user feedback.

### Information exchange

Achieving sustainable design involves collaboration between multidisciplinary teams (Bouchlaghem et al 2005, Gana et al, 2017). This is usually in the form of information flow between team members from the early stages of the project. This is important for a successful project. The Architecture has this to say

**Interviewer:** 'How often were your meetings with other teams?'

**Architect:** 'Usually, every month, well the designers will meet every 2 weeks, the meeting with the client would be once a month'.

**Architect:** *they were held in sub-groups. The clients would never meet the sub-contractors really. The clients would meet initially, they would meet the consultants always, the Project Manager and Architect, sometimes ....as well. Then when the contractor became involved, the main contractor once a month but these sub-contractors would meet the main contractor separately and sometimes the consultants would be part of that sometimes not depending on the situation.'*

From the answer above, we can deduce that there were several levels of communication going on. Each line of communication will have to be given adequate importance to avoid excluding important stakeholder or information overload. Dainty, Moore and Murray (2006) discovered that poor communication can lead to lower job performance. The information exchange does not only include communication between teams but also the timing of delivery. Good quality information will be 'the right information reaching the right person or team at the right time.'

The Project Manager on the issue of Information exchange during meetings  
*'Our meetings were organised in such a way that the activities which took longer were discussed first. So, in this case, I was in meetings with the design team a lot during the early stages. I will speak to XXXXX (name of Architect) on the phone several times a day. The meeting with the design team was once a week to check on the progress of work. Later those went to once a month or when we needed to discuss something important.'*

**Interviewer:** 'What of the sub-contractors?'

**PM:** 'We had our meetings with them once a week, in the beginning, sometimes we combined the meetings with the design team and discussed a wide range of issues especially during the thermal assessment. After that, the meetings were on need basis really.'

As with every construction project, the Project Manager recognises the benefit of giving information only when it is of importance to the receiver, as it was the case with the client and sub-contractors. Otter and Emmitt (2008), highlighted the importance of face to face meetings to review designs, share information and make decisions on their project. Stressing the situation,

*'Although team members usually work on design tasks themselves in their design offices, team communication via face-to-face communication is essential to facilitate and stimulate design processes' (Otter and Emmitt, 2008).*

The design team kept to the Soft Landings core principles by keeping the flow of information to relevant team members and making sure that the timing of the information is right by regular face to face meetings. The Engineer confirmed

**Interviewer:** 'How often were your meetings with the design team?'

**Engineer:** 'At the beginning of the project there was a lot of paper work to go through so we met nearly every day. The discussions moved on to their concepts of the design, they wanted to hear our ideas so there was a lot of brainstorming at this stage. After all the decisions were taken, our meetings tapered off to once a month. The design team could produce their drawings. We carried on our team meeting, which was usually once a week'.

## Conclusion

This paper highlights the collaborative process that is necessary for a Soft Landings project. The level of information sharing was high and frequent between all stakeholders. This does not guarantee success for the project (as seen from the missed targets in table 1) but it allows each member of the project contribute to solving the critical problems that usually arise (Gana et al, 2017). The lesson learnt from other school construction projects gave the team an advantage in the use of laminated timber frames instead of using steel. Although the project achieved its airtightness and electricity target, there were issues with the thermal comfort of the building and heat loss through the windows.

The project would have benefited from a dedicated Soft Landings champion as the feedback from the end users were not properly coordinated. The project needed to have a more effective system of cataloguing feedback for use in design. A system in which end user contribution could be classified into essential and non-essential feedback, thereby concentrating on only the essential feedback.

The implication for the design team is the understanding that engaging the end user is not enough, that a process of synthesising the feedback must be in place to take advantage of end user participation. Further research will focus on developing a communication framework that will allow design teams effectively catalogue and prioritise end user feedback.

## Temporal Indoor Overheating risk management challenges for free-running spaces: Highlighting the demand functions for decision-support

Linda Gichuya<sup>1</sup>

<sup>1</sup>Behaviour and Building Performance research group, Department of Architecture University of Cambridge, 1-5 Scroope Terrace Cambridge CB2 1PX. United Kingdom.

**Abstract:** A key question with regards to managing indoor overheating risk is: In the current carbon constrained environment, what is the most effective design or space use strategy? Although there exists numerous passive techniques to reduce indoor overheating instances, the decision-making process of appraising these tactics, at the various decision-making stages of a building's lifetime, remains a challenging task. This is true especially when making decisions for heterogeneous urban landscapes, while considering the effects of time frame uncertainty. In this paper, an empirical study has been undertaken to characterise practical decision-making challenges incurred when managing temporal indoor overheating risk. The study discusses results from real-time indoor thermal monitoring carried out using digital data loggers in free-running office spaces in 30 different buildings in Nairobi-Kenya, for the period between 2008 and 2015. The trend of indoor overheating in these spaces has been reviewed, as well as a comparison made between building attributes with the corresponding indoor overheating risk levels. The review implicates a need to clarify and make transparent both factors and information that shape the form and content of decision support when managing temporal indoor overheating. Three demand functions of decision-relevant information, presented alongside overarching goals for managing indoor overheating risk, have been conceptualised.

**Keywords:** Indoor overheating risk, Thermal comfort, Temporal decision-making,

### Introduction

Existing definitions and insights into overheating<sup>1</sup> outline three main factors that shape its outcome: 1) The technical aspects of a building's design and the occupancy patterns of its occupants; 2) The building's response to the prevailing climatic conditions and its Urban context; and 3) The assumptions about occupant(s) thermal comfort threshold. From the outlined descriptions of overheating, it is evident as well that emphasis has been laid on two key factors that characterise occupants' thermal comfort assumptions. One factor being the upper benchmark or threshold temperature limit beyond which a person can express their dissatisfaction with the thermal environment. The second factor is the length of time of

<sup>1</sup> Anastasia et al (2015, p.3) have defined Overheating as "The phenomenon of a person experiencing excessive or prolonged high temperatures within their home, resulting from internal and/or external heat gains, and which leads to adverse effects on their comfort, health or productivity". Overheating phenomenon has also been "generally understood to be the accumulation of warmth within a building to an extent where it causes discomfort to the occupants". (NHBC, 2012, p.1). Further, CIBSE TM36 (2005) has summarised overheating as: "When the benchmark temperature is exceeded, the building is said to have 'overheated' and if this occurs for more than the designated amount of time, the building is said to suffer from 'overheating'."

thermal discomfort is sustained above the threshold temperature. It can then be argued here then that the measured understanding of overheating can be expressed as the departure from an upper thermal comfort threshold of an occupant, both in magnitude and length of time of discomfort, for any given space. Taken together, these dimensions define the **vulnerability** level of a free-running<sup>2</sup> space to indoor overheating. Depending on the resultant level of vulnerability of such a space to overheating, a **response** to overheating is elicited, comprising acceptance and/or heat mitigating action. Risk theory terms the latter efforts as a form of risk management<sup>3</sup>. In this case, these efforts could be in the form of seeking the best possible adaptive opportunities a space has to offer and/or the need to work out a preparedness plan in case of future thermal discomfort.

The outlined understanding of indoor overheating risk management depicts it as a decision-making exercise. An exercise that is accompanied by the need to meet a certain level of thermal comfort expectation that is to be considered alongside other values and ambitions of the built environment decision-making stakeholders. This measured understanding of indoor overheating risk characterization has been adopted in this paper to paint a clearer picture of practical decision-making challenges incurred when managing both existing and future indoor overheating risk in a case study area of Nairobi. Results from real-time indoor thermal monitoring carried out using digital data loggers in free-running office spaces in 30 different buildings in Nairobi, for the period between 2008 and 2015 have been discussed. This monitored data has been translated to indoor overheating risk assessment. The question on how to manage whole-life thermal performance in free running spaces, while accounting for both variation and uncertainty in the short and long-term future has been explored. Ultimately, implicating the need to clarify and make transparent both factors and information that shape the form and content of decision support<sup>4</sup> when managing temporal indoor overheating. Three demand functions of decision-relevant information have been conceptualised and presented alongside overarching goals for managing indoor overheating risk.

### **Temporal Indoor overheating risk management challenge: A case for Nairobi-Kenya**

Nairobi experiences tropical warm climatic conditions all year round, and as a result, indoor overheating challenges underlie a considerable portion of existing buildings. Added to that, the diversity of Nairobi's non-domestic building stock and its cosmopolitan nature presents wide-ranging thermal comfort expectations and associated building adaptation decision-making challenges. Currently, no legislation governs building design in relation to climate in Kenya. This lack of clear bio-climatic design guidelines has partly contributed to the variety of building styles cropping up in the country and particularly in Nairobi, over the years expressing a range of worldwide influences and building styles. A few that have outstanding passive design strategies fit for a low latitude tropical climate, some illustrated in Figure 2, while quite a number of designs, on the other hand, have had their mistakes cushioned using very energy intensive means to afford their occupants favourable indoor thermal comfort.

<sup>2</sup> The term "free running" in this paper applies to a building which is neither mechanically heated nor cooled.

<sup>3</sup> Risk Management has been defined as "coordinated activities to direct and control an organization with regard to risk" ISO 73:2009

<sup>4</sup> Decision support has been defined as "a set of processes intended to create the conditions for the production of decision-relevant information for its appropriate use" .(IPCC, 2014, p. 202)

Various scholars in Nairobi have investigated the indoor thermal performance of some relatively well-performing buildings over the years under different theses with varying research objectives. (Loki, 2009; Njeru, 2008; Gichuyia, 2010; Nyole, 2011; Deogun, 2011; Njoroge, 2012; Kuria, 2012; Nyole, 2015; Njoroge, 2015; Mworia, 2015) These studies are seen to have a common theme of establishing the trend of the indoor thermal performance of free-running buildings investigated, and in addition, they have attempted to compare building design and use attributes with the corresponding indoor thermal performance, endeavouring to inform current practice. Some of the buildings studied over the years and which are the subject of inquiry in the section below are presented in Figure 2.

### **Real-time indoor overheating results of some monitored office buildings in Nairobi**

Figure 1 presents the quantified indoor overheating risk results from the real-time indoor thermal monitoring carried out using digital data loggers in 30 different buildings in Nairobi, for the period between 2008 and 2015. To be noted here, all spaces investigated are not mechanically cooled with the exception of House of Van-Guard whose indoor temperature readings were used to establish an acceptable upper level of thermal comfort threshold, which averaged at 24.4°C. Based on this, a major assumption has been made in the calculation of indoor overheating levels in this paper, that once indoor temperature threshold of 25°C has been exceeded, the space monitored is said to have overheated. This provided a general criteria for identifying an upper limit of thermal discomfort for these preliminary evaluations. Indoor overheating has been calculated using the degree-hour criterion (Carlucci & Pagliano, 2012), a cumulative index employed to quantify the average daily accumulation of indoor overheating for each space investigated. The amount by which the indoor temperature for every given hour monitored exceeds 25°C was calculated for each space. The hourly values of indoor temperature above this thermal comfort threshold were then calculated per hour for each day, and the net value of thermal discomfort in degree centigrade hours (°Ch) was then tabulated. This was then averaged per day for comparative analysis purposes, as the total number of days of indoor temperature monitoring in the spaces investigated differ (Figure 1).

### **IOR results highlighting the demand functions for decision-relevant information**

Despite the relatively small pool of non-domestic spaces investigated, which are by no means representative of the entire non-domestic building stock of Nairobi, there is significant evidence of **heterogeneity**, illustrated by the clear differences in building characteristics (Figure 2). This has been characterised by the variety of building forms, facade design styles and building materials used, in addition to the different urban contexts and boundary conditions around the individual buildings. Consequently, how these building-related features combine at varying magnitudes and frequencies in the spaces monitored and time slot considered resulted into a relatively broad spectrum overheating output that ranged from 0°Ch/day to 64.17 °Ch/day for the non-air-conditioned spaces. This varying range of overheating levels was not only true across all spaces monitored but was also inherent in each of the spaces as elaborated below, in the case of:

- a) The same space monitored on consecutive days: A closer look at the daily indoor temperature profiles for each space monitored indicates the lack of a typical daily thermal profile in most of the spaces monitored. In only a few cases is this variation of temperature subtle, as was in the case of FCC, which recorded an almost constant temperature of 21°C during the days of monitoring. The only other two cases were KRHq. and the ADD buildings.

b) The same space monitored in different months/years: GEM, BS, and OM buildings are good examples illustrating this variation. The three spaces in each of these buildings were monitored in October 2009 and again in April 2010, and thermal logged at exactly the same time in both instances. Yet, OM seems to rank lowest in indoor overheating in April 2009 and rank highest in overheating levels in October 2010 among the three buildings. It could be argued here that all factors constant, the thermal performance rankings would have remained the same in both instances but that was not the case.

c) Further evidence of indoor overheating variation can be seen in the case of the same space monitored in different zones as exemplified in the case of CUEA Lib. The reading space in the reading carrels recorded 0.8°CCh/day of overheating while the reading space near the atrium recorded 0°CCh/day overheating, although the two spaces were monitored at the same time and in the same open space, a few metres apart. The case of TPT is a similar example where spaces in its 1st floor, 5th floor, and its 13th floor, were monitored at the same time but had their overheating levels relatively varied, at 3.6°CCh/day, 4.74°CCh/day and 7.29°CCh/day respectively.

Taken together, this variation in thermal performance exemplified above for each space, both at an hourly, daily, weekly, monthly and yearly scale, grounds the view that **each space comprises a heterogeneous compilation of character over a given length of time**.

The two spaces logged in SA and KEMU buildings recorded the highest IOR level. These spaces had their indoor temperatures way above 28°C for a relatively long time and went on to record indoor temperature highs of 41.52°C and 32.03°C respectively. The question on **what are the building and/or use related attributes that contributed the most to this high indoor overheating risk** becomes fundamental here. What is apparent from the two buildings, is that they have in common a relatively high window to wall ratio of 100% Curtain walling. Although SA has a ring of 600mm deep spandrels running around its West facing facade, the logged space was in the curved glazed part of the building that is not shaded. Based on this and the fact that they share similar building use attributes, there is a compelling reason to argue that the high window to wall ratio or the curtain wall glazing used could have been responsible for the high indoor overheating levels in both cases. However buildings including LH, BS, GEM, GBP all have a similar 100% external curtain walling, and yet they recorded relatively better thermal performance.

Along the same lines, there is a presupposed argument by various scholars in this region that since the advent of the use of extensive curtain walling with less sun-shading strategies from the 1980's onwards the risk of indoor overheating has become higher. Nyole (2014) in her dissertation investigating the role of the building envelope in ensuring internal thermal comfort levels are achieved, went on to investigate four buildings with the varied use of curtain walling. The four buildings which included the CCK, GBP, CBA and DL buildings had spaces in their western facades monitored at the same time. From the results, also included in this study, one would expect the CCK building with the least window to wall ratio and most sun-shading strategies comparatively to have performed better based on this argument, but the IOR results contradict this prevailing view. Sun-shading strategies have been recommended as some of the most favourable strategies for cutting substantial solar gains that occur directly through window transmissions and indirectly from hot surface conditions and radiation for this type of climate as cited earlier. The question on **What is the measured reduction in indoor overheating offered by each building design and user strategy in singularity** becomes important here. That is, considering spaces like GWML and CH with significant use of sun shading on their building envelopes, yet none of the two

recorded zero overheating levels. **This is a clear indicator that the ranges, magnitudes, and frequencies of other building design and use attributes are a major factor in the overall indoor thermal performance of space.**

Following closely regarding relatively high indoor temperatures were spaces monitored in the KNA building, UNON and 3rd floor CCK buildings, whose indoor temps were mostly above 25 °C at the time of monitoring, with highest indoor temperatures recorded at 27.51°C, 31.52°C, 32.76 °C for each building respectively. These three particular buildings have been acclaimed for their application of innovative passive design strategies (Loki 2009). Just by reviewing the technical aspects of their built form, facade design, building envelope treatment, thermal properties of building materials used, there is a relatively high level of thermal performance expectation. **Thermal performance expectation seems to differ from the measured reality** here as one would expect that spaces monitored in these three buildings would have lower overheating risk levels compared to spaces in for instance: GEM, BS, and CT that have lower ranking climate responsive technical aspects. However, to be noted here is that the logged spaces are not a representation of the thermal performance of all spaces in the entire building.

An even higher level of thermal performance expectation was placed on spaces logged in the OM building and particularly the award-winning CCHq. building, based on their impressive passive design strategies. The CCHq. building, for instance, boasts of a myriad of features that make it a truly unique building. This is shown by its solar shading style where all north facing windows are inset in its relatively thick external wall creating a box profile that further provides self-shading, and includes the additional solar shading ring louvres running around its North facing wall. This is in addition to its light coloured, and relatively thick external wall with relatively high thermal mass; Its south facing curtain wall is shaded using a relatively deep crescent shaped canopy; A green roof garden that acts as a recreation area and ensures that there is minimal heat gain into the building through the roof top; The use of undulating earth mounds on its grass-covered landscape, helps conceal the half basement parking and partly shades the ground floor direct sun rays. This is to mention just but a few external physical aspects. More can be said about its built form configuration and orientation as well as its ventilative cooling strategies. Based on the scientifically understood principles of all the strategies it has in place, one would expect its spaces to be at zero risk of indoor overheating and no chance of the use of mechanically cooled spaces. On the contrary, the building has quite a number of air-conditioning units installed to support cooling of the spaces (Gichuyia 2012). This then begs the questions on **how much is enough design effort without over-providing or under-providing for thermal comfort? Are building use parameters the more prominent risk factors to indoor overheating in passively designed spaces?** How did spaces monitored in CUEA, UF, Add, CM achieve the optimum combination of building design and use attributes, having recorded zero overheating risk levels? Moreover, is the ultimate question of: Even after achieving that optimal combination of building design and user related attributes that ensure a space has a low overheating risk in the current context, **how do we ensure that these strategies stand the test of time? Especially in a future where the climate, boundary conditions around the building, modification of the space and its use are not likely to remain stationary?**

## Discussion

Based on the above frame of reference, there is a glaring resolve that just the understanding of scientifically understood principles of achieving thermal comfort in their

detached singularity is not enough information for decision support. However, to appraise and adjudicate between the numerous heat mitigating decision options, a review of all the intersecting components of causal factors of the external climate, building related attributes, assumptions about thermal comfort thresholds, alongside passive heat mitigating interventions at varying frequencies and magnitudes over time, is necessary. Such a review would need to accommodate the three different dimensions of capacity needs of risk management as discussed by Cardone et al. (2012) that can be differentiated as 1)Capacity to anticipate indoor overheating risk, 2)Capacity to respond to indoor overheating risk, and 3)Capacity to recover and change from indoor overheating risk (Table 1). A review, cutting across all three dimensions, would require means of uncovering the dynamic complexities of the cause-vulnerability-response interactions of the thermal space variables under conditions of diversity. Diversity in this case capturing the effects of heterogeneity and uncertainty brought about by the rich array of building styles and space use characteristics on the one hand, and the highly unpredictable world on the other.

Table 1: Table highlighting three main demand functions of decision-relevant information necessary for managing indoor overheating risk as drawn out from the Nairobi case study.

Demand functions for decision-relevant information	Corresponding questions posed in the case of Nairobi
<b>Capacity to Anticipate</b> Actions that take into account the cause and effects impacts of risk, towards risk prevention (Cardona et al., 2012, p.74)	a) How to anticipate for the range of possible overheating due to factors of heterogeneity and uncertainty. What are the building and/or use related attributes that contribute the most to indoor overheating risk? b) How do we achieve the optimum combination of building design and use attributes, that ensures zero overheating?
<b>Capacity to Respond</b> Actions necessary to react in the event of a risk, while accounting for the vulnerability to risk and the ability to offset this. (Cardona et al., 2012, p.74)	a) What is the measured reduction in indoor overheating offered by each building design and user heat mitigation strategies? b) How much is enough design effort without over-providing or under-providing for thermal comfort?
<b>Capacity to recover and change</b> Actions that push the recovery from risk towards a transformation of systems to effect lasting responses that look to avoid vulnerability (Cardona et al., 2012, p.75).	a) How to manage thermal performance expectation gaps from the measured reality? b) How do we ensure that these strategies stand the test of time? Especially in a future where the climate, boundary conditions around the building, modification of the space and its use are not likely to remain stationary?

## Sustainability performance tracking of social housing: the tale of two projects in Brazil

Vanessa Gomes<sup>1</sup> and Mariana Adão<sup>1</sup>

<sup>1</sup> School of Civil Engineering, Architecture and Urbanism, State University of Campinas, Campinas, Brazil

**Abstract:** A number of mandatory and voluntary 'sustainability' rating systems emerged over the past twenty years. However, they are usually restricted to environmental assessments carried out at individual buildings scale, which seems to be inappropriate to capture and describe environmental, economic and social challenges faced in social housing development contexts. Assessments should be adapted to neighborhood scale and local conditions, and involve residents in the process. Against this backdrop, this paper aims at verifying sensibility and adequacy of two rating systems - Selo Casa Azul (Brazil) and Housing Quality Indicators, Hqi (UK) - to assess two selected Brazilian social housing developments. Casa Azul was applied to both projects, whilst Hqi required detailed information only available for one of them. Our results suggest that Casa Azul is insensible to distinguish performances, despite having been developed to assess Brazilian residential projects, including social housing. Hqi also has points not applicable to our cases, for either not have been designed for social housing application or for not admitting adjustments to contexts other than the original British conditions. Combination of features from different systems seems promising to meaningfully consider sustainability performance aspects and allow for reflection and improvement of such design models.

**Keywords:** social housing, sustainability assessment, Selo Casa Azul, Housing Quality Indicators

### Introduction

Sustainability assessment tools have been recurrently used to monitor building performance and success of public and sectorial initiatives and policies. Such tools follow a common overall content and structure, however no similar consensus regarding scope and, particularly, assessment procedures seem to exist. Most assessment systems still focus on environmental aspects and ignore social and economic issues which are relevant for developing countries, and often do not integrate stakeholders in tool development and feedback processes (Sharifi and Murayama, 2013), which can be specially critical for social housing projects.

Social housing (SH) developments typically implemented with public funding to reduce housing deficit, and targets low income, socially vulnerable and education-deprived population. Demand for this housing model is especially high in developing countries or in areas devastated by natural or environmental disasters. Developments frequently deliver thousands of housing units at once, which virtually shapes new neighbourhoods or even towns. Assessment scope therefore extrapolates the building scale and also demands examination of neighbourhood scale (Berardi, 2011; Sharifi and Murayama, 2014) and local conditions (Retzlaff, 2009). To involve and deliver meaningful actions to future dwellers,

development of assessment tools would benefit from embracing participative approaches (Sullivan and Ward, 2012).

In this paper, we aimed at analysing two housing assessment systems, devised in different background contexts, regarding their comprehensiveness and sensitivity to distinguish projects' performance on important sustainability aspects. In particular, we checked for uncovered sustainability aspects relevant to SH, adequacy to mixed scales, and adaptation to local context.

## **Method**

In this study, two tools - Selo Casa Azul (Brazil) and Housing Quality Indicators, HQI (UK) - were selected to assess sustainability of Brazilian social housing developments: 'Project Várzea', a development in early design stage in Rio de Janeiro state, and 'Paraisópolis Condominiums E and G', a favela development certified at Casa Azul's highest level. Casa Azul assessments were carried out for both developments; whilst information available on 'Paraisópolis' was insufficient for performing HQI assessment.

### ***Selected developments***

#### ***Project 'Várzea que Queremos'***

'Project Várzea' is a partnership between private contractors and the municipal administration of Niteroi, in Rio de Janeiro state, funded by the federal housing program 'Minha Casa, Minha Vida, MCMV' ('My House, My Life'). The project will be built in a redevelopment area located 25 Km from downtown, adjacent to the State Park 'Serra da Tiririca', fully preserved on the project. The neighbourhood has one municipal and eight intercity bus lines, five public schools, a day care centre and two hospitals in a three-kilometre radius.

Design (Figure 1a) is currently in conceptual design stage and aims at reducing parking area, while providing broad access to public spaces and leisure areas, universal design, and green streets. Only 20% of the assigned land was parcelled to accommodate seven condominiums with individual leisure areas. Residential lots occupation is below 22%, and total residential building footprint is less than 5%. A total of 2,020 housing units (HUs) complies with monthly income ranges for MCMV Program track 1 (0 to 3 minimum wages) and track 2 (3 and 6 minimum wages). Track 1 HU areas are 42.90 m<sup>2</sup> (two bedrooms, living room, kitchen, service area, and bathroom). Track 2 HUs have 47.65 m<sup>2</sup> and include a little balcony. Complete infrastructure is provided, encompassing pedestrian lanes, street network, transportation modes and demand management, bikeways, bus station, and use diversity in the development's centre (commerce, leisure, sports, schools, institutional, cultural, health, and social equipment).

Main concepts emphasise recovering degraded areas, reducing dependency on motor vehicles, and preserving habitat, wetland and water bodies. To achieve these aims, Project Várzea applies the Transit-Oriented Development (TOD) principles and guidelines from two Brazilian sustainability-related certifications: 'Procel-Edifica energy-efficiency label' and 'Selo Casa Azul'.

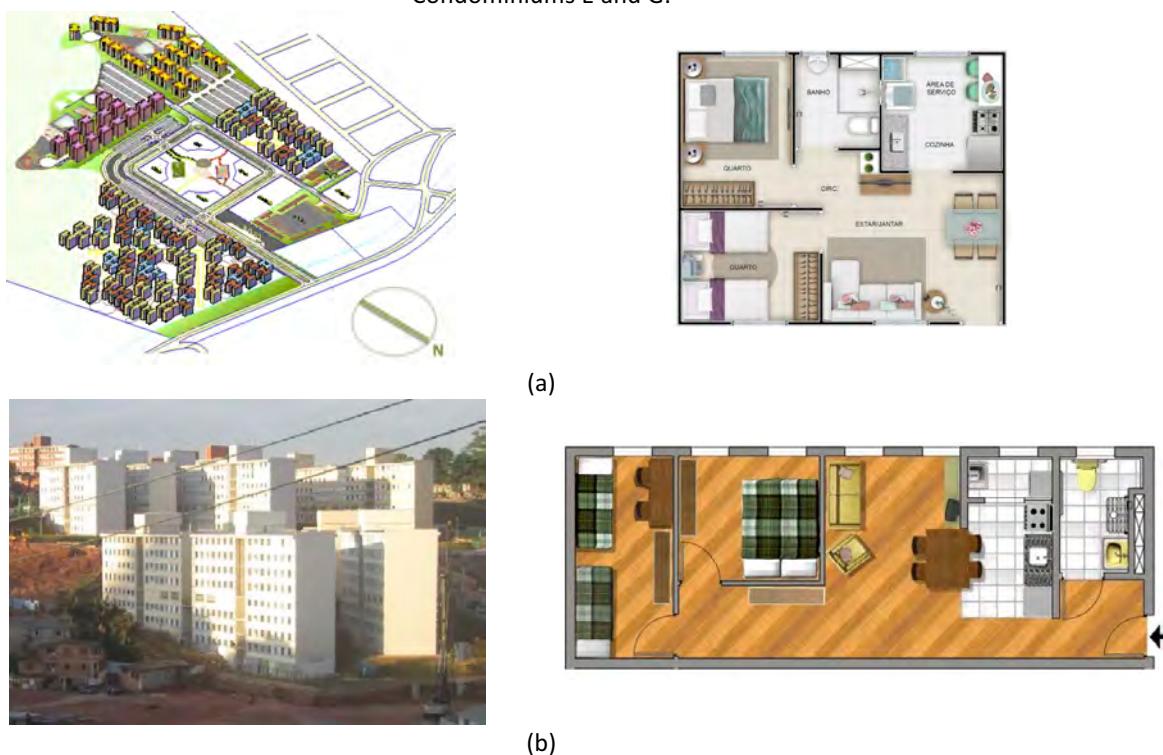

TOD focuses on integrating sustainable transport and land use. It can be used both as *guidance* for creating laws to urban design, transportation design, land use and parking lots, and as *assessment* at planning or design stage of conditions for creating walkable

communities; prioritizing use of bicycles over cars; creating dense and connected road networks; increasing population density in areas with greater capacity for public transport stations to increase efficiency; arranging regions according to job offer to decrease travel time and needs; promoting changes that encourage the use of public transport, cycling and walking; and encouraging diversified activities through mixed use (ITDP, 2014).

Procel-Edifica was launched in 2009 by the Brazilian Energy Ministry as part of the National Program for Energy Conservation to assess performance of office and residential buildings regarding energy efficiency, natural ventilation, indoor environmental comfort and accessibility (Gonçalves, 2016).

Selo Casa Azul ('Blue House Label') is a voluntary rating scheme developed by an expert group for Caixa Econômica Federal (CEF), the largest public housing financing bank in Brazil. Casa Azul was launched in 2010 to acknowledge housing developments that adopt more efficient solutions related to buildings construction, maintenance, use and occupation. It was the first rating tool completely developed for the Brazilian context, and can be used by construction companies, public authorities, public companies, housing cooperatives, associations and social movements entities during the feasibility stage. Casa Azul is applicable to any development eligible for the CEF financeable portfolio, and provides guidance for more sustainable housing projects, from establishing partnerships between the bank and project proponents.

Figure 1. Site view/plan and respective HU layouts of (a) 'Várzea que Queremos' and (b) 'Paraisópolis' Condominiums E and G.

#### *Project Paraisópolis - Condominiums E and G*

Ten Brazilian developments achieved Casa Azul certifications, being one of them labelled as silver and the remaining certified at gold level. Paraisópolis Condominiums E and G (Figure 1b) achieved the highest score among the gold-certified projects. 'Paraisópolis' is a favela located 15 kilometres away from the centre of São Paulo, which went through several urbanization interventions over the past years. As part of this process, important public

facilities were installed within its boundaries or nearby, like the ‘Social Pavillion’, the ‘Sanfona Park’, which permeates the complex, and the ‘Grotão Music Factory’. At medium distance, is located the Monotrail ‘Paraisópolis’, and a little farther away is the ‘Córrego Colombo Linear Park’. The neighbourhood also counts on mobility, green, public transport, and centralities networks. Also as part of the urbanization interventions, the Housing Secretary of São Paulo built the ‘Paraisópolis’ Complex’ in 2012, a set of seven condominiums. Condominiums E and G have, respectively, 127 and 44 housing units (HUs), with 50 m<sup>2</sup> each, composed by two bedrooms, living room, kitchen, service area, and bathroom; equipped with individual metering of gas and water. The common staircases are day lit, and each condominium has an open patio and a small equipped playground. Community participated in the design and construction process through social inclusion actions and work with local leaderships, important aspects of Casa Azul social sustainability goals. During construction, selective waste collection kits were distributed along the construction site to facilitate and ensure correct waste management and destination by licensed companies. Construction workers and future residents had environmental education training. Future dwellers also received capacity building program for adequately managing and maintaining the implemented features.

### ***Selected assessment tools***

#### ***Selo Casa Azul***

Casa Azul requires compliance to the Brazilian accessibility standard and has 19 mandatory and 34 free-choice criteria divided into six categories (John and Prado, 2010). Projects that comply with mandatory criteria only are rated ‘Bronze’, while higher ratings vary with the the number of free-choice criteria met: ‘Silver’ (minimum of 6 free-choice criteria) and gold (over 12 free-choice criteria).

Table 1. Selo Casa Azul categories and criteria. Source: (John and Prado, 2010)

Categories	Criteria
Urban quality	Quality of the environment – infrastructure*; Quality of the environment – impacts*; Improving the environment; Rehab of degraded areas; and Rehab of buildings.
Design & Comfort	Landscaping*; Flexible design; Community interrelation; Alternative transportation; Collection of use recyclables*; Recreational equipment*; Thermal performance – envelope*; Thermal performance – orientation*; Daylighting – common areas; Ventilation & daylighting – bathrooms; and Adaptation to local topography.
Energy efficiency	Efficient light bulbs – private areas**; Occupancy sensors – common areas*; Solar heating system; Gas heating system; Individual gas metering*; Efficient elevators; Efficient appliances; and Alternative energy sources.
Material resources	Modular design; Quality of materials and components*; Industrialized or prefabricated components; Reusable molds and anchors*; Construction and demolition waste (CDW) management*; Optimized concrete mix; Use of low-clinker cement types CIII and CP IV; CDW pavement; Durability of facades; and Use of certified wood.
Water management	Individual water metering*; Dual flush devices*; Water efficient devices – aerators; Water efficient devices – flow regulators; Rainwater harvesting; Stormwater retention; Rainwater drainage; and Permeable area*.
Social practices	Education for CDW management*; Employees’ environmental training*; Employees’ personal development; Employees’ professional training; Inclusion of local workers; Community’s participation in the project design; Orientation to the new residents*;

---

Residents' environmental training; Capacity building for entrepreneurship management;  
Actions for social risk mitigation; and Actions for employment and income generation.

\* Mandatory criteria

\*\* Mandatory criteria for MCMV Track 1 projects

### *Housing Quality Indicators*

Housing Quality Indicators (HQI), launched in the 1990s, was created to incorporate quality as assessment criterion of housing financed by the UK Department of the Environment, Transport and the Regions' Housing Corporation. This system was developed to ensure housing adequacy to laws and included aesthetic quality as an essential issue. Over a trial period it was transformed into a flexible tool that can be used in any project phase, by consumers and developers, for new buildings or retrofits, public or private buildings, isolated units or mixed housing types. It is currently used by the Housing Corporation as a screening tool for financing approvals (Harrison, 1999).

The scope of its fourth and latest version (2008) is divided into two parts - form and spread sheet - comprising three main categories: location, design and performance. The form collects information regarding project description and ten indicators: 1. location; 2. site – visual impact, layout and landscaping; 3. site – open space; 4. site – routes and movement; 5. unit – size; 6. unit – layout; 7. unit – noise, light, services and adaptability; 8. unit – accessibility within the unit; 9. unit - sustainability; and 10. external environment – Building for Life. The Building for Life criteria is an external assessment composed by 20 criteria covering four themes: 1. character; 2. roads, parking and walkability; 3. design and construction; and 4. environment and community. Finally, the spread sheet converts the collected answers into points, which demonstrate the project's performance according with each indicator. All indicators are considered equally important for quality, but users can change weighting according to regional priorities (Harrison, 1999; The National Affordable Homes Agency, 2008).

### **Results and Discussion**

'Project Várzea' Casa Azul assessment profile (Table 2) differs from Paraisópolis in only seven items, despite important differences in concepts and contexts. As for urban quality, both projects reached the performance same criteria, and only failed to meet building rehab requirement. Both projects were delivered with basic infrastructure (e.g. water and energy supply, services, bus stop), the surroundings do not have harmful impact fonts (e.g. highways, airports, dumping ground, industries), and improved them as well as recovered degraded sites. Making improvements in development surrounds is a way to increase the project sustainability, but for this, a wider urban context must be incorporated (Sharifi and Murayama, 2014). Though this category considers a broader context, integration and relationships between urban infrastructure and the project, it is only focused on environmental aspects.

In design & comfort, no project met the community interrelation criterion, which assess negatives impacts of development in neighbourhood. The combination of land limitation and pressing need for delivering numerous HUs prevented that all current neighbourhood conditions were respected. Paraisópolis also did not score in alternative transportation criteria, because topography does not allow using bicycles, and it does not

have private collective transportation, nor ventilation and daylighting in bathrooms. For Project Várzea, design detail was not sufficient yet to assess flexible design, daylighting in common areas and adaptation to local topography criteria. TOD application helped this project to meet the criterion for alternative transportation, but TOD addresses many other improvements than Casa Azul, i.e. existence of bikers, bike paths or collective private transportation. This category depends on local climatic conditions, i.e., strategies to achieve comfort vary according to Brazilian bioclimatic zone, what confers some adaptability to the tool. However, like verified in other research (Retzlaff, 2009), tool adaptability is restricted to this issue.

Regarding energy efficiency, it was not possible to assess solar heating system for Project Varzea, a criterion that Paraisópolis did not meet. This is the category with worst performance for Paraisópolis that did not comply with 'gas heating system', 'efficient elevators' (not applicable to that design), 'efficient appliances', and 'alternative energy sources' requirements. This strongly contrasts with most sustainability expectations, which normally have energy as the most valued criterion. Project Várzea did not comply with 'efficient elevators' and 'efficient appliances'. 'Material resources', 'modular design', 'industrialized or prefabricated components' and 'façades durability' could not be assessed for Project Várzea due to lack of information in the available documents. From the criteria assessed, 'optimized concrete mix', 'use of cement types CPIII and CP IV' and 'CDW pavement' were not met. Paraisópolis also did not score in the latter two criteria, besides 'usage of certified wood'. With some simple modifications in these items, the project would improve its score. For different reasons, none of the projects scored in elementary water management aspects. Project Várzea has not reached design detailing enough to allow assessment. Paraisópolis, however, did not score in rainwater harvesting and rainwater drainage, which is quite surprising. Given the considerable annual precipitation in the region, these are valid and usually feasible strategies solutions for saving water.

Paraisópolis scored best regarding social practices, meeting all of the criteria. For not have been built yet, Project Várzea could not be assessed employees' personal development and professional training, residents' environmental training, and capacity building for entrepreneurship management criteria. These social aspects do not incorporate adaptation, i.e. the differences between countless Brazilian regions and housing typologies that Casa Azul is applicable to. Though it considers some economic criteria, Casa Azul does not offer a broader assessment of costs relationship to deliver, own and maintain sustainable social housing. No residents participation was registered in development or feedback processes, despite being highlighted by previous research (Retzlaff, 2009; Sharifi and Murayama, 2013; Sullivan and Ward, 2012) as important to social and economic issues. Since several criteria could not be assessed, Project Várzea's score would range between 33 and 46, whilst Paraisópolis achieved 39 points. This difference is however irrelevant for certification purposes, and both projects would reach gold level, the maximum rating. Hence, Casa Azul seems to be unable to distinguish important conceptual and sizing differences.

Table 2. Selo Casa Azul assessment results for 'Paraisópolis' and 'Project Várzea'

Categories	Paraisópolis	Project Várzea
Urban Quality	4/5	4/5
Design & Comfort	8/11	7 to 10/11*
Energy Efficiency	3/8	5 to 6/8*

Material Resources	7/10	4 to 7/10*
Water Management	6/8	6 to 8/8*
Social Practices	11/11	7 to 11/11*
Overall score	39	33 – 46*
Level	Gold	Gold

\*Project's minimum and maximum scores, depending on performance results for criteria non-assessed here

In the HQI assessment, Project Várzea scores best for 'location', 'site' and 'external environment' (Table 3). Like in Casa Azul, aspects beyond project site are considered only in one indicator (location). For 'routes and movement', and 'external environment', scores were boosted by TOD application, which however did not change the Casa Azul award level. Simple design adaptations would increase the HQI score; however, at increased investment.

Table 3. HQI assessment results of 'Project Várzea'

Criteria	Score
Location	72%
Site	Visual Impact, Layout and Landscaping
	Open Space
	Routes and Movement
Unit	Size
	Layout
	Noise, Light, Services & Adaptability
	Accessibility within the unity
	Sustainability
External Environment - Building for Life	Environment and Community Character Streets, Parking and Pedestrianisation Design and construction
Overall score	47%

Worst scores are related to open spaces and unit aspects. In open spaces, the main cause of low score is the lack of children's playgrounds and the existence of open spaces without specific use. The last issue causes vulnerability to safety and security, once these areas can be intrusively used. For unit aspects, size of Brazilian social housing units is not consistent with the UK standards that ground HQI. Units in Project Várzea range from 42.90 m<sup>2</sup> to 47.65 m<sup>2</sup> for four bedspaces. In HQI, the minimum sizing for accommodating four residents is between 67 and 75 m<sup>2</sup>, so the examined project falls more than 10% short of its lowest limit, and has no extra room above the minimum required by the HQI standard. All spaces but bedrooms meet sizing requirements for furniture provision, access, circulation and activity zones, but none of them does so by exceeding the minimum requisite. Additional features related to suitable rooms to activities beyond usual are also weakly attempted. Regarding 'noise, light, services & adaptability', the project does not achieve any characteristics for noise reduction (which includes but is not limited to UK requirements), and have a weakly service provision, no additional features for services and no characteristics for adaption.

Finally, 'sustainability criteria' in HQI refer mainly to UK standards and regulations and do not allow for change or adaptation, following the standard of most sustainability assessment systems (Retzlaff, 2009, 2008; Sharifi and Murayama, 2013). The indicator is

divided in three parts - Code for Sustainable Homes, EcoHomes and Rehabilitation – from which one must be chosen. The first two parts refer to new projects and are exclusive to UK context. Rehabilitation is subdivided into energy, lighting, water and others sustainability aspects. Total score in sustainability indicator for Project Várzea results from this last part, to provide low-energy fittings in every room and solutions for good water management.

### Final Remarks

Casa Azul balances environmental and social issues but did not distinguish performance of very different assessed projects. Complete assessment is hampered at early project stages. On its turn, HQI focuses on environmental issues and is based on British standards and practices, which establish requirements that Brazilian social housing projects are not able or not expected to meet, such as unit sizes. Furthermore, despite admitting certain weighting adjustments, this adaptability is limited to the UK context.

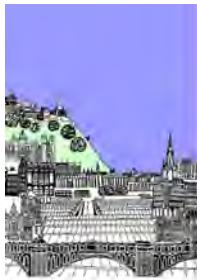

None of the systems consider a broader range of economic aspects or increased urban complexity at neighbourhood scale. Residents' participation is also unexplored. Our assessments confirmed that both tools have limitations and - if used in isolation – would not adequately describe fundamental sustainability aspects. A mixed or adapted set of indicators, encompassing housing unit, context and user character, from environmental, economic and social perspectives, is therefore needed to provide more meaningful results and design inputs, as well as serve as effective funding screening tools.

email: rgupta@brookes.ac.uk, alexis.kotopouleas@brookes.ac.uk

**Abstract:** This paper presents findings from a national meta-study of the difference between designed and as built thermal performance of the building fabric of 188 (50 Passivhaus and 138 non-Passivhaus) low energy dwellings in the UK, which were evaluated as part a national Building Performance Evaluation Programme. The majority was social housing constructed with masonry and timber frames and equipped with MVHR systems. Design and measured data including airtightness, whole house heat loss and external wall/roof U-value was evaluated comparatively and assessed statistically along with the review of thermal imaging data. The findings revealed a prevalent performance gap rooted in thermal deficiencies occurring across the building fabric. The gap was more profound in terms of airtightness and smaller in regard to thermal transmittance and whole house heat loss. The extent of underperformance was minimal among Passivhaus structures and considerable among non-Passivhaus which presented an average gap of  $2\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$ . The results demonstrate the need to improve site workmanship and re-enforce the need for in-situ performance verification to bridge the gap between design intent and as built performance.

**Keywords:** Building fabric performance, low energy dwellings, Passivhaus, airtightness, space heating energy

### Introduction

Mounting evidence since the 1990's has firmly established that buildings, residential and commercial, often demonstrate a discrepancy between predicted and in-use energy consumption (Carbon Trust, 2011). The causes of the "performance gap" span throughout the building process and can be broadly classified into those relating to occupancy, energy performance of services and systems and the thermal performance of building fabric, which is the focus of this paper. Heat loss through the fabric is primarily the result of air leakage and of repeating and non-repeating thermal bridging. In a typical new build dwelling, thermal bridging can account for 20-30% of the total heat loss (Zero Carbon Hub, 2016) while the respective share of air leakage may be up to 50% (Energy Saving Trust, 2009). Underperforming fabric elements can therefore have significant impact on energy use and particularly on space heating which, accounting for over 60% of total energy, is by far the biggest slice of UK household energy use (DECC, 2013).

In response to the worldwide shift towards the use of building energy regulations and codes aimed at reducing energy consumption, there have been a number of studies on the evaluation of building fabric performance. Much of the work however has been case-study-focused and as a result findings have been largely fragmented. A study of 44 cavity masonry homes found a third of the pressure-tested properties underperforming, highlighting the impact of design complexity on the performance gap (Wingfield et al, 2008). Considerable discrepancies in the range of  $0.8\text{-}4.7\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$  were identified in 5 dwellings built to

EcoHomes Excellent and CSH 5&6 (Gupta et al, 2013), similarly to 6 CSH 4&5 dwellings where the actual airtightness was up to two times worse than design expectations (Gupta and Kapsali, 2015). Further representative of the air permeability gap in low energy housing were the discrepancies of  $6.2\text{-}8.6 \text{m}^3/\text{h}/\text{m}^2$  @ 50Pa in 6 timber dwellings built to CSH 4 which resulted in 50% higher heat loss (Bell et al, 2010). Failure to meet the design target has been also seen in Passivhaus dwellings, where however the gap is considerably smaller spanning up to  $0.7 \text{m}^3/\text{h}/\text{m}^2$  @ 50Pa (GHA, 2014 & Johnston et al, 2016).

Co-heating tests are currently the only established method of determining the thermal performance of a whole building envelope. The extent of publicly available data is not extensive, but the increasing number of such tests reflects the need to investigate post-construction performance. An evaluation of 3 dwellings built to EcoHomes Excellent and CSH 6 highlighted deviations from the SAP calculations in the range of 3-23% (Gupta et al, 2013), while a study of 25 dwellings built to Part L1A 2006 or better yielded 1.5 times higher HLC than predicted denoting an average gap of 50% (Johnston et al, 2015). A wide range of discrepancies has been reported in respect to CSH 4 dwellings; from 12-15% (Farmer et al, 2014) in two detached dwellings to 54% across 6 timber-framed homes (Bell et al, 2010) and even higher, 131-189% across 7 dwellings of different construction (AIMC4, 2014). Higher heat loss than calculated has been additionally identified in Passivhaus constructions, where the gap however is generally lower and of similar magnitude (6-21%) across the different studies (Guerra-Santin et al, 2013; Johnston et al, 2016; Johnston & Siddall, 2016).

The frequent inconsistency between design and in-situ thermal transmittance provide further evidence for the building fabric performance gap. The large-scale study at Stamford Brook is a representative example where the effective U-value was twice the design U-value of the external wall and nearly three times that of the floor and ceiling (Wingfield et al, 2008). Another study of 25 dwellings found the whole building U value over 1.6 times higher than the steady state predicted value (Johnston et al, 2015). Deviations from the design targets have been seen in Passivhaus dwellings as well, however similarly to airtightness and heat loss, the gap appears to be much lower and often negligible; U-value measurements of external walls and roofs have revealed discrepancies in the range of  $0.01\text{-}0.06 \text{ W/m}^2\text{K}$  and  $0.05\text{-}0.06 \text{ W/m}^2\text{K}$  respectively (Guerra-Santin et al, 2013; GHA, 2014; Johnston et al, 2016).

The performance of building fabric is largely determined by design and construction. Aiming towards a comprehensive understanding of the fabric performance gap in low energy housing and its effect on actual space heating energy, this study uses the meta-study approach to evaluate with increased statistical power the difference between design and as build air permeability, thermal transmittance and whole house heat loss of dwellings from comparable studies, thus allowing for conclusions applicable to the wider new build housing population.

### **Overview of the study: data sources and methods**

The study comprises an extensive review and analysis of the “as designed” and “as built” fabric thermal performance data generated in 53 studies of new build and low energy dwellings in the UK, in the course of the £8 million Building Performance Evaluation programme (2010-2014) funded by Innovate UK (Innovate UK, 2014). The dwellings were located across 44 developments in N. Ireland (1 out of 44), Wales (2 out of 44), Scotland (9 out of 44) and predominantly England (32 out 44), and were occupied during the “in-use” phase of the studies. The fabric performance had been investigated using diagnostic field tests including an air-permeability test, whole house heat loss test, heat flux measurements

and infrared thermal imaging surveys. Using a range of data sources such as the studies' final report, SAP and DomEarm spreadsheets the study developed a large database of air permeability, whole house heat loss, external wall and roof U-values and thermal imaging data. The database comprises 138 non-Passivhaus (NPH) and 50 Passivhaus (PH) including 94 houses, 89 flats and 5 bungalows with floor areas from 37m<sup>2</sup> to 346m<sup>2</sup>, designed to diverse standards from Passivhaus and Fabric First approach to Code of Sustainable Homes (CSH 2-6) and Building Regulations. The construction types included structural insulated panels (SIPs), steel, concrete and predominantly the traditional masonry (73 out of 188) and timber frames (80 out of 188). In terms of ventilation strategy, passive systems for natural ventilation (NV) and mechanical extract ventilation (MEV) were adopted in 10% and 5% of the dwellings respectively, whereas the overwhelming majority (85%) used Mechanical Ventilation with Heat Recovery (MVHR). The most common tenure type was social housing (133 out of 188). Figure 1 illustrates the percentage distribution of these characteristics separately for the PH and NPH dwellings.

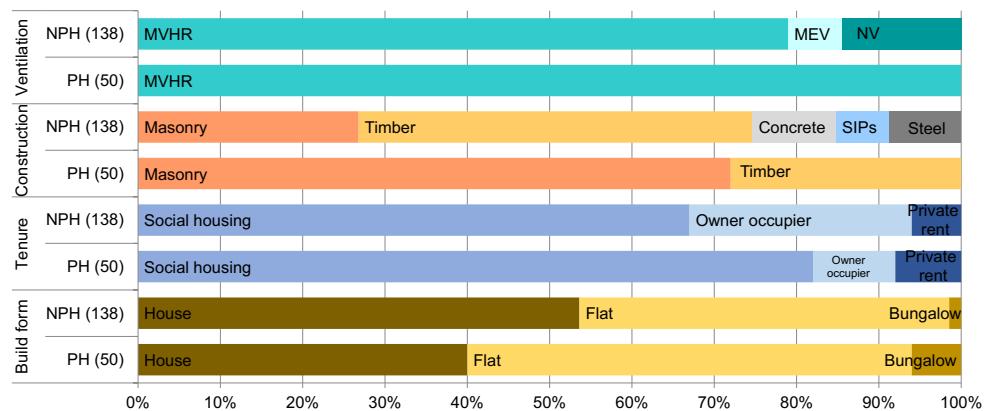

Figure 1: Build form, tenure type, construction system and ventilation strategy for the 188 dwellings reviewed, separately for Passivhaus (PH) and non-Passivhaus (NPH) dwellings.

Data was analysed by means of the Statistical Package for Social Sciences (SPSS). A statistical analysis plan was developed to maximise uniformity in data analysis and ensure validity of results. Thermal imaging data was analysed at the development level while air permeability, heat loss and U-value data at dwelling level with the respective sample sizes varying between 188 for air permeability and 29 for heat loss due to data availability (Table 1).

Table 1: Sample size of dwellings (and developments for thermal imaging) reviewed.

	Air permeability	External wall U-value	Roof U-value	Whole house heat loss	Thermal imaging
Passivhaus	50	14	5	6	10
Non-Passivhaus	138	48	15	23	34
Total	188	62	20	29	44

## Results

### **Designed and measured airtightness**

Design and in-situ data were reviewed for 188 dwellings in 43 developments. The measured data originated from air permeability tests conducted to the ATTMA standard (ATTMA, 2010), though the test had been extended to include both pressurisation and depressurisation with the final air permeability result represented by the average of the two. The average measured air permeability over the 188 dwellings (3.8m<sup>3</sup>/h/m<sup>2</sup>@50Pa) was

marginally lower than the average design target ( $4.0\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$ ), however the median design and measured values were 3.0 and  $4.0\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$  respectively denoting a performance gap. This was validated from the weak statistical relationship between design and measured air permeability for PH and no relationship for NPH (Figure 2a) as well as from the large number of dwellings (96 out of 188; 51%) that failed to meet design air permeability (Figure 3). This was the case with over half the PH dwellings (29 out of 50; 58%) and nearly half the NPH dwellings (67 out of 138; 49%) which presented an average gap of 0.5 and  $1.9\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$  respectively.

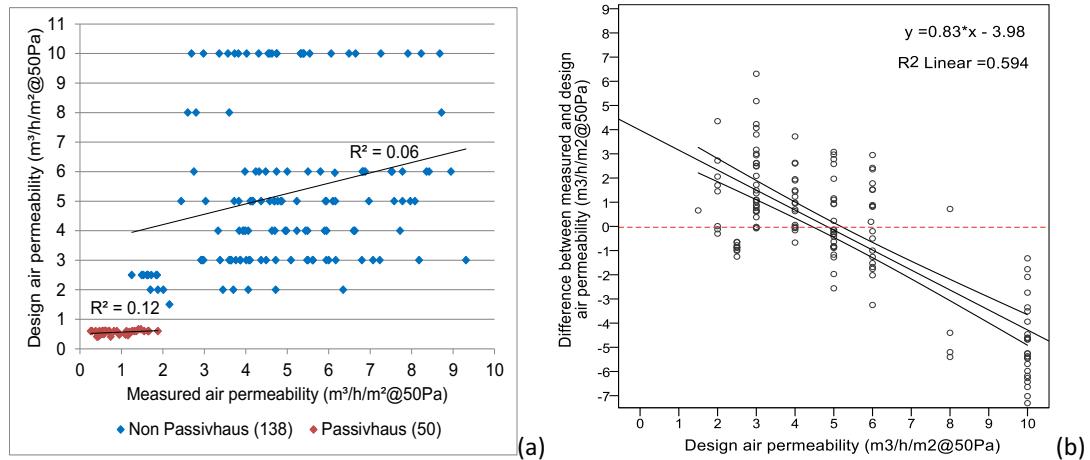

Figure 2: (a) Relationship between design and measured air permeability, (b) rate of change of the difference between measured and design air permeability with changes in the design target for 138 NPH dwellings.

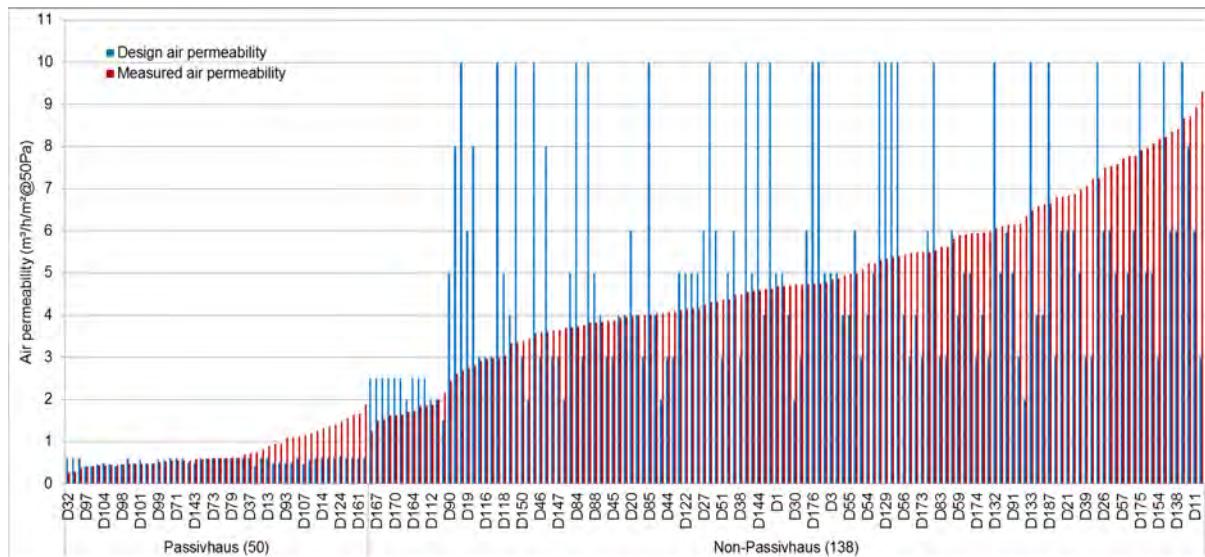

Figure 3: Design and measured air permeability for 50 Passivhaus and 138 non-Passivhaus dwellings.

Further scrutiny of the airtightness data revealed a strong tendency of NPH envelopes designed to  $5\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$  or better to demonstrate an air permeability gap. The regression model in figure 2b (significant at  $p<0.05$ ) shows that the lower the design air permeability, the difference between measured and design air permeability increases, indicating the importance of workmanship in achieving high levels of airtightness. The model implies that for every  $1\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$  decrease in design air permeability the gap between actual and intended airtightness increases by  $0.8\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$ , with the cut-off point at  $5\text{m}^3/\text{h}/\text{m}^2@50\text{Pa}$ .

### **Thermal transmittance of building elements and whole-house heat loss**

In-situ external wall U-value (measured in accordance to ISO 9869; ISO, 1994) was compared against the design intention for 14 PH and 48 NPH dwellings in 37 developments. The mean measured U-value was higher than designed by only 0.03 W/m<sup>2</sup>K (+27%) in PH dwellings and by 0.07 W/m<sup>2</sup>K (+39%) among NPH dwellings. The intended performance was not achieved in 8 out of 14 PH and 29 out of 48 NPH, denoting an average gap of 0.05 W/m<sup>2</sup>K and 0.14 W/m<sup>2</sup>K respectively, while in 12 cases the measured U-value exceeded the Part L1A limit.

Roof U-value data was reviewed for 5 PH and 15 NPH dwellings in 14 developments. Similarly to external walls, the mean measured roof U-value was marginally higher than designed in both PH and NPH dwellings, by 0.04 W/m<sup>2</sup>K (+44%) and 0.10 W/m<sup>2</sup>K (+71%), and the gap among the underperforming dwellings was higher among NPH. The roof element had failed to perform to its design intention in 4 out of 5 PH and 11 out of 15 NPH presenting an average discrepancy of 0.04 W/m<sup>2</sup>K and 0.15 W/m<sup>2</sup>K respectively.

The investigation of whole house heat loss involved data from 6 PH and 23 NPH buildings in 21 developments. The co-heating tests had been undertaken in accordance to the Leeds Becket University protocol (Wingfield et al, 2010) though in certain cases deviations were necessary. The majority of dwellings - 5 out of 6 PH and 15 out of 23 NPH - was seen to underperform demonstrating an average gap of 4.5 W/K and 42.1 W/K respectively. The percentage deviation across the total sample of PH dwellings was only 5% but significantly higher at 20% among NPH dwellings, regularly exceeding the generally accepted close match between predicted and measured HLC of 10-15% (Bell et al, 2010).

### **Link between fabric performance and measured space heating energy use**

Measured air permeability and HLC data was analysed against measured heating energy data to investigate the impact of fabric thermal performance on space heating. The results indicated an overall very weak relationship ( $R^2=0.18$ ) with air permeability (Figure 4a), which is inexistent for NPH dwellings ( $R^2=0.07$ ) and moderate for PH dwellings ( $R^2=0.65$ ), demonstrating that high levels of airtightness do not guarantee low heating energy as other factors such as type of heating system, controls, and occupant behaviour are also important contributors. Interestingly, a very strong relationship was found between space heating energy and HLC (Figure 4b), implying that a comprehensive building fabric test may be more reliable than just an air permeability test currently required in the Building Regulations.

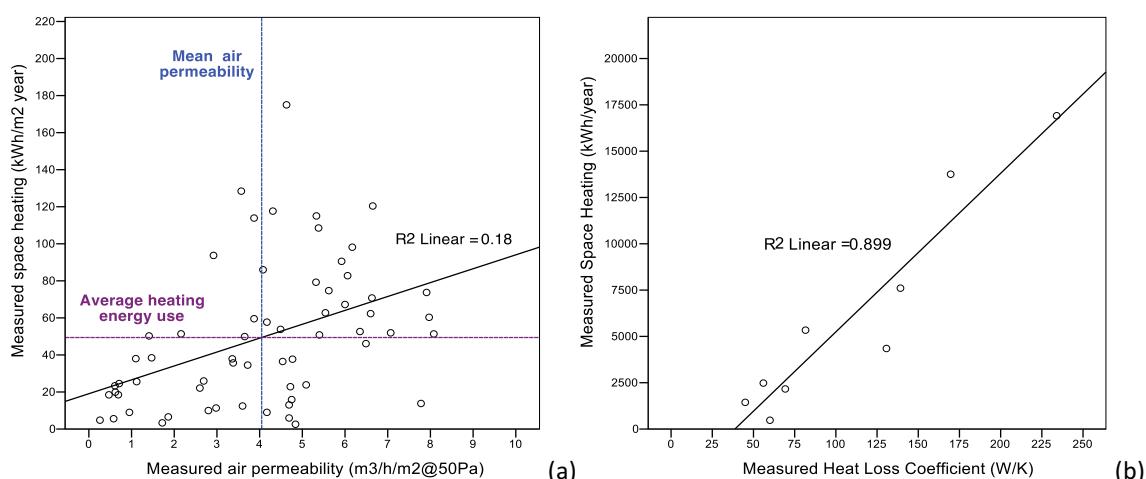

Figure 4: Relationship between space heating and (a) air permeability for 188 dwellings and (b) heat loss coefficient for 9 non-Passivhaus dwellings.

### ***Identifying likely thermal defects using thermal imaging survey data***

A review of the qualitative data gathered through internal and external thermal imaging surveys in the 44 developments was undertaken to identify the breadth and frequency of fabric locations with thermal deficiencies. The results highlighted openings as the weakest fabric element; heat loss and air leakage through windows and doors were identified in the vast majority (84%) of developments (Table 2). Common areas of weakness, as pinpointed in nearly half the developments, were also the junctions and joints as well as the roof at the eaves level and loft space with common causes the inadequate insulation and/or poor packing of insulation into the eaves and heat loss from the loft hatch and interface with the ceiling. In a smaller, yet considerable fraction of sites (25%), localised thermal bridging was found in walls (34%) and ceilings (25%) as well as in service penetrations and fittings (23%) such as MVHR supply vents and extract fans. Other defects with similar frequency of occurrence include air leakage through boxed-in sections and unregulated heat gain from insufficiently insulated heating manifold cupboards, heating and hot water pipework, overall indicating that thermal deficiencies can occur anywhere within the building fabric.

Table 2: Faulty areas and frequency as revealed from thermal imaging surveys in 44 developments.

	Roof/Eaves & loft space	Junctions & Joints	Walls only	Ceilings only	Windows & Doors	Fittings/Service penetrations	Slab/ground level	Other
Overall (44 developments)	20/44	21/44	15/44	11/44	37/44	10/44	4/44	11/44
Passivhaus (10 developments)	2/10	0/10	3/10	3/10	10/10	1/10	0/10	2/10
Non-Passivhaus (34 developments)	18/34	21/34	12/34	8/34	27/34	9/34	4/34	9/34

A comparison between the NPH (34) and PH (10) developments revealed a significantly lower frequency of defects among the latter, thus highlighting the importance of attention to detail. Defects associated with the roof, eaves and loft space for instance, were revealed in only 2 out of 10 PH developments and in over half (18 out of 34) NPH developments. Moreover, thermal deficiencies in junctions and joints were found in over 60% (21 out of 34) of the NPH developments and in none of the PH developments (Table 2).

### **Discussion**

The analysis of fabric thermal performance data from 188 new build homes revealed widespread deviations from the design intent in the majority of dwellings. The greatest discrepancies were seen in airtightness whereas the gap in terms of whole house heat loss and thermal transmittance of roof and external wall was smaller. With nearly all developments presenting deficiencies at windows and doors, thermal weakness at openings seems to be endemic across the sector (Table 2). The review of thermographic data however indicated that thermal defects can occur anywhere within the building fabric, from junctions/joints and roofs to slab/ground level and service penetrations, thus highlighting the need to improve detailing, specification and workmanship. The prevalence of the fabric performance gap amongst this sample of dwellings designed and constructed to low energy standards by expert teams who were aware of the monitoring and testing commitment, indicates a widespread occurrence of this gap across the UK new build housing population.

PH dwellings require meticulous attention to detail to achieve the high airtightness levels required for certification. Although the fraction of underperforming dwellings was higher among PH builds, the deviation from the design intent was most often insignificant and within expectations. On the contrary, the gap was consistently higher among NPH dwellings across the entire spectrum of fabric performance including airtightness, thermal transmittance and whole house heat loss, thus highlighting the design and attention to detail as key differentiating factors between the performance gap in PH and NPH dwellings.

While airtightness is a key determinant of space heating, the weak relationship between actual air permeability and heating energy use (Figure 4a) indicates the influence of other factors, denoting that designing and building airtight homes does not necessarily lower space heating energy use. This also suggests that a holistic approach to building monitoring is necessary that includes services, systems and measurement of occupant behaviour. The strong relationship between space heating energy use and HLC (Figure 4b) shows that a comprehensive fabric test would be more reliable than air permeability test as currently required. The prevalence and extent of the fabric underperformance, such as the air permeability gap of  $1.9\text{m}^3/\text{h}/\text{m}^2$  @ 50Pa among NPH dwellings, also raises the need to have accurate and updated as-built energy models that are based on measured data and capture the impact of design or construction changes on energy use.

## Conclusions

This research has undertaken a meta-study of the building fabric thermal performance gap in 188 low energy dwellings in the UK, including Passivhaus (50) and non-Passivhaus structures (138), drawn from the Government's Building Performance Evaluation Programme. Actual air permeability, whole house heat loss and thermal transmittance of external wall and roof, determined from in-situ measurements, were compared against the design intention and reviewed along with thermographic survey data. The findings show that building to the design intent is not commonplace. The prevalence of the fabric performance gap, more profound in terms of airtightness, and the occurrence of thermal defects across the building fabric has raised the need for better construction quality and diagnostics. A comprehensive fabric test including air permeability, heat flux measurements and thermal imaging in all dwellings can be more reliable than just an air permeability test in a sample of dwellings as currently required in Building Regulations and can inform as build energy models to produce predictions closer to actual performance. Ultimately, identifying the underlying causes of the fabric performance gap is important to a range of key stakeholders including designers, M&E consultants, constructors and policy-makers. Such knowledge should inform the future versions of Building Regulations, which can require more in-situ testing of the building fabric during the construction and completion stages.

<sup>4</sup> Stichting Stadslab Buiksloterham, Amsterdam, The Netherlands

**Abstract:** The traditional way of supplying energy to the built environment is no longer suitable: New buildings with high energy performance and decentralised renewable energy generation, together with the desire to become fossil-free, involve the need for new, more flexible and more integrated energy systems. The district of Buiksloterham was a test case to develop feasible and potentially desirable energy supply scenarios for the built environment at district level. It is not possible to develop Buiksloterham, and similar areas with high density, into an energy neutral area within the current legal framework (without wind energy it is not possible). About 1/3 of the energy use in buildings (building-related and user-related) can be supplied by renewable energy. In Buiksloterham a low temperature supply of heat is essential for a maximised use of renewable input. A fourth, low temperature, energy concept, consisting of local heat generation from solar and waste, thermal storage, and heat pumps, seems the best integrated energy system. The non-technical lesson learned is that new energy-efficient energy systems require very good, early planning, appointments, and cost and support of existing energy suppliers. Extracting a CO<sub>2</sub> neutral society by 2050 also depends on implementation aspects i.e. not only CO<sub>2</sub> and costs but also circularity parameters such as the use of resources for equipment, water, biodiversity, health, adaptability and resilience must be considered.

**Keywords:** Energy, Systems, District

### Introduction

The traditional way of supplying energy to the built environment is no longer sustainable: New buildings with high energy performance and decentralised renewable energy generation, together with the desire to become fossil-free, need new, more flexible and more integrated energy systems. The city of Amsterdam has a large programme for new buildings (Gemeente Amsterdam). At the same time, the city's ambition is to become independent of natural gas for energy supply to the built environment by 2050. New buildings, therefore, should not be connected to the gas grid anymore.

Innovative scenarios for a flexible and integrated energy system are developed within the Buiksloterham Integrated Energy Systems (BIES) project for the suburb of Buiksloterham located in Amsterdam-North, see figure 1. The results of this study should also be applicable to other new construction sites with high energy ambitions and high densities. Both technical and organisational boundary conditions are considered in this research.

The Buiksloterham area is located on the North side of the IJ-river relative to Amsterdam Central Station and can be reached within five minutes from the Central Station

with a free ferry service. The construction of the new “North-South” metro line, which will link the historic centre of Amsterdam with the northern side of the river, is scheduled for completion in early 2016 and will provide an important means of additional access. Buiksloterham, a former industrial area, is one of the larger new housing estates (around 100 ha) where 3500 new dwellings and around 200.000 m<sup>2</sup> working space is planned within the next 10 years.

Figure 1. The area of Buiksloterham (source: Bestemmingsplan Buiksloterham 2009)

## Literature

The starting point for the development of the technical energy concepts was the energy potential mapping approach by Dobbelsteen et al. (2007) and Broersma et al. (2013). The ‘toolkit duurzame gebiedsontwikkeling 2012’ and the report by Jablonska et al. (2011) were used for the development of both new energy concepts and new energy approaches.

However, the ambitions of the BIES project went beyond matching the energy potential to the demand. The wish of the district of Buiksloterham is to become a leading example of Circular City development in Amsterdam (Circular Buiksloterham report). This enforced the development of an integrated energy system that was sustainable in all its aspects. The district of Buiksloterham as a living lab required that the economic feasibility had to be taken into account to assure an affordable integrated energy system in the near future. And last but not least, to realise an integrated energy system in Buiksloterham is impossible if the political, social, technological, legal, and governmental aspects of the PESTLEG analysis are not considered.

The detailed quantitative analysis of the energy concepts and their evaluation on all the aspects mentioned above required an enormous amount of background literature. The energy demand of the buildings is based on the Dutch RVO (2015). An overview of all the other applied literature can be found in the final report of the project (Jansen et. al, 2016, in Dutch) as the page limit of this paper it too restricted to cite them all. Apart from the literature, a lot of information was also gained from stakeholders active in the area.

## Methods

For the development of the energy concept an integral approach was developed where circularity in all its aspects was taken into account as well as the political, economic, social, technological, legal and governmental aspects. The approach consisted of two routes that were followed simultaneously. The first route is the theoretical development of the basic energy concepts. The second route is the practical approach where stakeholder meetings

were used, as well as meetings with potential suppliers from industry, in order to improve the basic energy concept.

The area consists of existing and new buildings. Given the diverse nature of the existing buildings, the main focus was the energy concept for the new buildings. Recommendations for the existing buildings and the integration between the two are proposed in the project but not described in this paper.

### **Development of the Basic Energy Concept**

An inventory was made of the existing buildings and the plans for the new buildings. Use was made of the “bestemmingsplan” (land us plan set up under the authority of the municipality) and the existing report about the circular ambition of Buiksloterham (Metabolic and Delva Landscape Architects, 2014). The inventory also included an inventory of stakeholders and existing energy infrastructures.

The energy concepts were assed using Key Performance Indicators (KPI’s). These KPI’s are developed within the following categories: energy, economy, circularity and implementation. The implementation category, in turn, consists of the PSTLG indicators: Political, Social, Technological, Legal and Governance. The main KPI’s for energy are: the fraction of local renewable energy and the amount of CO<sub>2</sub> with the subcategories: energy use of existing buildings, energy use of new buildings and renewable energy potential, see the annual energy flow scheme in figure 2. The energy use data of existing buildings was obtained from [www.energieinbeeld.nl](http://www.energieinbeeld.nl). The energy potential on-site was estimated based on average roof surfaces for solar and average production of waste and waste water.

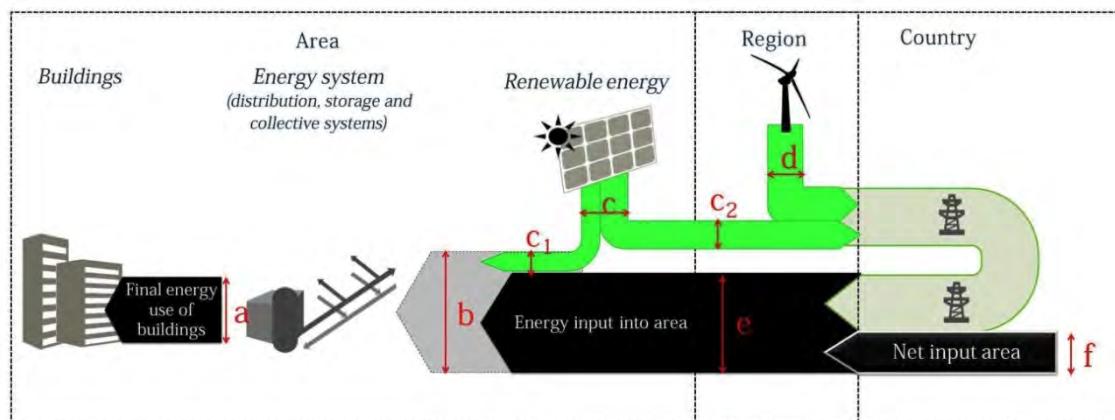

Figure 2. Schematic illustration of the Energy performance indicators in GJ/y (Jansen et al. 2015)

Two options were used as the starting point for the energy demand of new buildings. The first option has an energy efficient building skin, i.e. the Energy Performance Coefficient (EPC) of 0.4 of the building is reached with a standard energy system (HR gas boiler, electricity from the grid) and no sustainable production. In the other option, the insulation values of the building skin comply with the minimum values of the Dutch Building Regulations so that the EPC of 0.4 can be reached with efficient/sustainable energy solutions. The demand data for heating, cooling, domestic hot water and electricity consumption of the new buildings were based on reference numbers from RVO, 2015.

Three basic energy concepts for energy supply for the new buildings were developed based on proven and existing technologies: 1. Gas and electricity, 2. All-electric (heat pump and ground source thermal storage) and 3. District heating with electricity. Experience in the area and existing agreements between stakeholders were also taken into account in the

development of these energy concepts. The efficiencies of the technologies involved were taken from RVO, 2015 and from the experiences of the project partners.

### ***Development of the Energy Concept Advice***

In February 2016, a first stakeholder meeting with around 25 people active in the area was organised to discuss the basic energy concepts. The discussions revealed that more attention had to be paid to the specific local situation in Buiksloterham. The evaluation of the basic variants generated ideas for improvements for the new and existing buildings. In May 2016, a second stakeholder meeting was organised where improvement ideas were presented and further developed. Finally, the basic energy concepts were evaluated and ideas for further improvements were created. Several literature sources and stakeholders were additionally consulted to obtain the most correct data.

## **Results**

### ***Energy demand***

The total energy demand for heating and cooling for new buildings is between 40,000 and 50,000 GJ/year for heating (room heating and domestic hot water) and between 11,000 and 14,000 GJ/year for cooling, see figure 3. The electricity demand between 42,000 and 48,000 GJ/year is the sum of building related electricity (mainly lighting and ventilators) and user related electricity (computers, TV, etc.). The total energy demand for the existing buildings is the actual energy use in 2014 (data from the utility company Alliander), see table 1.

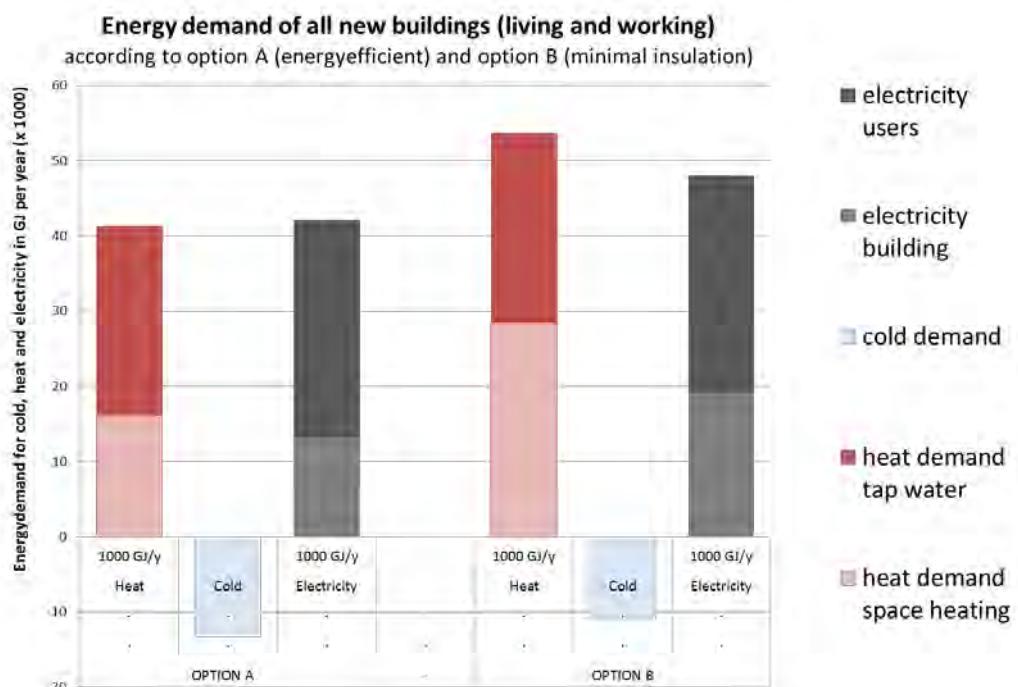

Figure 3: Total energy demand of the new buildings of Buiksloterham till 2024 for space heating, cooling and tap water. Option A and B represent different grades of insulation (A is very energy efficient and B according to the minimal values of the Dutch Building Regulations).

Table 1. Total energy use existing buildings (2014 data from utility company Alliander).

	Electricity usage existing buildings	Gas usage existing buildings
usual units	$27.0 \times 10^6$ kWh/year	$2.47 \times 10^6$ m <sup>3</sup> /year
GJ/year	$97.4 \times 10^3$ GJ/year	$86.7 \times 10^3$ GJ/year

## Energy potentials

The energy potential of the new buildings is shown in figure 4. The production of solar energy, electricity as well as heat, is considerable as the ambitious assumption is made that almost the entire roof area of the new buildings can be used for PV. PV on the facade is not taken into account.

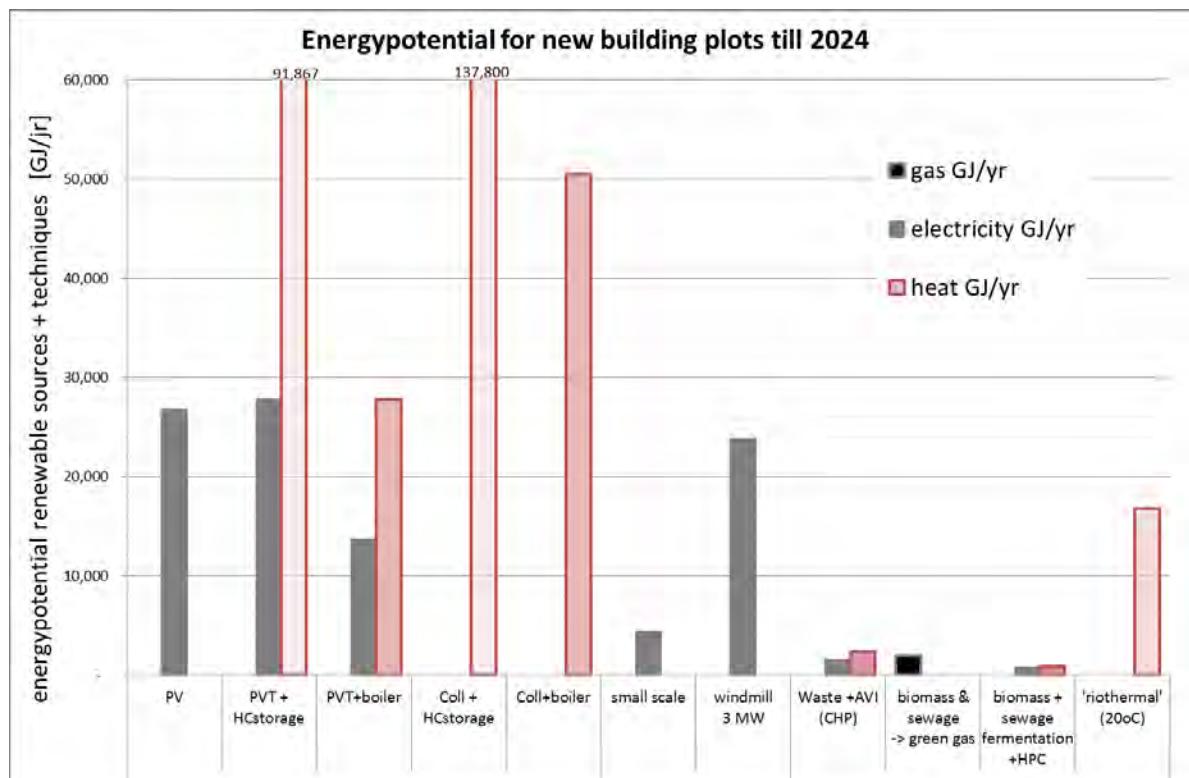

Figure 4. Energy potentials of new buildings from sun and wind on roofs and from waste and sewage.

The availability of local heat at relatively low temperatures (15 to 35 °C) is large. The PVT panels and solar collectors can produce more heat when the heat can be delivered at lower temperatures, for example combined with heat and cold storage in the ground instead of a boiler tank. Heat recovery from the sewage system, also called 'rio-thermal' energy, is another source of low temperature heat. Rio-thermal heat recovery has the advantage that this heat is also available in winter when there is less sun from the solar systems. A heat pump is, however, always necessary to upgrade the low temperature heat for room heating or domestic hot water. Attention should be paid to the fact that the necessary electricity for the heat pump is lower when the source temperature is closer to the supply temperature, even if the necessary amount of heat is the same.

The energy potential for waste is calculated assuming maximum reuse of recyclable elements. This means a high amount of organic waste and a low amount of refuse remaining after separation of recyclable elements. The remaining refuse after separation of recyclable elements can produce electricity and heat in a waste incineration plant and the organic waste can produce electricity and heat in a heat and power plant (after fermentation). Compared to the energy demand, only a very limited amount of biogas can be produced from the available waste and black water in the area.

Table 2. Overview of the assessment of the different energy supply concepts for new buildings

	Criterium	Concept 1	Concept 2	Concept 3
<b>1 ENERGY</b>				
	% local renewable	38%	55%	36%
	% Total (local + regional) renewable	54%	100%	49%
	CO2 emission [ton CO <sub>2</sub> /y]	2.443	-	787
	Selfsufficiency	Entire heat demand not self-sufficient	Local heat covered electricity not yet	Entire heat demand not self-sufficient
<b>2 ECONOMY</b>				
Costs Enduser		TOTAL € 12.919,-	TOTAL € 17.482,-	TOTAL € 20.522,-
Societal costs (use of existing infrastructure and need for new infrastructure)	Infrastructure gas	neutral	average	average
	Infrastructure electricity & peak power(MWp)	average (7,65)	average (7,65)	average (7,65)
	Infrastructure district heating	neutral	neutral	average
<b>3 CIRCULARITY</b>				
	Use of natural resources	circularity not possible	some bottlenecks	many bottlenecks
	Water	many bottlenecks	some bottlenecks	many bottlenecks
	Energy cumulative	some bottlenecks	many bottlenecks	many bottlenecks
	Biodiv. & Ecosystems	many bottlenecks	some bottlenecks	many bottlenecks
	Health & wellbeing	many bottlenecks	some bottlenecks	some bottlenecks
	Adaptivity & resilience	circularity not possible	no bottlenecks	many bottlenecks
<b>4 IMPLEMENTATION (PSTLG)</b>				
	Political	not possible	not possible	is promoted
	Social implications	bottlenecks	neutral	bottlenecks
	Technological	neutral	neutral	neutral
	Legal	not possible	bottlenecks	is promoted
	Governance	neutral	bottlenecks	neutral

### Energy concept assessment

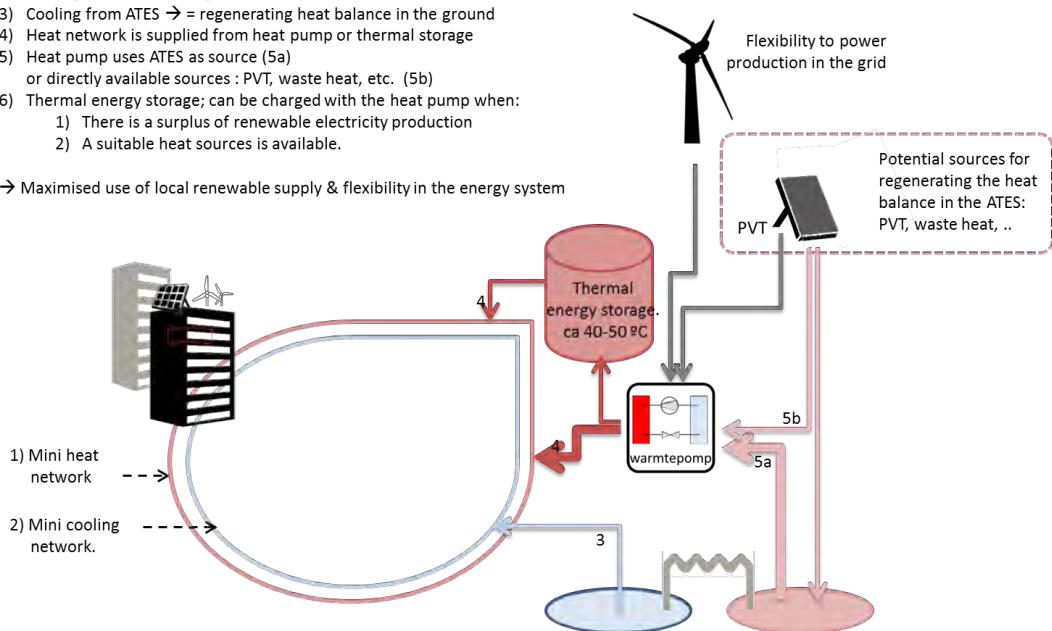

Table 2 shows the assessment of the energy concepts for the new dwellings. The assessment shows that concept 1 is by far the most favourable in terms of costs, followed by concept 2, and then 3. Concept 2 is the most favourable related to energy performance and overall sustainability. Given the existing agreements in Buiksloterham only concept 3 is applicable. The assessment also shows that none of the basic concepts is truly an integrated

energy system, where synergies are sought and flexibility for the grid is achieved. For example, the expected large quantity of installed PV power may even lead to an upgrade of the power grid.

To eliminate these shortcomings, a fourth variant was developed, based on maximum use of local heat, use of a collective heat pump and a mini heat network at low temperatures, around 40 °C, see figure 5. Storage of thermal energy is an essential part here, since in this way more local heat can be exploited and flexibility in the network is increased due to the flexible use of the heat pump. The ideal temperature and scale for such a collective energy concept and mini heat network remains to be investigated.

From the assessment of this fourth, alternative concept, it appears that the integrated approach can lead to more benefits than the basic concepts. The combination of more local heat produced with large (seasonal) thermal energy storage can increase the use of local renewable heat and increase the flexibility for the electricity grid. Collective systems can also have a higher efficiency, especially when thermal storage is involved. However, the problem with this kind of development is mainly the governance; only few parties can make large investments and exploit such systems. In Buiksloterham this proves especially difficult due to the different timing of different developments.

- 1) Space heating and domestic hot water with mini heat network
  - 2) Cooling with mini cooling network
  - 3) Cooling from ATES → = regenerating heat balance in the ground
  - 4) Heat network is supplied from heat pump or thermal storage
  - 5) Heat pump uses ATES as source (5a)  
or directly available sources : PVT, waste heat, etc. (5b)
  - 6) Thermal energy storage; can be charged with the heat pump when:
    - 1) There is a surplus of renewable electricity production
    - 2) A suitable heat source is available.
- Maximised use of local renewable supply & flexibility in the energy system

*Figure 5. Scheme of a fourth energy concept for the new buildings developed to overcome the shortcomings of the basic variants 1, 2, and 3.*

## Conclusion

It is not possible to develop Buiksloterham, and similar areas with high density, into an energy neutral area within the current legal framework (without wind energy it is not possible). About 1/3 of the energy use in buildings (building-related energy plus user-related energy) can be supplied by renewable energy. It is possible to identify which concepts result in the highest fraction of renewable supply: The BIES project concludes that a low temperature supply of heat is essential for a maximised use of local renewable input. The fourth energy concept developed seems to meet the ambitions related to maximum

renewable supply and system integration. This concept is based on local heat generation, thermal storage at relatively low temperatures, produced from solar energy or by upgrading low temperature (waste) heat by means heat pumps.

What can be learned from this project, besides the technical conclusions, is that new energy-efficient energy systems require very good, early planning, appointments, and cost and support of existing energy suppliers. Achieving a CO<sub>2</sub> neutral society by 2050 depends not only on technological innovation; implementation aspects have a significant impact. In the assessment of the most future proof and sustainable energy system an integrated approach is needed, that is: not only looking at CO<sub>2</sub> and costs but also including circularity parameters such as the use of resources for equipment, water, biodiversity, health, adaptability and resilience.

## Modern Buildings and Environmental Comfort – Reuse of Existing and Vacant Buildings

Nathália Mara Lorenzetti Lima<sup>1</sup> and Roberta Consentino Kronka Mülfarth<sup>2</sup>

<sup>1</sup> Master's student at the Faculty of architecture and Urbanism, University of São Paulo, São Paulo, Brazil, nathalia.lorenzetti@usp.br.

<sup>2</sup> Professor at the Faculty of architecture and Urbanism, University of São Paulo, São Paulo, Brazil, rkronka@usp.br.

**Abstract:** The incompatibility between the vacancy of built edifications and the demand for housing in the central region of São Paulo is the prime motivator of this work. The purpose of this article is to prove, through environmental-simulation software, as well as spatial and ergonomic analysis, how urgent it is to rehabilitate buildings produced between 1930 and 1964, for residential purposes. The methodology involved the selection of two commercial buildings which are currently in state of disuse, and whose typologies strongly resemble the majority of buildings constructed in the same period (and for the same purposes), so that the solutions explored in this research can be replicated. Through rehabilitation, these constructions have been improved and have had their qualities explored to the fullest, in order to contribute to their overall autonomy and energetic efficiency. The ergonomic performance was studied through the analysis of tasks in order to assure it is possible to realize both conventional and non-conventional tasks in the residential environment. The article concluded that the constructive characteristics of the buildings, ergonomic performance improvements and users' behavioral changes have a strong influence on the overall performance of the units, increasing the potential for housing in the center of the city.

**Keywords:** Retrofit. Environmental performance. Ergonomic comfort.

### Introduction

A compact urban space doesn't necessarily mean twenty-story buildings around every corner. In fact, exploring the possibilities of mixed-use buildings so that the infrastructure can be exploited to its fullest is what defines a city's body. Having a transportation system operating optimally not only reduces the average time of daily trips, but also renews parts of the city who have been neglected by public administration.

Although São Paulo's central area has a seemingly intense use, it is filled with under-used infrastructure, since its usage is four times bigger during the day than it is during the night. This can be explained by the fact that the central portion of the city holds 24% of all the jobs, while most of the workers come from peripheral regions (data collected from the 'Renova Centro' program). Besides, the current vacancy rate of this same area is close to 30%, which makes the possibility of rehabilitating these buildings stand out, once the infrastructure is already there. Requalifying them means recovering their dwelling characteristics, who have been lost due to the changes on the users' necessities and on the demands of the region itself. The environmental conditions of a construction can vary based on the changes on its surroundings: taller buildings can block ventilation; the increase of

motorized vehicles creates vocal stress, and the temperature rises thanks to both of these situations.

In that context, it is of great importance to analyze environmental comfort parameters while in conception of a new building or while evaluating an existing one. This analysis consists of *an individual perception concerning physical space, influenced by values of convenience, adequacy, expressivity, comfort and pleasure* (VIRILIO, 1993).

Apart from the users' demands, it is crucial to implement systems with low energy consumption, seeing that our planet has limited natural resources and we should preserve them.

### **Building-choice standards**

Some characteristics make themselves present in most of the constructions built at the time, such as the large gaps between columns, big sized windows, ceiling heights around three meters – all that made possible with the use of reinforced concrete. Furthermore, thick walls propitiate increased thermal inertia, or, in other words, they guarantee the temperature variation range is smaller inside the building than on the outside, avoiding exacerbated peak temperatures. This is one of the main constructive features of the buildings that date from the years of 1930 through 1960.

Since the scope of the edifications that are being dealt with includes only commercial and trade and services constructions, the stories are fairly unobstructed, which makes layout solutions quite simple. However, the purpose of this research is to keep the proposed spaces as flexible as possible, so that it is viable to answer to whatever demand the different domestic environments may present.

After observing which are the most recurring typologies in the city of São Paulo, with emphasis on abandoned or sub utilized edifications, two were chosen to be explored in this study. Through those typological patterns it is intended to come to adaptable solutions to these buildings. From this, some of the most common characteristics inside these two typologies were listed, such as: mixed use; presence of commercial units on the ground floor; remaining floors holding various services; vertical circulation through stairs and elevators. Those characteristics helped narrowing down which would be the studied constructions. Following the described steps, two buildings were chosen, one of them located at Paula Souza Street and the other one at Capitão Salomão Street. For the purpose of this article, only the first one was explored, since it has a wider amount of possible solutions given the multiple obstacles and difficulties faced when attempting to rehabilitate it.

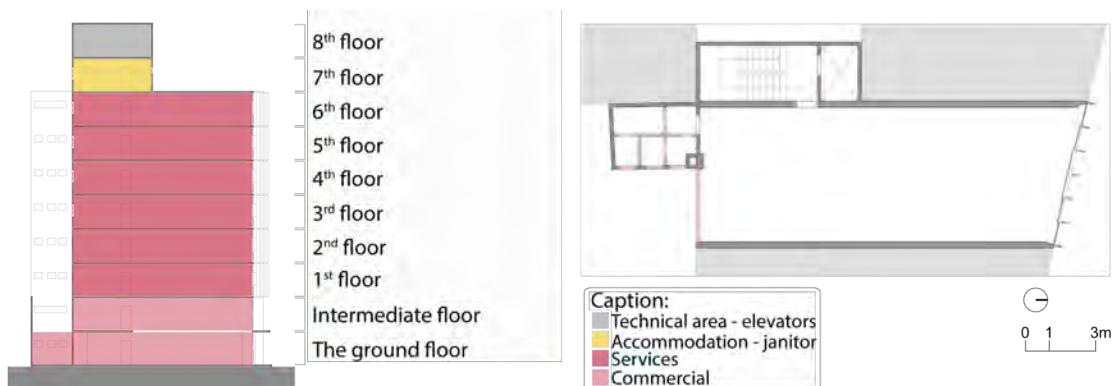

Image 1: Section with usage labels and typical floor plan of the building located on Paula Souza Street.

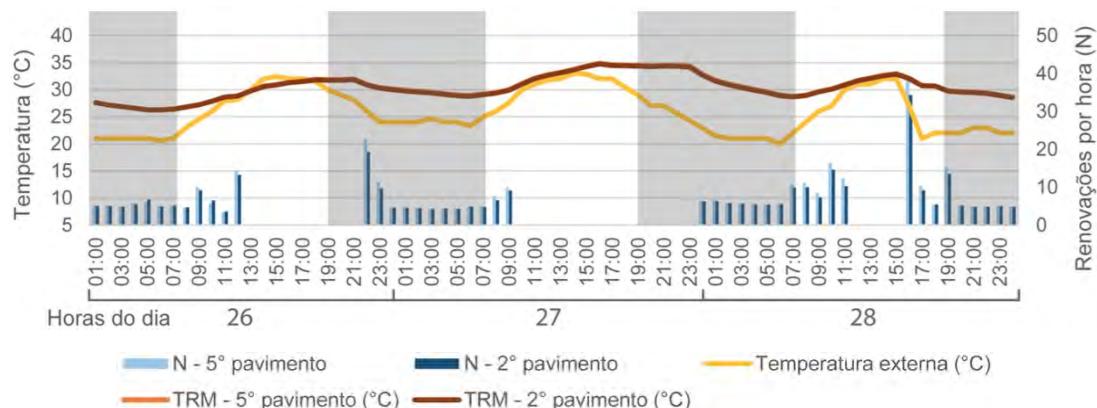

## Thermal simulations

Simplified models were elaborated for the virtual simulation of the studied objects using the software EDSL/Bentley Thermal Analysis Simulation, also known as TAS, which features thermal analysis simulation tools, available for academic use at the Laboratory of Environmental Comfort and Energetic Efficiency (LabAUT) in the Faculty of Architecture and Urbanism of the University of São Paulo. Moreover, the simulations were run only in the second and fifth floors of the model, contemplating all its different materials and openings. Since the original use of the building is different from the proposed one, the internal thermal loads were considered to be equivalent to the standard load in residential use in both the original and the designed situations, so that the differences showed by both simulations would come exclusively from the planned interventions.

The facade windows of the Paula Souza Street building have 20% openings while the remaining ones have 50% openings. The infiltration rate is equal to 1%. Moreover, the windows remain open as long as the temperature varies between 20°C and 30°C.

With this information in hands, four days were chosen for the simulations: days 26, 27 and 28: hot and sunny; days 10, 11 and 12: hot and cloudy; days 200 and 202: cold and sunny; days 187, 188 and 189: cold and cloudy. The results shown relate exclusively to the hot and sunny days, which are the most critical in the city of São Paulo.

Graphical analysis was generated for the construction's original situation concerning external and internal temperatures (average radiant temperatures - TRM) and natural ventilation (**N** air renovations per hour).

Graph 1: Results of the simulation made through the TAS software regarding days 26, 27 and 28 (hot and sunny) for the second and fifth floors of the original Paula Souza Street building. Elaborated by the author.

Observing the graphic above, it is clear to see the how the internal temperature is always higher than the external temperature. This happens due to the buildings large, unobstructed and north-facing openings, which generate great heat gain through direct radiation during most of the day. As a result of the edification's huge thermal mass, the TRM curves regarding internal environments show smaller variation, which represents more stable temperatures.

In an attempt to diminish excessive heat gain around noon (when there is the most solar radiation), horizontal *brisés* were installed on the facade, once direct incidence is the biggest contributor for temperature increase. However, on winter days, this radiation comes in handy, since it keeps the inside warmer than the outside. The elements of protection consist of 30 centimeter stems with 64 centimeter gaps between each of them, according to the studies of Uzum (2017).

## The Ergonomic Studies

As it has been mentioned, when it comes to ergonomic analysis the studied buildings can be easily reorganized in many ways, given their lack of obstructions due to the reinforced concrete structure. Seeking to improve thermal comfort, the ergonomic designs aimed to favor the user's operation toward the control of incident sunlight and ventilation, and also keeping the elements isolated, so that there are no safety issues as a result of either improvising when using them or of lack of room for proper handling. The users are able to tilt the brises as well as control the size of the openings on the windows. This is very convenient, since it transforms each user's autonomy into a tool to have the best possible internal conditions.

The rooms designed to be living/dining rooms were planned to answer to whichever demands the dwellers might have, even to complement their income, such as having a home office, a place to do craftwork, cooking, etc. The kitchen was also arranged in a less sealed way than usual – with no walls delimitating its boundaries – so that, with the proper layout, it can be easily adapted to receive a larger production of food than the ordinary household needs, since selling homemade treats is a common way to complement a family's income.

Several analysis were made on the circulation areas in order to prove the ergonomic quality of the proposal, ensuring every possible trajectory is safe and free of any discomfort. This also guarantees access to the windows and to the lighting control elements, reassuring the user's independence. Moreover, there were studies made concerning the usage of furnishings and general household equipment according to Panero (2002), where areas are established based on the performance of tasks related to the aforementioned equipment, to assure the environment is safe and comfortable for regular use.

Furthermore, rooms of sporadic use such as the laundry were planned to be out of the units in both cases, on a common area, specifically on the roof. Beyond that, there is an idea to invite the dwellers to participate in a community garden located in the unsheltered area, also on the roof.

Two distinct forms of typical floor occupation were proposed for the Paula Souza Street building. The first one features two *kitchenettes* and the second possesses a single unit with three bedrooms. Having two types of occupation and being able to alternate them throughout the stories makes it possible to attract a wider range of people who might want to live in the center of the city.

There is also the proposition for an atrium, since the edification has a very lengthy floorplan that prevents light and ventilation from reaching certain areas in adequate amounts. It would allow more flexibility regarding not only layout possibilities but also the number of units per level.

Furthermore, the unit with three bedrooms was planned so that it can shelter people who need a wheelchair, having the appropriate widths, turning radius and extra space on strategic sports for one to maneuver a wheelchair independently throughout the whole apartment.

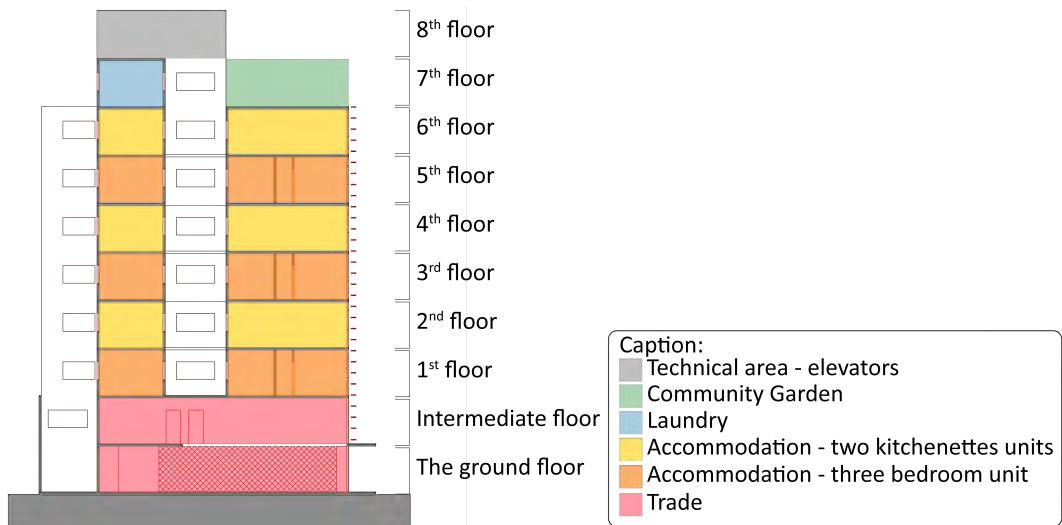

Image 2: Longitudinal section portraying the proposed usage for the Paula Souza Street building. Drawing made by the author.

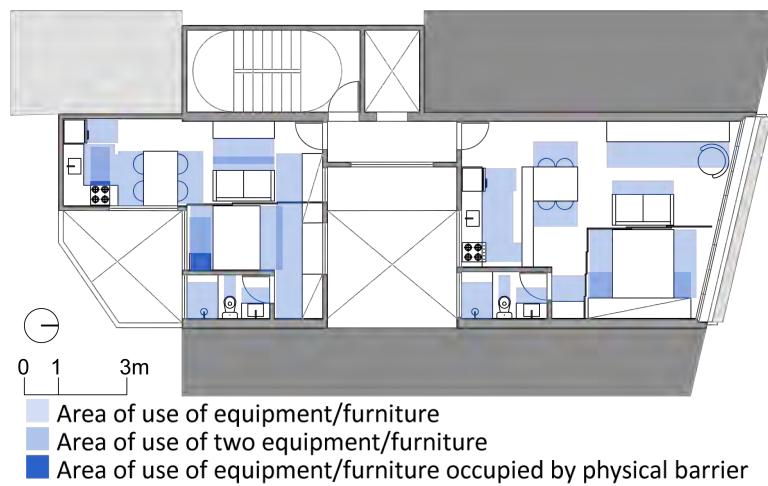

Image 3: Typical floorplan for the rehabilitation proposal, featuring two residential units of the Paula Souza Street building, with highlights on layout and household equipment usage areas. Drawing made by the author.

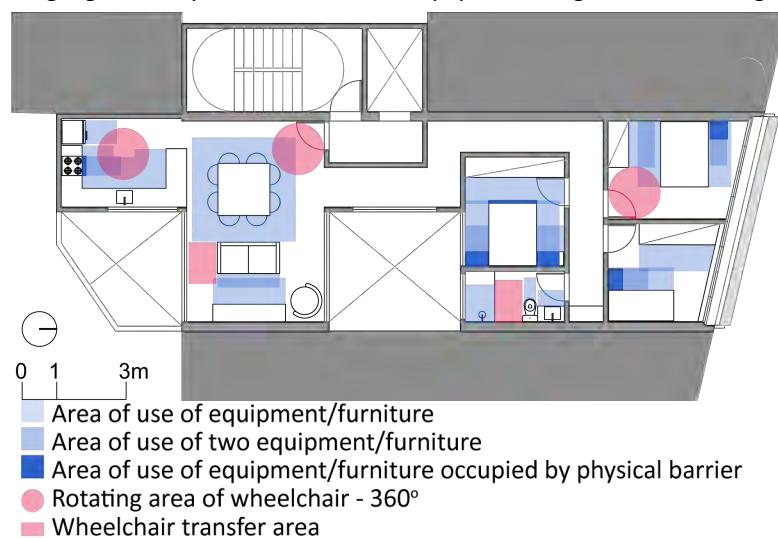

Image 4: Typical floorplan for the rehabilitation proposal, featuring one residential unit of the Paula Souza Street building, with highlights on layout and household equipment usage areas. Drawing made by the author.

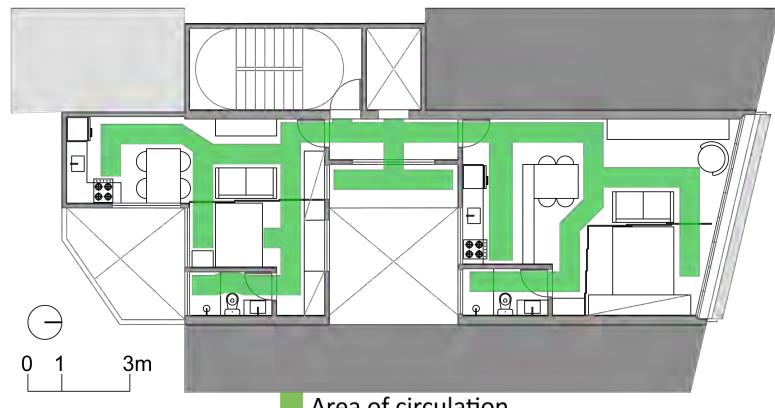

Image 5: Typical floorplan for the rehabilitation proposal, featuring two residential units of the Paula Souza Street building, with highlights on layout and internal transit areas. Drawing made by the author.

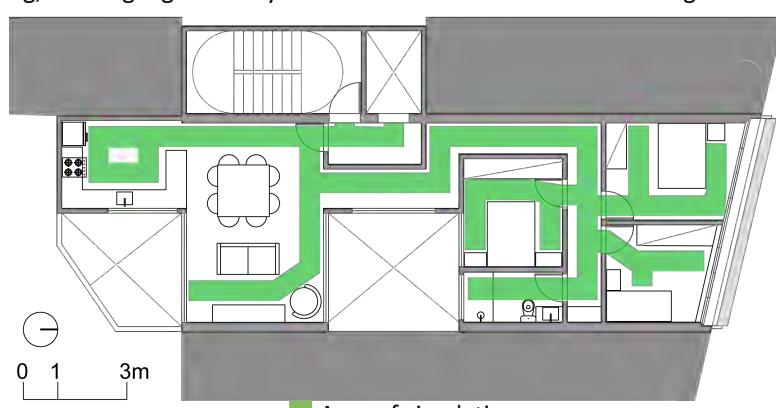

Image 6: Typical floorplan for the rehabilitation proposal, featuring one residential unit of the Paula Souza Street building, with highlights on layout and internal transit areas. Drawing made by the author.

### Proposals: Thermal Evaluation

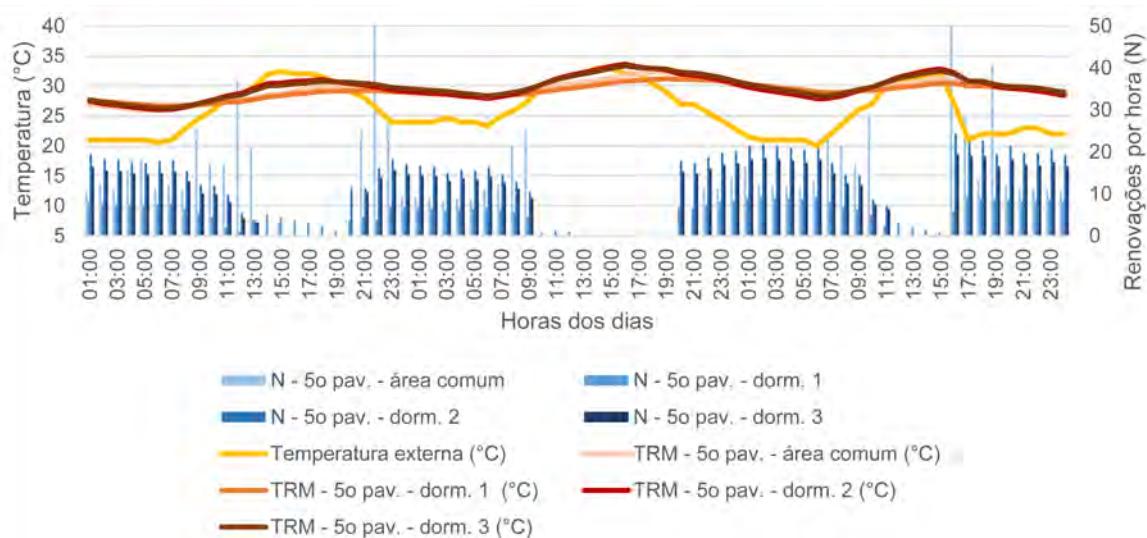

After applying the imagined conditions to the model, the simulations prove how effective these changes can be when it comes to thermal comfort. The gathered results were grouped in units, that is, each graph shows outcomes for each unit, in order to make them visually neat.

The material, climatic and thermal parameters were identical to the ones used in the previous simulations. Moreover, the same days of the year were analyzed. The hot and sunny period was picked for review because it features intense direct solar radiation, which is what contributes the most for internal temperature increase on north-facing facades.

The simulated environment portraying a three-bedroom unit on the fifth floor of the Paula Souza Street building was enumerated as follows:

Image 7: Labels for each room on a three-bedroom unit of the Paula Souza Street building. Drawing made by the author.

Graph 2: Results of the simulation made through the TAS software regarding days 26, 27 and 28 (hot and sunny) for the fifth floor of the Paula Souza Street building. Elaborated by the author.

The simulated environment portraying two *kitchenettes* on the fifth floor of the Paula Souza Street building was enumerated as follows:

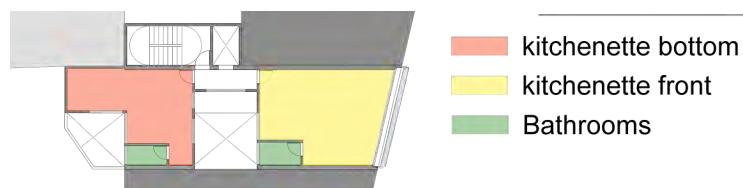

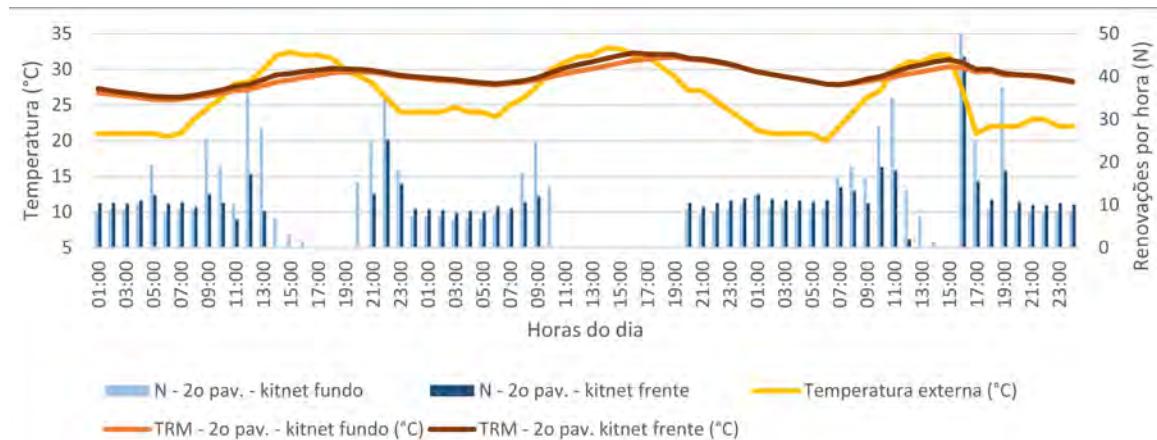

Image 8: Labels for each room featuring two kitchenettes of the Paula Souza Street building. Drawing made by the author.

Graph 3: Results of the simulation made through the TAS software regarding days 26, 27 and 28 (hot and sunny) for the second floor of the Paula Souza Street building. Elaborated by the author.

The aftermath shows how the temperature curves referring to the internal rooms tend to flatten, even staying below the outside temperature curve during the hottest periods of the day.

When comparing the results gathered by the simulation model, it is clear to see the difference between the original situation and the proposed one, since the atrium propitiates huge increment concerning natural ventilation throughout the whole edification. The temperatures have less abrupt changes, mainly on the critical hours of direct solar radiation, seeing that among the hours of the day, there are many on which the outside temperature exceeds the one on the inside (on the model with the applied modifications), not alike what

the original model simulation reveals about itself – the number of hours with inner temperature lower than outer temperature are virtually nonexistent in the former condition.

## Conclusion

In possession of the outcomes of this study, it was possible to evidence how well the buildings created at this time can be readapted, given their constructive particularities that provide good thermal characteristics as well as versatile layout solutions. Adding this to the great stock of idle buildings in the central region of São Paulo, the rehabilitation of this type of edification becomes not only possible, but also necessary. This idea can be supported by the fact that there are many illegal occupations in buildings with similar characteristics, even with very little salubrity and precarious living conditions.

There is a great benefit from allying constructive aspects to ergonomic ideas that allow users to exercise full control of openings and a project that aims for softened effects when it comes to direct solar incidence. Moreover, two different unit formats have been presented, so that it is viable to house as many different families as possible. Since the majority of the units were thought to be accessible for disabled people, they can also fit the elderly who can develop special needs or even someone who has been through some kind of trauma and might need a wheelchair temporarily.

Through a different point of view, although still concerning the same buildings, it was possible to re-evaluate the need of a personal laundry room for each unit, since it is something that exists based on cultural reasons only. Once the units have limited areas, it seemed like a reasonable solution to relocate the laundry onto a common space, since it doesn't have an intimate essence as most rooms in a house. Being the building thought to house different types of families, a common laundry room shouldn't have concentrate usage, which answers best to everyone's needs. The same applies to the community garden, although it has an even greater potential of bringing people closer, besides creating free food.

It is also important to notice that the proposals elaborated have a good chance of being replicated, once the buildings in the region have very similar characteristics to the ones analyzed in this research. That being said, this paper comprehends possibilities which may work as future reference for interventions and rehabilitations such as this one, in hope to encourage more idle buildings to be readapted not only in São Paulo but in every city lacking appropriate dwellings close to the majority of their work places.

## Development of Generic Energy Efficiency Category: An Accreditation Comparison of Different Green Rating Systems for a Case Study in Canada

Sherif Mahmoud<sup>1</sup>, Tarek Zayed<sup>1</sup> and Mohammad Fahmy<sup>2</sup>

<sup>1</sup> Department of Building, Civil, and Environmental Engineering, Faculty of Engineering, Concordia University, Montreal, QC, Canada, sherifahmed679@gmail.com, tarek.zayed@concordia.ca;

<sup>2</sup> Department of Architecture, Military Technical College, Cairo, Egypt, md.fahmy@mtc.edu.eg

**Abstract:** As part of developing a generic rating system for green constructions, this research introducing a comparison between the credits owned by different international rating systems and the generic rating category developed for energy efficiency. One of Concordia University campus buildings in Canada has been simulated using the IES-VE simulation tool to calculate energy consumed applying different constraints of various rating systems against the developed one. The generic developed category describes international credits that suit those mentioned in LEED USA, BOMA BESt Canada, BREEAM UK, Greenship Indonesia, CASBEE Japan, BEAM Hong Kong, and Green Building Index Malaysia rating systems. By considering five rating systems, the case building fails to achieve the prerequisites of energy category in LEED USA and Canada, Greenship Indonesia, Green Building Index Malaysia, and the developed rating system, while it is rated in the case of Hong Kong. Hence, a comparison is conducted to stand for the amount of energy saving required to achieve the credits between each of the five selected rating systems and the developed one. The results show that the generic developed energy category surpasses the other rating systems as it requires more energy conservation for the building to be rated. The difference between the energy saving needed in the developed rating system and the existing ones ranging between 2,181.11 MWh /year, and 6,503.71 MWh /year.

**Keywords:** Sustainability rating systems, energy performance, LEED, BREEAM, HK-BEAM

### Introduction

The building sector accounts for 32% of global energy consumption, 19% of energy-related CO<sub>2</sub> emissions, 51% of global electricity consumption, and 9% of the world petroleum consumption (IIASA, 2012; IPCC, 2014). Moreover, building sector emits per electricity use 8.6 GTCO<sub>2</sub>-eq., 0.4 GTCO<sub>2</sub>- eq. CH<sub>4</sub>, 0.1 GTCO<sub>2</sub>- eq. N<sub>2</sub>O, 1.5 GTCO<sub>2</sub>- eq. Halocarbons (CFC and HCFC) and 35-40% of CO<sub>2</sub> emissions from the use of fossil fuels (Urge-Vorsatz et al., 2007).

There are many rating systems throughout the world that aim to assess sustainability. However, there are noticeable variations between these systems of the same grade or rating, such that BREEAM Excellent and LEED Platinum, are not equivalent in terms of sustainability performance. Therefore, it difficult for buildings' stakeholders, especially property investors who purchase buildings in different countries, to compare the sustainability performance of their buildings on a consistent basis (Dixon et al., 2008). Also, there is no unified concept or definition of sustainability assessment attributes that can be utilized to express the key aspects of sustainability and to be adopted in different regions (Baharetha et al., 2012; Banani

et al., 2013). Moreover, previous studies highlighted the importance of developing an international system to mitigate the global impact of buildings on our environment (Reed et al., 2009; Todd and Geissler, 1999). Hence, it is needed to utilize a global thinking concerning sustainability of buildings by using globally working rating systems.

Energy is considered the most important criterion in the sustainability assessment (Al-Geelawe and Mohsin, 2015; Berardi, 2012; Perez-Lombard et al., 2008; Schwartz and Raslan, 2013). As a part of a proposed generic rating tool (Mahmoud and Zayed, 2017), the energy category is selected to spotlight on the generic concept of sustainability assessment. This research highlights 1) the proposed energy assessment attributes, 2) comparison between the proposed attributes and the others of different rating systems, 3) energy consumption and carbon emissions of a case through simulation in five regions, and 4) the results of simulation showing the amount of energy that can be conserved using different systems and the proposed one.

## **Methodology**

The methodology is divided into four parts: first, introducing the proposed energy factors for the developed energy category as a part of a proposed generic rating tool. Second, conducting a comparison between the proposed method and some existing rating tools to stand for the attributes that were overlooked in these tools. Third, developing a simulation utilizing IES VE software to stand for the impact of regional environment on the energy consumption, even using the same building. Finally, the fourth part, performing a comparison between the proposed assessment method and five existing ones concerning energy consumption and degree of conservation in energy.

### ***Proposed energy category***

The primary targets of the energy assessment are reducing both the energy consumption and the unwanted impacts of the life cycle of buildings. The proposed energy category includes four factors as depicted in Figure 1. The first is energy performance measures percentage of reduction in energy use through the minimum required energy performance, and optimizing energy performance. Second, provision of energy management evaluates the existence of energy operating plan for the building, energy audit, energy monitoring and metering for the operated equipment to stand for their energy consumption, commissioning and testing for analysing energy demand and end-uses and to provide an ongoing commissioning, building automated system which monitors and controls all the building systems, emissions reduction then reporting them to identify building performance parameters which reduce conventional energy consumption and quantify these reductions, and finally, sustainable maintenance to ensure that all the systems will perform in an efficient way according to the designed building maintenance. Third, energy efficient systems estimates using of efficient systems to reduce energy consumption such as: interior lighting and zone control, renewable energy systems, energy efficient circulation system and efficient ventilation in car parks. Finally, energy efficient equipment assesses the amount of utilizing energy-efficient appliances and cloth drying facilities, energy-efficient AC equipment and high-efficiency equipment.

A comparison was conducted between eight rating systems selected from the World Green Building Council member list (Worldgbc, 2016) concerning the proposed assessment attributes. The already established green building tool is the key selection criteria of these eight rating tools. The eight rating tools are LEED (USGBC, 2009), BREEAM (BRE, 2015), HK-BEAM (HK GBC, 2012), BCA green mark (BCA, 2012), Greenship (GBC Indonesia, 2012), Green

Building Index (GBI, 2011), BOMA BEST (BOMA Canada, 2013), and CASBEE (JaGBC, 2008) as shown in Table 1. The comparison aims to spotlight on the fundamental attributes and the overlooked ones that affect the sustainability of existing buildings, which should be integrated into the developed rating tool. As shown in Table 1, all the tools include the *provision of energy management* and *energy efficient systems* factors in their assessment framework, contrarily, *energy efficient equipment* has the lowest share.

### **Case study building**

The case study building is located in Montreal, Quebec, Canada, which is one of the Concordia University buildings called the EV Building, which accommodates the engineering departments and the art departments. The gross building area is 54,335 m<sup>2</sup> which comprises sixteen above floor levels and three basement levels. A BIM model using Revit software was developed to extract different data that will be utilized in the sustainability assessment such as: the floor area of each room, the gross area of each floor, the total area of the entire building, the area and material of walls and partitions, the cladding area and type, number of fixtures in each bathroom, the height of each floor, and generating XML file to develop the IES model. The GBXML model has been exported to IES VE software to perform energy simulation which is based on the actual size and the materials of the building as shown in Figure 2. The developed IES model is utilized to stand for the building energy consumption in yearly and monthly as shown in Figure 3 and Figure 4 respectively.

Actual Building

BIM model (Revit)

IES VE Model

Figure 2. Case study different modeling stages

### **Simulation results**

A simulation of the EV building has been performed for one city in each of the seven different countries as illustrated in Figure 3 which are: Hong Kong, China; Jakarta, Indonesia; New York, Malaysia; Cairo, Egypt; London, England; Kuala Lumpur, Malaysia; and Montreal, Canada. The accuracy of the simulation model was compared to the actual data of energy consumption. The actual total energy consumption of the building is 23,000 MWh, while, according to the simulation results and as shown in Figure 3 is 23,656 MWh with an error of 2.85% which increase the confidence in the results that has been extracted from the simulation. Consequently, according to Figure 3 and Figure 4, the total energy consumption (in MWh) in the cold weathered cities, i.e. Montreal and New York, is much higher than the other warm weathered countries due to the high increase in the demand for space heating and hot water provision. These energy demands are reflected in the carbon emissions which are the primary sources of GHG which result in increasing the global warmth. Unfortunately, in all the cities, a single building is responsible for high carbon emissions. However, the cities with the highest energy consumption have the largest share of GHG emissions shown in Figure 5.

Further, based on the simulation results, a comparison has been conducted between five rating system and the proposed one to determine the degree of improvement in energy performance that the proposed model can perform when compared with each of the selected rating systems as illustrated in Table 2. These rating systems are LEED, USA; LEED, Canada; GreenShip, Indonesia; Green Building Index, Malaysia; and HK-BEAM, Hong Kong. These five

rating systems have been selected as they utilize energy consumption in their assessment not the amount of carbon dioxide emissions as BREEAM.

Moreover, all the rating systems in Table 2 except Green Building Index have minimum energy performance prerequisites that obligate an achievement of a certain amount of energy to start the assessment. The proposed rating system requires a fulfillment of a 19 % of energy conservation above a baseline which is the median of weathered normalized energy use intensity (EUI) in the Energy Star Portfolio Manager website. This concept of assessment is also adopted in LEED. The rationale for using this method in evaluation in the proposed that the Energy Star Portfolio Manager possess a large library of weather stations and building baseline database of most of the countries of the globes with different weather stations in each city. Additionally, the aim of the proposed rating system is to set a unified basis of assessment in most of the sustainability categories, especially the energy category, so based on this argue, the energy simulation and the EUI are used for the assessment.

The baseline EUI for each of the USA, Canada, Indonesia, Malaysia, and Hong Kong are 31,427.16; 16,403.85; 31,392.07; 31,430.63; 31,430.63 MWh/ year respectively. The current EUI assessment of the five countries, according to simulation, are higher than the median with 0.8 %, 86.7 %, 4.6 %, 3.8 %, and 23.3 % respectively. Besides, the energy category is not rated in three out of the five rating systems, as the energy performance of the building does not fulfill the prerequisites except for the Green Building Index and HK\_BEAM. While applying the proposed rating for assessing energy category implementing the simulated consumption of the five countries, the energy category is not rated in four countries using the developed rating tool while it is rated in Hong Kong. The amount of energy reduction required for the building to be rated using the developed rating system is 5,971.16, 17,338.9, 7400.53, and 7,166.75 MWh/ year, while the amount of energy reduction required to be rated with the other four rating systems are 3,790.05; 13,393.3; 896.82; and 4,872.78 MWh/ year. Consequently, the proposed method surpasses the other rating systems in energy reduction and is capable of conserving 2,181.11; 3,945.60; 6,503.71; and 2,293.97 MWh/ year.

## Conclusion and discussion

This study aims to spotlight on the importance of considering globally working rating tools to set a unified method of sustainability assessment while considering the regional variations. Also, this study showed a part of a proposed generic rating tool, focusing on the energy category and describing its assessment attributes. The methodology explored various aspects. First, it demonstrated a comparison that had been conducted between the proposed rating tool and eight existing ones, showing the attributes that were covered in the proposed one. Second, a simulation utilizing a case study building was performed in different countries which illustrated how the regional variations could affect the energy consumption drastically even using the same building. This highlighted the importance of using a consistent method

of assessment to compare the energy performance of the buildings in different regions, which is the urgent demand of many building's stakeholders where ever they want to compare the performance of their widely-spread properties using an international language. Finally, the third part was a comparison had been conducted between the proposed assessment method to be used globally, and different rating tools in various regions, showing that the proposed method can compete the existing tools in achieving more energy conservation which is the main aim of the sustainability assessment tools.

## An online decision-making guide for the sustainable refurbishment of Belgian Walloon schools

Catherine Massart<sup>1</sup>, Coralie Cauwerts<sup>1</sup>

<sup>1</sup> Architecture et Climat, LOCI, Université catholique de Louvain, Belgium,  
catherine.massart@uclouvain.be

**Abstract:** Belgian Walloon's school building stock is old and energetically inefficient. The major obstacles to their renovation are the lack of financial means and the difficulty to coordinate renovation works with school activities. This paper presents an online guide developed for helping managers and architects in this school refurbishment. The objective is to lead choices towards reduction of environmental impacts as well as improvement of well-being, health and working performance of occupants. The tool is available online since summer 2016 (in French) at [www.renovermonecole.be](http://www.renovermonecole.be).

**Keywords:** school, renovation, retrofit, children comfort

### Introduction

Most of Belgian Walloon schools are old. High ambitions are often pursued for new school buildings but the most efficient way to reduce environmental impacts of schools is surely to accelerate and improve the renovation process of existing ones. The objectives of this research were (1) to help managers and designers to integrate environmental and well-being objectives in any school renovation process, with a long term high quality level standard, and (2) to create a tool that considers specificities of schools, renovation and specific context of Wallonia.

### Context of school buildings and school renovation process

The design of the online guide described in this paper started with an analysis of context, regarding both existing buildings and usual renovation process.

First, we observed that Belgian Walloon school buildings stock is characterized by:

- three education systems (free, Federation Wallonia Brussels official, municipal/provincial official)
- a great variety of building types and scales following the location and the level of teaching (infant, primary, secondary). There is no useful database on Walloon schools. The complicated context of three different education systems and a lack of financial means explain the situation.
- a globally poor energy efficiency (see Fig.1)

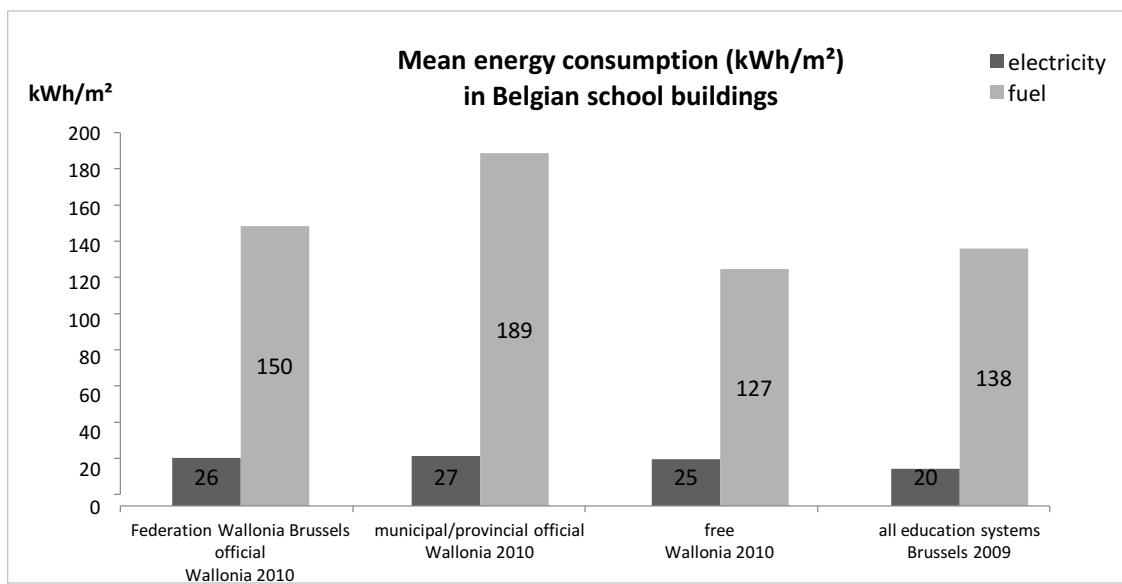

Figure 1. Mean energy consumption in Belgian school buildings, depending on the education system and the location.

Meetings with school directors, school building managers in the public sector (municipalities or Federation Wallonia Brussels) and architects specialized in school design helped to clarify specificities of school buildings and multiple challenges of school renovation (see Fig.2). We concluded that processes and situations differ from a school to another, from an educational system to another but all meet financial and organisational difficulties. Renovation work are usually carried out to answer a specific problem (roof leak, lack of space, heating system breakdown, fire safety rules...) and/or to benefit a specific opportunity (special funding, available competence...). Hard financial and organisational context, often coupled with old buildings lead to many emergency situations and partial renovation actions carried out with a lack of global long term vision and little concern about environment and occupants wellbeing. Tools and guidelines claiming for ambitious targets (zero energy buildings...) without considering the difficult context may miss the point because actors have a realistic and poor vision of their short term possibilities. And often, they consider that ambitious objectives are not possible to reach. Regarding motivations, reducing environmental impacts is rarely a primary objective. Energy consumption is mainly considered from a financial point of view. Reduction of water consumption, atmospheric pollution or waste or increasing biodiversity on school sites are almost never taken in account in renovation processes.

From visits and discussions with a “Facilitateur énergie dans les écoles”<sup>1</sup>, we may consider that:

- regarding heating systems, typical radiators systems with gas or fuel kettle is the most common system. Regulation is rarely performant and easy energy savings can be done there. This has been demonstrated with results of a PLAGE program<sup>2</sup> led on

<sup>1</sup> The « Facilitateur énergie dans les écoles » is an energy consultant of the Walloon region. He has a good global perception of schools situation thanks to his numerous visits of schools.

<sup>2</sup> PLAGE is a Local action plan for energy management. Such a program has been led with 110 schools in Brussels between 2009 and 2014.

110 schools in Brussels. In average, energy consumption for heating have been reduced of 21% during the action, mainly by improving heating systems regulation.

- many schools have no proper ventilation system. Hygienic ventilation is often only dependent on manual window opening. Therefore, CO<sub>2</sub> concentration is above advised threshold of 1000 ppm most of the time in Walloon classrooms.
- electric lighting is inefficient and visual comfort is rarely assured. Main causes are the old age of the installation and its lack of maintenance. Daylight, space and occupancy managements are strategies rarely implemented.

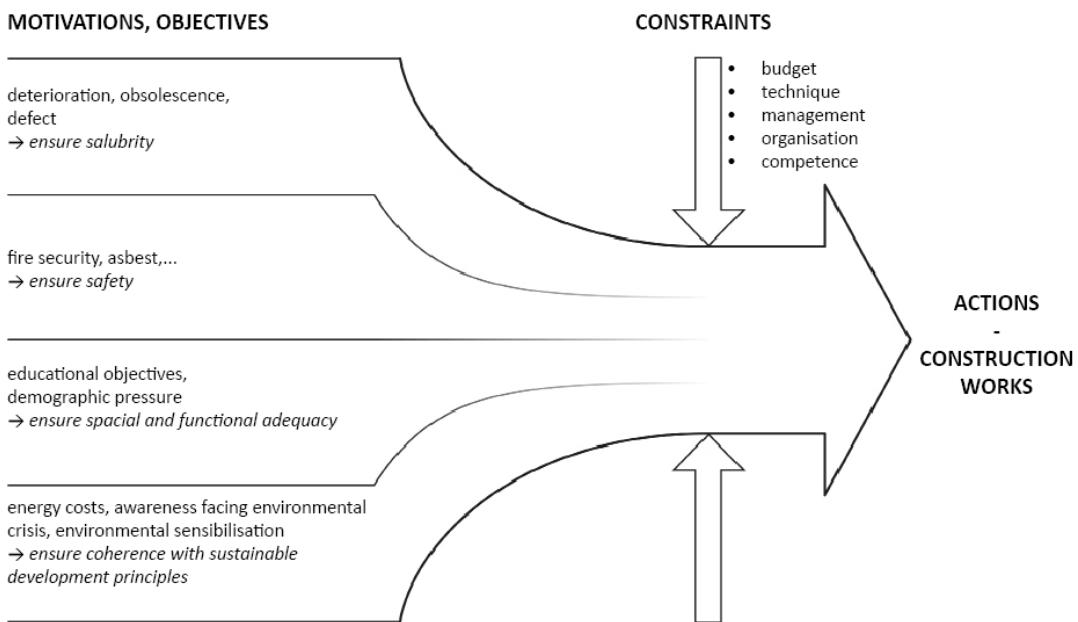

Figure 2. Identification of goals and constraints that lead to effective actions and renovation works in schools.

Last, from literature, links between the occupant comfort (thermal, visual, respiratory...) and its health, performance and well-being<sup>3</sup> have been showed. Furthermore, children appear to be more sensitive to bad conditions than adults. This is due to physical particularities (small body mass, low sweating capacities...) and to school activities (learning, new skills development...) (Wargocki and Wyon, 2006, Toftum et al, 2015).

Beyond the Walloon context, the following specificities of school buildings have been identified:

- low time occupation rate. Schools are usually occupied for 15-20% of the time since teaching schedules are mainly:
  - 8.00 to 16.00
  - 4.5 days/week
  - less than 38 weeks a year
- high space occupation rate (20-30 children/classroom). School surface ratio are 2.3-3.6m<sup>2</sup>/person (ratios for office buildings are 12-15m<sup>2</sup>/person).
- many different spaces types and functions: classrooms, eating room, technical workshops, library, offices, sport facilities, outside spaces...
- many different users: children from 2.5 to 20 years old, teachers, parents, administrative and technical workers...

<sup>3</sup> The word "well-being" is used in this paper to speak about comfort, health and learning/teaching performances.

- teaching and learning place: schools have a key role to play for our common future, with a possible leverage effect towards a more sustainable society

### Content of the online guide

The tool developed is an online guide called “Step by step towards a sustainable school”. It is free and available online at [www.renovermonecole.be](http://www.renovermonecole.be) since June 2016. Content is written in French. Expected users are school directors, school building managers and architects. Since this tool cannot have an influence on the financial and organisational means of schools, it was developed to adapt to the way renovation works happen to be carried out in reality. That is, step by step, with limited financial means (see Fig.3). The purpose is to enhance the global efficiency of renovation work done by improving actor's knowledge and competence regarding sustainable development principles applied to school buildings.

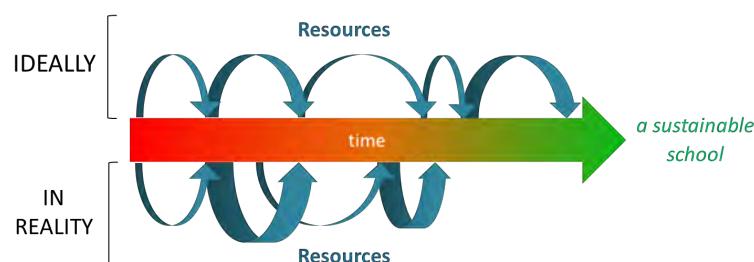

Figure 3. Renovation process towards a sustainable school, through a series of partial renovation works.

Ideal use or resources (less resources used, higher sustainability level reached)  
vs. real use of resources (more resources used, lower sustainability level reached).

The guide is developed to offer to the user:

- the opportunity to make connections between the various renovation works and also, between renovation works and objectives of well-being and impacts on environment;
- several levels of reading from a global, simplified and summarized information to an accurate technical and complete one on some specific topics.

The website focuses on school specificities. For non-specific information about sustainable architecture, links to other websites are made.

Guide content is based on:

- case studies;
- results of dynamic thermal simulation (ENERGYPLUS) on various buildings models to estimate effects of actions on the heating energy demand and on overheating problems;
- results of lighting simulations (DAYSIM) to estimate potential energy saving thanks to daylight and occupancy management.

Information given is:

- decision trees (see example in Fig.4);
- Excel tools:
  - to evaluate the impact of four renovation types on the heating energy demand (roof insulation – façade insulation – window replacement – mechanical ventilation with heat recovery installation). Calculation are based on EPBD method (simplified static thermal calculation).
  - to evaluate the impact of wall colours on light level;
  - to help in the diagnosis of the electric lighting installation.

- costs indications if possible;
  - a lot of drawings and pictures to make the content clear and understandable.

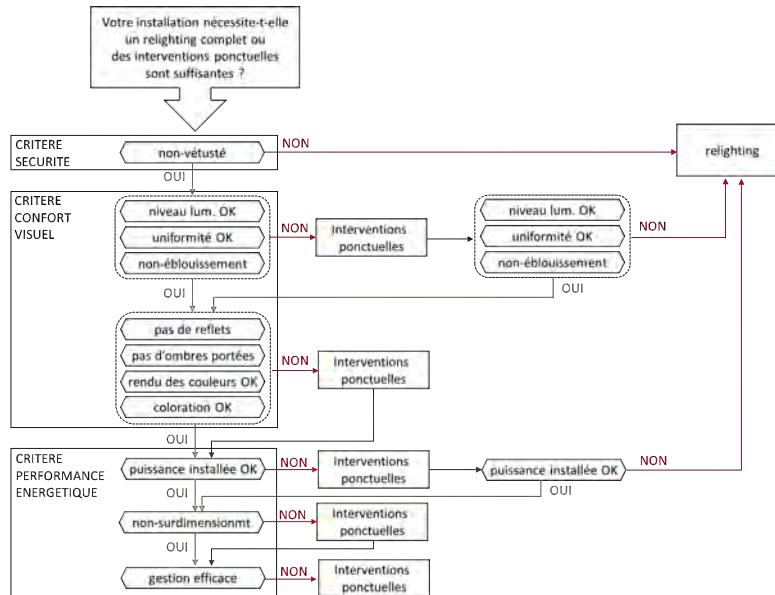

Figure 4: Example of a decision tree.

## **Structure of the online guide**

The online guide is designed to give information with two different access modes (see homepage in Fig.5):

- access by objectives (well-being or environment);
  - access by specific renovation works.

Figure 5: Homepage of the online guide

## *Access by objectives*

Objectives can be *environmental objectives* (to limit impacts of energy consumption, to limit impacts of use of building materials, to reinforce biodiversity and to limit impacts on the

water cycle) or *well-being objectives* (thermal comfort, visual comfort, respiratory comfort, acoustic comfort, connexion with nature and accessibility for all).

Each particular objective is developed from two basic questions: *Why?* And *How?*. For each objective, a *Why?* section explains why the objective is important, what are the impacts on the environment, on health and on the performance of occupants (children and teachers). The *How?* section explains how the objectives can be reached, how to evaluate the situation, what are the recommendations... The *How?* section links objectives section to renovation works section. For example, in the “How to ensure respiratory comfort” section, the visitor will find links to works such as “I want to install a ventilation system”, “I renovate windows”, “I want to do painting works”...

#### *Access by specific renovation work*

Access by specific renovation work aims at guiding the user from the renovation work he has decided to carry out (to renovate the roof, to renovate windows, to renovate the façade, to improve the heating system, to install a ventilation system, to renovate the lighting system, to limit overheating problems, to improve acoustical comfort, to improve outside spaces, to do painting work, to install solar panels, to install water saving bathroom facilities).

Each particular work is developed from the two basic questions, again: *Why?* And *How?*. The *Why?* section describes the effects that can be expected from this specific type of work, especially in the field of environmental impacts and occupants' well-being. For example, changing windows can be carried out for heating energy savings but it will also have impacts on daylight distribution, possible intensive ventilation, overheating problems... The *How?* section explains how the work can be done, what are the technical options, what has to be considered to lead to optimized design, what are the multiple criteria...

### **Conclusions**

The tool has been designed as a website to ease its spread among the potential users and to permit multiple links between topics and towards other websites. To ensure the diffusion of this web tool, several communication actions have been carried out:

- a public oral presentation of the tool in a seminar on public buildings;
- a poster in a meeting on sustainable buildings;
- a web mailing to all energy managers and municipalities;
- paper articles;
- a short TV spot.

So far, comments on the tool have been positive. Results of the communication process can be seen in the website statistics. Daily visits now turns from 20 to 40 sessions per working day. A survey is available on the homepage of the website to collect opinion of the users on the tool. Only a few answers have been collected until now but we can already say that a more user-friendly website plan, an easier access to it and a listing of available Excel tools could improve the navigation.

## 'Ventilate Right' – Methods of Effective Communication to New Residents

Rosalie Menon<sup>1</sup>, Janice Foster<sup>1</sup>

<sup>1</sup>Mackintosh Environmental Architecture Research Unit (MEARU), Glasgow School of Art, 167 Renfrew Street, Glasgow, G3 6RQ

**Abstract:** Post occupancy evaluation in housing often places emphasis on energy efficiency and the residents habits that affect this. Whilst it is straightforward to measure energy consumption and obtain the residents thermal comfort perception, the measurement and perception of ventilation is less tangible. The importance of adequate ventilation is often not communicated to residents of new housing. With buildings being constructed to be more airtight to conserve space heating energy, indoor air quality and ultimately health and wellbeing can be compromised if the planned ventilation strategies are not understood and operated by the occupant. This paper assesses methods of communicating key information to occupants, making reference to two projects undertaken in conjunction with social housing providers. One case study assesses the impact of a short film describing effective ventilation methods intended for circulation to new residents by housing providers via the internet; the other introduces the production and use of a paper based occupant guide that is unique to the home. The success of each method is discussed, concluding with an outline of innovative alternative media formats that can enhance communication with occupants to improve indoor air quality and occupant's health and wellbeing.

**Keywords:** Post occupancy evaluation, indoor air quality, short film, occupant guides, ventilation

### Introduction

Occupant understanding is a fundamental element in helping to ensure an occupied building meets its as designed energy consumption target, whilst maintaining good indoor air quality (IAQ). In a social housing context, advice to tenants regarding condensation and moisture control is not new, but there is an implied perception that ventilation advice is not so essential. In the drive to improve energy efficiency and lower dwelling carbon emissions in line with government targets, infiltration rates have been reduced. However without providing a planned, effective ventilation strategy the unintended result could be for a more hazardous indoor environment, with concurrent and significant negative long-term and undesirable impacts on public health and the building fabric. Since 2010, the Mackintosh Environmental Architecture Research Unit (MEARU) has undertaken research with residents of over 200 households in properties built to modern airtight standards in Scotland and London. This has revealed widespread evidence of poor ventilation, with bedrooms presenting a particular IAQ problem, and little awareness of potential consequences of this. Further research investigated mechanical ventilation systems and found that while these systems can deliver positive IAQ outcomes there is a risk of poor air exchange if the systems are not designed, installed and operated correctly; which was often the case. Findings from a study of housing in Scotland indicated that 83 % of mechanical extract systems were underperforming with 42 % operating below Building Regulations moisture control

requirements and 82 % of people had received no advice on ventilation (Howieson et al, 2013).

In the social housing sector where there is a relatively high turnover of tenants, simple and effective communication of good ventilation practices together with concise advice on improving energy efficient habits is of particular importance. The handover process for new residents varies significantly between social housing providers with several housing officers reporting that new tenants are handed a set of keys with little information or an introduction to their new home. Residents will often therefore apply established operational habits in new properties unaware that the new home may require a different ventilation strategy and methods of control.

The most common method of property handover in social housing involves issuing new residents with a tenant handbook. These normally consist of a series of individual manufacturers technical data sheets covering a wide range of operation and maintenance information relating to the building and its services; the residents often consider these as being too technical and are often not referred to.

Good IAQ is of particular importance and is being widely researched due to improved airtightness and the potential health impacts associated with inadequate air exchange within the home (The Royal College of Physicians, 2015). The measure of carbon dioxide ( $\text{CO}_2$ ) concentrations is frequently used as a proxy for assessment of the adequacy of ventilation air changes and the Scottish Building Standards Division (BSD) recently introduced a regulation requiring a  $\text{CO}_2$  monitor with alarm to be installed in all principal bedrooms in new housing. With the aim of alerting residents when indoor air quality is reduced to prompt action to introduce fresh air (Scottish Government, 2015). This is a step towards highlighting the importance of good IAQ however it also stresses the need for landlords to supply clear advice to their residents when occupying a new build dwelling.

### **Context of Occupant Guides**

The Scottish Technical Handbook (Domestic) provides a clause for provision of a 'quick start guide' for new homes. This is the need to inform residents of how to operate their homes for optimum efficiency, as the design intent, via a clear occupant guide (Scottish Government, 2015a). This requirement stemmed from research undertaken by MEARU for the BSD which proposed a bespoke template for such a guide in booklet form. This was trialled on new tenants in both the private and social housing sector. This research identified that whilst many residents valued the document, as it was tailored to their home, many admitted they had put the booklet into a drawer until needed (Menon and Sharpe, 2013). Many tenants admitted a 'trial and error' approach to operating heating systems, timers and ventilation systems within their home and several noted that asking a neighbour for advice seemed to be the best option, potentially perpetuating poor ventilation or energy efficiency habits. With increasingly airtight homes the importance of good ventilation practices is paramount and the occupant guides are a simple way of conveying the ventilation design intent.

Further MEARU research undertaken as part of the EPSRC funded domestic laundering project identified that moisture loads in homes can be significant and are further exacerbated by residents drying clothes on radiators in key living spaces. The project surveyed resident habits ( $n=100$ ) relative to ventilation regimes and identified that even in naturally ventilated homes, occupants often do not adjust trickle vents or open windows regularly. There was a general lack of appreciation of the importance of simple ventilation (Menon & Porteous, 2012). With increasingly sophisticated mechanical ventilation systems

including whole house mechanical ventilation with heat recovery (MVHR) becoming progressively mainstream, residents need clear and effective guidance to allow the confident operation of these for effective dwelling ventilation.

A recent survey undertaken by Ofcom, the independent regulator and competition authority for the UK communications industries, highlights that online video is becoming increasingly popular, with more than half of adults (54 %) watching television or video on a computer or mobile phone in 2015 (Ofcom, 2015). Almost a quarter (23 %) of respondents also said they had watched short video clips within the week of the survey, highlighting the popularity of video on social media. Smartphones have overtaken laptops as the most popular device for accessing web-based information, with record ownership and use transforming current communication methods. Within the social housing sector, the use of these technologies and associated applications could be developed further to allow greater access to occupant guidance and information. With this in mind, MEARU commissioned a filmmaker to produce a short information film titled 'Ventilate Right' to test the medium of film as a communication tool principally for social housing providers and their residents. The film was hosted as an online video on the website 'Vimeo' to increase accessibility and coverage.

Within that context, this paper examines alternative methods of communicating good practice for dwelling operation with a particular focus on ventilation and compares the effectiveness of a paper-based occupant guide with that of a short public advice film (hosted online) which gives helpful advice to maintain a healthy indoor environment in a simple, accessible and highly visual format.

## **Methodology**

The film, commissioned by MEARU in November 2015, was produced over a short period of time (three months from initial scriptwriting until final editing) with limited funding. The brief to the filmmaker was to produce five minutes of footage which clearly communicated the importance of maintaining good indoor IAQ levels and reducing indoor moisture loads with simple advice of how this could be achieved in both naturally and mechanically ventilated homes. The greatest challenge was to visualise the concept of 'air and moisture movement' within the house. Whilst poor ventilation can manifest itself visibly in the form of dampness and mould growth, stale and polluted air does not have such a tangible quality. In order to address this for the film, artist Rachel Duckhouse was commissioned to illustrate various moisture and potential pollutant flows for overlay animation on the film by the editorial team.

## **Film production structure**

The film was structured in such a way to address key findings of previous MEARU research with regards to moisture reduction, CO<sub>2</sub> and VOC's within the home environment. Each common resident habit and its consequences were documented and then the relevant occupant advice was integrated. Filming was undertaken at two houses in the Kingdom Housing Association development in Dunfermline, Fife, Scotland in houses which were constructed in 2013 to 2010 Building Regulations. The houses were semi-detached but each were constructed to varying thermal standards with different modes of ventilation. House 1 was Passive House certified and an MVHR system was installed. House 2 was naturally ventilated with mechanical extract fans in the kitchen and bathrooms. Residents in each house were willing for their houses to be filmed internally and assisted in demonstrating the

use of their ventilation controls as part of the filmmaking process. The film was aimed at both housing providers and residents and it was also free to access via the internet. The key challenge was to ensure that the film was not too simplistic but sufficiently technical and informative to communicate useful ventilation advice. The film content was intentionally pitched so as not to cause occupant alarm by not over stressing the health risks associated with under ventilating, instead it promoted the positive impact of a healthy indoor environment.

There is increasing evidence of a general lack of awareness of trickle vents with many occupants being unsure of where they are and when they should be used, leading to them remaining in the closed position for most of the year. Often these are inaccessible at the window head or are occluded by blinds and curtains (Sharpe et al., 2014a). The film encourages residents to locate these within their home and become familiar with opening and closing them on a regular basis. During the filmmaking the researchers noted that the living room trickle vents in House 2 had previously been taped closed by the occupant.

Potential sources of moisture within the home including showering, cooking and laundry were identified and good practice suggestions were made to minimise the impact of moisture loads with the home. The importance of opening windows was highlighted particularly for when drying clothes indoors to prevent a build-up of moisture in the home. An EPSRC funded project undertaken by MEARU in 2008 recorded the prevalence of the practice of indoor clothes drying within living spaces and bedrooms which in turn increases the moisture loads these key spaces (Menon et al., 2008).

The cleaning and maintenance of ventilation grilles and filters is critical to ensuring that the systems are working efficiently and are removing air at the rate in which they were designed. Housing Associations have varying advice and practices on the resident's level of involvement in this process but the film highlights good practice and identifies that filters should be cleaned (whether this is done by the resident themselves or for a call out to the maintenance team), the frequency of this is provided in the manufacturer information (Menon, 2015). Whilst the responsibility is on the occupant to maintain good ventilation regimes, if the means of doing this is compromised by ineffective mechanisms then their IAQ could equally be compromised. This is of particular importance in homes with MVHR systems where the resident is more reliant on this system to introduce outside air into their homes.

The film makes particular reference to houses with MVHR systems which are becoming increasingly mainstream in response to improved thermal energy requirements. MVHR systems have controls which are relatively straightforward but residents need to know when to operate 'boost' settings to increase the rate of air exchange when rapid moisture removal is required during activities such as cooking or showering. At a very basic level, residents also need reassurance that the system consumes minimal electricity and concerns regarding energy consumption should not lead to the disabling of the system.

There is increasing concern regarding high levels of volatile organic compounds (VOCs) within our indoor environments - these are off-gassed from building materials, fire retardants in soft furnishings (Figure 1) and everyday cleaning products (Liddell et al., 2008). The film aims to raise awareness of this in the context of the importance of maintaining good access to fresh air to remove any potential pollutants.

Upon completion of the film a launch event was held at the Glasgow Film Theatre (GFT) to promote the film within the social housing sector and among key policy makers and stakeholders. An invitation was sent to each Housing Association in Scotland and the event

was well attended with an engaged audience willing to provide detailed critical feedback during a question and answer session following the film screening. Subsequently the film was uploaded to 'Vimeo', a film based media website which allowed a platform for monitoring views but also allowed organisations to link to it on their own websites.

Figure 1 Potential VOC release from fire retardants in soft furnishings

In order to gain further feedback, one year later (February 2017), a follow up postal survey was sent to housing officers within Housing Associations across Scotland to ascertain whether they were aware of the film; whether they would consider using it as part of their handover process and to gain further feedback regarding the content of the film itself. In addition to this, the survey asked social landlords probing questions regarding their current handover procedures and whether these could be improved by the use of enhanced digital media communication tools.

#### **Data-Feedback from housing providers**

For the purposes of this paper feedback from the film is centred on a short survey questionnaire which was distributed by postal service to Housing Associations ( $n=60$ ) across West Central Scotland. Whilst the return rate was only 25 %, the information returned was significantly detailed and many respondents expressed a willingness to host the film on their website and engage in the development of further occupant guidance via web-based communication tools.

When asked whether it is standard procedure within their organisation for a housing officer to accompany a new resident when they first move in 60 % agreed this to be the case indicating that 40 % of residents are given keys and require to understand the workings of the home themselves. 67 % of respondents confirmed that their Housing Association issue new tenants with a handbook relative to their property however of this figure only 20 % could confirm that this included technical guidance on the use and maintenance of the mechanical ventilation systems (including both extract fans and MVHR systems).

It is evident from feedback that a lot of practical advice is delivered verbally by housing officers and maintenance departments with 73 % of Housing Associations confirming that advice regarding moisture control in the home is provided to residents. Whilst this is likely to be beneficial to the occupants, a more formal documented process which could allow residents to re-visit it once they have settled into their new dwelling or allow those family members not present at the handover meeting to benefit from the information.

Housing Associations certainly have the resource in place to deal with any residents having difficulty operating mechanical ventilation systems, 73 % identified that a maintenance officer, technical inspector or estates team member would deal with such problems however there seemed to be less clarity ascertaining who was responsible for changing filters on mechanical ventilation systems with only 53 % of respondents noting that they undertake this scope of works. Of those 53 %, only 25 % would only change a filter if a problem was identified by a maintenance officer thereby implying that filters were not changed on a regular basis. 67 % of respondents noted that their tenants were expected to clean ventilation grilles themselves yet little or no advice was contained in the tenant handbook of how to go about this or how to determine whether the fan itself was indeed performing as it was designed to.

Of the Housing Associations surveyed, only 33 % noted that they currently host occupant guidance on their website with most commenting that their primary method of communication with residents is through a resident newsletter or e-bulletin. However, in response to a question enquiring whether they would consider hosting information regarding ventilation and IAQ on their own website, 100 % answered positively.

The questionnaire progressed with a request for the respondent to view the film online at <https://vimeo.com/163384704> and provide feedback on the content, duration, style and target audience. 67 % of respondents viewed the film and feedback was varied and sometimes contradictory - some reported the film was too long and detailed whilst others noted it could have benefited from more discussions of the impact of poor IAQ and more examples of the potential causes. 60 % however reported that the film provided simple and effective advice and was pitched correctly for its target audience. When asked if they thought that a film is a better way of telling residents about the importance of ventilation than a technical manual, 100 % of respondents agreed with several noting that paper-based documents often get misplaced in the home therefore a digital format was deemed more beneficial.

The feedback concluded with an open question asking their opinion of the best method of advising tenants how to ventilate homes. The majority of respondents noted that the 'face to face' approach was favoured as it is not only the most effective method of locating and demonstrating controls but it also established a relationship between the housing officer and the resident which is key to any Housing Association. Several respondents appreciated that coordination of this handover was a fairly labour intensive process. It was also noted anecdotally that given the high percentage of non-English speaking residents within the social housing sector, highly visual formats of communication are much more beneficial. One respondent suggested a digital format which could be distributed via mobile technology may be relevant in the coming years given the prevalence and accessibility of social media across all social sectors.

In addition to the survey data, the feedback on the effectiveness of the film was garnered at a film launch hosted at the GFT which included a screening of the film and then discussion panel, feedback from industry. Some feedback suggested that the film was not technical enough whilst others disagreed and highlighted that it hit its target audience. Several Housing Associations present at the event requested DVD formats of the film so they could be used as a training video to their housing officers. On the day of the film launch the BBC covered the story and following this the subject of IAQ became a feature on BBC Breakfast on prime-time UK television. The web-based BBC news article provided a link to the film and the number of views was tracked which since the film was launched it has been

viewed nearly 2,000 times. This has also prompted several Housing Associations and other organisations to host the film on their respective websites.

## **Discussion**

The data clearly demonstrates that there is currently no standard handover procedure for new tenants in social housing and whilst a tenant handbook is available, the content and method of issue varies significantly. It is evident that whilst many housing providers have housing officers who show a tenant around the house demonstrating the key features of the home others simply give a set of keys to new tenants and they are left to a process of 'trial and error' or forced to consult overly complicated technical manuals. Respondents anecdotally indicated that new residents are too overloaded with information on the day they move in and often the maintenance officer is required to deal with any problems which arise at a later date. This highlights that a more accessible medium which could be re-visited by members of the same dwelling may be beneficial, as such, the online film can be hosted on landlords website or on social media and accessed when required. Given the statistics regarding the increasingly widespread use of smartphones using this as a tool to provide advice to residents seems to be advantageous.

In comparison to the effectiveness of the paper based logbook, a film advising residents how to use their home is clearly an effective tool. Issues relating to residents ability to read plans to locate systems and controls are removed and whilst the film based advice guide may not be particular to their home, residents can instantly make visual connections to similar features in their homes and where they are located. Home log book providers have been developing digital platforms to provide digital storage for manuals and technical brochures which is certainly a step towards addressing previous resident feedback which suggested that keeping a manual in the drawer is the norm.

## **Conclusion**

This paper highlights the potential demand for further public advice films for occupants with regard to the changes that require active ventilation to balance energy efficiency and indoor air quality. The 'Ventilate Right' film has succeeded in its aim to raise awareness of the importance of ventilation for general living environments. It has been an excellent pilot study to enhance and further develop occupant guidance using a variety of media which can be potentially integrated with the ever increasing popularity of mobile technologies. It is also important to note in the context of the building performance gap between designed performance and actual recorded data that whilst occupant behaviour is an important factor there is an understanding that the ventilation systems in the house should be installed correctly, are well maintained, are simple to operate in the first instance and the planned ventilation strategy must be effectively communicated. A resident can only expect to regulate their indoor environment if these systems are in place and are performing as designed. The consumer market for indoor air monitors and alerts synchronised with an application on mobile technology is in its infancy but as the awareness of healthy indoor environments increases the popularity of such devices will no doubt develop and has the potential to be combined with occupant guidance for dwelling operation.

Housing Associations are currently addressing occupant guidance with varying degrees of success. Ultimately good ventilation advice is critical to social landlords as they have a duty of care to their residents to provide indoor environments which are not only thermally efficient but also healthy.

Housing providers which have developed new build housing stock since the October 2016 revision to the Scottish Building Regulations will require to develop a body of practical advice and tips for residents regarding to help with maintaining good IAQ particularly in light of the requirement for CO<sub>2</sub> monitors in principal bedrooms, which will no doubt trigger a new realm of queries from residents.

To conclude, more research is needed in this area with enhanced engagement with housing providers to develop tools to help them deliver occupant advice effectively and consistently. Further research to test the effectiveness of the occupant guidance whether in paper based format or using media such as short film could be undertaken through a programme of environmental monitoring before and after the guidance has been issued – this would allow an assessment of the impact of occupants habits. This research together with the potential use of mobile smartphone technologies as a platform for resident engagement are exciting propositions.

### Acknowledgement

The authors would like to express thanks to Kingdom Housing Association, their residents who kindly gave access to their homes for the film shoot; the funders The Glasgow School of Art, Historic Scotland, Innovate UK and Zero Carbon Hub who without their kind contributions the film would not have been possible. We would also like to thank Thermal Image UK and Scottish Housing Best Value Network who supported us through the planning, filmmaking and dissemination. Finally, the production team at The Gate Films and artist Rachel Duckhouse.

## How Can the Combination of BREEAM and Soft Landings Successfully Deliver a Low Energy, Comfortable Building?

Sahar Mirzaie<sup>1</sup> and Gillian Menzies<sup>2</sup>

<sup>1</sup> PhD Candidate, sm76@hw.ac.uk

<sup>2</sup> Associate Professor/Senior Lecturer

<sup>1, 2</sup> Centre of Excellence in Sustainable Building Design, School of Energy, Geoscience, Infrastructure and Society, Heriot-Watt University, Edinburgh

**Abstract:** The performance gap is an industry-wide challenge, disreputably known to all building practitioners. Design teams spend a good portion of the project timeline designing a building that often fails to deliver the project targets without them even being informed. This seems unjustifiable when there are many tools available for advanced performance modelling, lifecycle sustainability strategizing, and stakeholder engagement, to plan, review, and meet the design specification. This paper presents a practical lifecycle guide, based on building phases, to design and deliver energy-efficient buildings with minimized performance gap with respect to energy use and occupant satisfaction. This guide offers a holistic approach for realizing the highest potential of BREEAM and Soft Landings (SL) to address the key contributing issues of performance gap and the inevitable future circumstances. It draws on the commonly used sustainability certification schemes, including BREEAM, NABERS, LEED, Living Building Challenge; as well as, Post Occupancy Evaluation (POE) procedures and Soft Landings (SL) framework. Furthermore, this study draws on the specific lessons learned from two major projects at the Heriot-Watt University Campus that utilized BREEAM and SL in their design and delivery.

**Keywords:** Performance Gap, Practical Lifecycle Guide, Soft Landings, BREEAM, POE

### Introduction

Increased energy use and diminished occupant satisfaction is known as performance gap, which is considered to have three underlying causes: (1) faults in building envelope and systems, for instance thermal bridging or low airtightness; (2) building users' influence, such as erroneous operation of the systems; and (3) inaccurate predictions including wrong assumptions and standards concerning internal and external conditions, i.e. use behaviour and pattern and weather conditions. (Menezes et al., 2012; Olivia and Christopher, 2015).

In many projects, energy modelling is performed to inform design-decisions and produce Energy Performance Certificates (EPCs) for compliance testing and building certification. EPCs are compared against Display Energy Certificates (DECs), which are for public display and are based on actual energy use after the twelve-month liability period (de Wilde, 2014). Practitioners do not recognize EPCs as reliable measures of building performance as they only consider heating and cooling loads, whereas DECs present measured values and include unregulated energy sources such as plug loads (de Wilde, 2014; Palmer et al., 2016).

Traditionally building use surveying was only performed for investigation of serious malfunctions or for research aims in a pilot or exemplary building. With the industry

embracing the concept of continuous improvement, designers and contractors are more interested in extended aftercare and building performance in-use (Olivia and Christopher, 2015; Preiser, 1995), as there are many project-specific as well as long-term industry benefits. Empirical data shows that the main barrier to studying the building performance in-use has been liability issues and financial incentive conflicts for investment beneficiaries of Post-Occupancy Evaluation (POE). These barriers are largely overcome by the industry interest in the lessons-learned and the consequential cost savings, besides, revised contractual agreements and procurement methods (Olivia and Christopher, 2015). Shi et al. suggest POE as a solution to the cost and functional effectiveness trade-off, which is a conflict between the developer/client and the end users (Shi et al., 2016). Project capital budget highly influences the ability of a project to perform POE (BSRIA, 2014). Low budgeted projects can tend to focus on building to the current regulations at the minimum capital cost possible (Gul and Menzies, 2012). Fortunately, technological advancement of smart monitoring systems, such as sensors, sub-meters, and building management systems (BMS) has made monitoring and evaluating procedures more affordable for most project sizes.

Typically, about 90% of company expenditure is on staff salaries and benefits, compared with approximately 1% energy use costs (Browning 2012; WGBC 2014). This shows the extent of financial benefits of the smallest increase in productivity of the building users and the importance of sympathetic operation of buildings and reliable evaluation of occupants' satisfaction, health, and wellbeing (Pottage and Jeffrey, 2016). Systematic performance evaluation throughout an asset's lifespan is essential to effectively and efficiently design and deliver buildings that meet the needs of stakeholders throughout their lifetime, or in other words are 'future-proofed' (Love et al., 2015).

In the UK, BREEAM is a well-established tool to incorporate low energy and sustainable solutions from the early design stage. BREEAM rates the environmental impacts of a new construction project at two stages: Interim Design Stage based on the Scheme or Detailed Design evidence (RIBA stage 3); and Post Construction Stage based on 'as-built' information following practical completion of building works (RIBA stage 5) (BRE Global LTD, 2014). Therefore, it is criticized for not holding projects accountable by certification based on actual use evidence (Tuohy and Murphy, 2014). Zero Carbon Hub recently advised that future standards should be linked to actual performance in order to close the performance gap (Zero Carbon Hub, 2014). NABERS, the Australian sustainability rating scheme that is based on actual annual energy use, has shown more successful results in reducing performance gap compared to BREEAM and LEED (Tuohy and Murphy, 2014)

Soft Landings (SL) is a strategy to ensure smooth hand-over and optimize operational performance through stakeholder engagement, systematic monitoring, and POE. Coordination among the design and construction team and all the significant project stakeholders is among the main pillars of SL to effectively achieve the design objectives (Li et al., 2011). The Soft Landings Framework (SLF) is a joint initiative between BSRIA and the Usable Buildings Trust (UBT), first published in 2009 and updated in 2014 to align with the RIBA 2013 work stages (BSRIA, 2014). Government Soft Landings (GSL) is a policy document for all centrally-funded projects as part of the public sector adopting Building Information Modelling (BIM) (BIM-Task-Group, 2013; BSRIA, 2014). SLF and GSL are aligned as they target reducing performance gap through POE in extended period and contract commitment beyond the typical defect liability period and closer integration of the design, construction, and operating parties involved (BIM-Task-Group, 2013). Both frameworks use structured familiarization workshops for handover; and walkthrough, surveys, and interviews for in-use

feedback collection to identify performance gap and teething issues (Pottage and Jeffrey, 2016). Yet, GSL is more prescriptive regarding incremental checks for BIM adoption and provides a mechanism to monitor costs. SLF is less strict about project objectives and focuses on increased collaboration and awareness of outcomes through stakeholder workshops and design reviews following the program defined by the SL Champion. Another main difference is that GSL starts at RIBA stage 0 or 1, whereas the SFL sets targets at stage 2 (BSRIA, 2014).

SL and BREEAM are a promising combination of lifecycle-oriented tools to future-proof buildings (Georgiadou et al., 2012). This paper presents a lifecycle plan of work for reducing performance gap through successful planning and implementation of BREEAM and SL into a project to achieve a low-energy, comfortable building. This action plan is prepared according to the RIBA Plan of Work 2013 and the UK Government Digital Plan of Work (BIM-Task-Group, 2013; HUNT, 2016; RIBA, 2013). All the recommendations are based on the reported lessons learned in white papers and academic publications concerning performance gap, POE, green building schemes, and BREEAM and SL documents; as well as, the knowledge collected from two actual case-studies at Heriot-Watt University campus that were procured and delivered using BREEAM and SL. Table 1 offers a summary of the guide and the organization of this paper.

Table 1. Summary of the practical lifecycle guide presented in the following paper sections.

Lifecycle Phase	Plan of Work	
<u>Strategy and Brief</u> (RIBA stage 0-1)	i. Explore regulatory and project specific objectives ii. Plan and set targets	
<u>Concept to Detailed Design</u> (RIBA stage 2-3)	i. Test objectives ii. Design and Model iii. Test modelled performance	BREEAM
<u>Tender Design and Construction</u> (RIBA stage 4-5)	i. Evaluate buildability ii. Construct	
<u>Handover and In-Use</u> (RIBA stage 6-7)	i. Familiarization Workshops ii. Fixing metering and sub-metering readings versus BMS iii. Identifying building defects and fine-tuning iv. Occupant Satisfaction Surveys after a year of occupation	

### Strategy and Brief (RIBA stage 0-1)

The transition from construction to occupation should be considered throughout the development of a project. An early adoption allows for allocation of an appropriate budget, conservative and prescriptive contract appointments, and inclusion of provisions in the briefing documents. In the first stages of project development, the client shall review the government and local regulations, feedback from similar projects and establish the project targets for the Project Brief. The brief shall include quantifiable project aspirations regarding: (1) project business case and schedule covering project capital and operational budget; (2) performance targets regarding: a) building functionality and effectiveness in operation and maintenance, b) commissioning plan, metering and monitoring strategy, and training and handover requirements; (3) sustainability aspirations: a) environmental, including: energy and water consumption, carbon emissions, and waste, b) social, including: occupier comfort, locally sourcing of materials and workforce, consultation and end-user involvement; (4) other requirement discovered through feasibility studies and site inspection (BIM-Task-Group, 2013; BSRIA, 2014; RIBA, 2013). The brief should be interrogated until excellence.

Along with the conventional design team, the following members shall be appointed from the outset: (1) a sustainability champion such as a BREEAM consultant and a SL champion to supervise the appropriate strategies (BSRIA, 2014); (2) construction team to involve them in review meetings to provide feedback on build concerns (Zero Carbon Hub, 2014); (3) facility managers or FM advisors to assist with ensuring that the design specifications are aligned with final users' needs and requirements (BSRIA, 2014). BREEAM encourages consultation with the end-users and the relevant third-party stakeholders prior to completion of the Concept stage (RIBA stage 2).

The two considered case studies had a rushed brief development, whereby the binding documents only mentioned BREEAM and SL, but did not impose any BREEAM target or SL procedure in detail. This allows the stakeholders to revert to the traditional performance indicators and familiar, traditional practices when facing budget or time schedule overrun.

### **BREEAM and Synergies with SL**

While minimized energy consumption and energy security are important factors in building future-proofing, benefits related to building and building users are claimed to outweigh energy cost savings considerably (WGBC, 2013). Although green building certification schemes consider all these beneficial factors, investment decisions are commonly founded on only energy and associated operational cost savings, mainly because the other benefits are too unpredictable to shape business cases (Pottage and Jeffrey, 2016). Table 2 presents the BREEAM credits that are aligned with the SL framework, along with their contribution to the total score for a new, fully-fitted BREEAM 2014 construction project. These credits contribute 7.66% to the overall score and have essential impact on reducing the performance gap through energy monitoring, user engagement, or occupant satisfaction.

Performing POE one year after initial occupation scores 1 point for the project and delivering an enhanced, quarterly POE over the first three years of occupation qualifies for 1 exemplary-level point (given that the POE findings are disseminated) (BRE Global LTD, 2014).

Table 2. BREEAM credits recommended by and are in line with the SL framework.

BREEAM Credit & Section	Credit Summary	X	Y	Z
Management	01 Project Brief and Design Stakeholder consultation: project delivery and relevant third parties.	2	0.57%	UE
	Commissioning and testing schedule and responsibilities	1		EM
	Commissioning building services	1		UE
	Commissioning building fabric	1		OS
	Handover (Building User Guide/Training schedules)	1		
	Aftercare Support to the occupiers	2		EM
	Seasonal Commissioning over a minimum 12 month period	1		UE
	POE one year after initial occupation and to disseminate the findings	1		OS
	Quarterly enhanced-POE over the first 3 years of occupation	+1		
			1%	
Energy	02 Energy Monitoring (Sub-metering) Major energy consuming systems	1	0.48%	EM
	High energy load and tenancy areas	1		

<sup>1</sup> X: Points achieved by abiding by the requirements of the credit

<sup>2</sup> Y: Section weighting (each point's contribution to the total score) for a new, fully fitted BREEAM 2014 project

<sup>3</sup> Z: Reducing performance gap by: EM=Energy Monitoring; UE=User Engagement; OS=Occupant Satisfaction

In addition to the credits presented in Table 1, BREEAM largely focuses on improving occupants experience and satisfaction by prioritizing their health and wellbeing through: appropriate glare control, view out, daylighting, and lighting levels; indoor air quality and thermal comfort studies, and thermal control zoning; improved acoustic performance and safety and security; and site selection based on good public transport linkage, proximity to essential amenities, and cyclist facilities.

Moreover, the Energy section of the BREEAM manual encourages energy efficient solutions through the following strategies: use of energy simulation methods to predict and reduce operational energy use and carbon emissions; specification of energy efficient lighting and equipment; provision of adequate drying space; analysis for adoption of passive design solutions and low/zero carbon energy sources. Similarly, the Materials section aims to raise awareness about green building materials that assist with emission reduction, higher asset value, reduced operating costs, and enhanced worker productivity due to healthier indoor environment.

### **Concept to Detailed Design (RIBA stage 2-3)**

During the concept development the project brief is revised to a final version that reflects specific requirements for design, construction, handover, and operation deliveries. It should include: (1) measurable targets and (2) strategies for assessment. In addition to the conventional design documents and specification, it is recommended to have a plan and an expenditure budget for operation management, commissioning, training and handover, and aftercare support. Budget plans must be reviewed and design development and value-engineering must be monitored to ensure design targets can be achieved. Whole life costing shall be performed at this stage. Clash detection must be performed throughout the design process to minimize services and fabric integration troubles on construction site

### **Tender Design and Construction (RIBA stage 4-5)**

At this stage the design and digital models are translated into a constructed building. From RIBA stage 4, the contractor is actively involved in document preparation. The contractor shall allow for the participation of relevant subcontractors in design reviews, and record and act on access, commissioning and potential maintenance risks identified, where appropriate (BIM-Task-Group, 2013). Requesting inclusion of all sub-contractors on a pre-tender list will allow comparison on issues such as energy related skills (Zero Carbon Hub, 2014).

The Technical Design documents including architectural, structural and building services information, specialist subcontractor design and specifications are prepared. Regular reviews are recommended to ensure that the set performance and cost targets are still within horizon and accurately strategized. Suppliers and facility management are employed to review the operation management plan and expenditure budget. Lack of adequate quality assurance on construction site has resulted in aspects of construction related to the performance of the completed building not being prioritised. The considered case-studies have also suffered from lack of monitoring and quality assurance during construction. Weak site energy performance management results in improper insulation fitting, incorrect services installation, and poor details construction (Zero Carbon Hub, 2014). Regrettably, SL does not include monitoring during construction and the extent of influence of project size, construction type, or contractual approach on this issue, is unclear. After construction is completed, taking thermographic images of completed buildings can assist with detecting problems with construction details (Palmer et al., 2016).

It is essential to plan for commissioning before handover along with the operational team to optimise the performance of the energy systems (BIM-Task-Group, 2013). At this stage the asset register and asset operation and maintenance manuals are prepared. Testing and commissioning are required for practical completion and allow clients the mandate to hold completion. It is recommended to hire independent commission specialists to police the M&E testing. Calibration of controls, metering, and complex mechanical or electrical systems can become challenging. Simpler systems and controls have proven to be more user-friendly and efficient (Palmer et al., 2016). The case-studies' users found inconsistent selection of controls within the building spaces confusing and inconvenience. BMS is a convenient centrally controlled method and can over-ride controls. However, it has proven to be complicated to regulate for commissioners and operate for occupants and facility managers. Therefore, similar to the case-studies, projects repetitively report BMS conflict with other system controls, which leads to confusion and wasteful energy use (Palmer et al., 2016).

### **Handover and In-Use (RIBA stage 6-7)**

Even though, RIBA stage 6 and 7 are named as two separate phases, namely, "handover and close out" and "operations and end of life"; SL blurs the line between these two phases by adding 3 to 4 years of building performance evaluation to reduce performance gap. The liability period is still at the end of the first year of occupancy, which is why it is essential to financially incentivize and contractually guarantee continuation in the following years.

Zero Carbon Hub suggests focusing on robust verification of energy performance, for example by Building Control Bodies or warranty providers. To reduce performance gap, it is essential to allocate sufficient time and financial incentives for a systematic and structured quality assurance process (Zero Carbon Hub, 2014). It is recommended to evaluate: (1) In-use performance for three years including meter and sub-meter recording, corrective actions and fine-tuning; (2) The desired against the achieved environmental performance goals; (3) Actual capital out-turn cost and operational costs for a period of three years (POE).

Performance monitoring and evaluation results identifying the areas where performance has required additional work beyond that envisioned (BIM-Task-Group, 2013). During the handover period, familiarization workshops shall be arranged for the facility management team covering the change control, metering, and monitoring systems, whereby the required operational skills are provided and training is documented for future reference.

There are various POE methods to choose from and it would always worth looking at a hybrid of methods or adapting one method to the scope and needs of the case without compromising the possibility of benchmarking against the available datasets. It is for the sake of benchmarking that generally applicable techniques are favoured by some prominent authors such as Bordass and Leaman. These methods should be broadly applicable, holistic, and robust, besides being free, simple, and quick to implement (Bordass and Leaman, 2005). For instance, the Building Use Studies (BUS) occupant survey and reporting method has a rich database of POE results that allows for benchmarking in several countries including the UK (The Usable Buildings Trust, 2007). Another benefit of this method is the quick data analysis performed by the UBT, which is essential to accelerate corrective, follow-up actions.

Because the POE process involves building managers and users and requires a considerable amount of time and other resources, it is essential to perform a pragmatic research and investigate only what is relevant. The selection should be based on the study objectives, depth, and nature, the reporting audience, and the available resources (Olivia and Christopher, 2015). These performance evaluations shall include building fabric tests such as

airtightness testing and thermographic survey, commissioning of building services and controls.

SL suggest evaluating building performance using three methods: (1) Regular inspection walkthroughs that check the building's operation looking for any emerging problems or wasteful operational practices; (2) Continuous survey of the energy use breakdown by type of consumption for example, heating, air conditioning, as well as space zones through energy sub-meters; (3) Assessment of occupant satisfaction using surveys and interviews, ideally one year after building occupation to cover at least one seasonal cycle (Agha-Hossein et al., 2015; Palmer et al., 2016)

## Discussions

Knowledge turnover is crucial for a system to evolve sustainably. In a stable system, such as the construction industry, knowledge turnover is abridged and new alterations are rarely continued. In such systems, it is recommended to start a variation from the less established parts, where faster knowledge conveying occurs and is appreciated (Shepherd, 2004). Therefore in order to transit the industry to where it can benefit from full digital design and delivery and allow for continuous improvement, we shall focus on extended aftercare and stakeholders' engagement that are not established practices and systematically collect data, record the lessons-learned and best-practice, and combine data collection and modelling verification for better forecasting.

Even though BIM is recommended as the catalyst to future-proof buildings (Love et al., 2015), the results of the recent Construction Manager BIM survey revealed stagnation in implementation since the mandate for adoption in publicly funded projects a year ago. This survey concludes that clients are not certain what to specify and how BIM should be applied per contract or procurement type; thus, clients see BIM as additional expense with no benefits (Chevin, 2017). Hence, until BIM develops to its full utility, the construction industry requires compensating tools that assist with future-proofing buildings within its current capacity and stable structure and smooth the transition to the digitalized industry.

The sources of performance gap as described in the introductory section can be managed through the SL steps described above that encompass a process of stakeholder involvement and POE and result in manifold of benefits at two levels:

- Project Specific: improved building performance and reduced operative costs and performance gap, achieved by: (1) fine-tuning; (2) proper use of building systems
- Continuous Improvement through developing a wider knowledge base, achieved by: (1) long-term competitive advantage; (2) informed policy developments; (3) intra-agency feed forward of guidance criteria; (4) improved services by designers, builders, facility managers; (5) more accurate simulation assumptions; (6) establishing baselines based on stages of building life cycle (Menezes et al., 2012; Olivia and Christopher, 2015; Preiser, 1995).

## Conclusions

BREEAM and SL rely on the current industry expertise and structure and do not require complex training or tools. They provide a common platform for dialogue and collective action and continuous improvement. Yet, a series of important steps must be followed to implement these frameworks successfully with minimum human and financial resources; to benefit from their synergies; and to ensure continuance. Accordingly, this paper presents a holistic plan of action for successfully adopting BREEAM and SL at different stages of a building lifetime.

This practical guide assists with effectively reducing the performance gap and designing and delivering low-energy and comfortable buildings through highlighting the underlying reasons for performance gap and recommending implementable actions at each stage of a project lifetime for a successful project target delivery.

Given that the two case-studies considered are at the end of their first year of occupancy and still in the process of fine-tuning, disclosure of their SL information and results were not yet possible. However, some of the focal lessons learned are discussed.

## Bridging the gap: A framework for a robust sustainable design process

Sarah O'Dwyer<sup>1</sup> and Vivienne Brophy<sup>2</sup>

<sup>1</sup> Welsh School of Architecture, Cardiff University, United Kingdom. odwyers@cardiff.ac.uk

<sup>2</sup> School of Architecture, University College Dublin, Ireland. vivienne.brophy@ucd.ie

**Abstract:** There is an ongoing deficiency in the application of sustainability theory through design by many construction professionals including architects. While sustainability knowledge has grown, importance should not be placed solely on its existence, but rather improving knowledge through its application and adoption in order to lessen performance gaps. While there are existing techniques to assist in meeting these challenges (e.g. design process guidance, environmental assessment guidance and software tools) research conducted by the author through a design charrette revealed limitations to this guidance in its current form. These findings indicated that of the guidance available, an integrated and informed design process has the most potential to be successfully developed to more effectively implement well-performing sustainable design. The author recommends a framework for the form, content and application this sustainable design process guidance should take, and suggests it would help give a bottom-up approach to how sustainability should be defined and implemented in practice; helping to move the current design process paradigm towards a sustainable design process one. Such guidance would be a practical tool that is universally accessible and capable of responding to changes in context in order to enable practitioners to create and deliver buildings that perform as intended.

**Keywords:** Sustainable design process, sustainable design guidance, inexperienced sustainable designers, performance gap, sustainability implementation

### Introduction

Building professionals require the knowledge, skills and tools to understand and implement sustainable design in practice; not solely to respond to a top-down legislative agenda but additionally to improve the user experience of buildings and respond to sustainability issues from the bottom-up. Architects are key professionals within this process as the building consultant with the earliest influence on the design, and the need for architects to possess the sustainable design skills to support this role is crucial for future sustainable development. Whilst there appears to be a reasonable understanding of concepts and theory surrounding sustainable design currently within design practice, there is an ongoing deficiency in the *adoption and application* of this theory through design. This deficiency manifests itself in continued high levels of building energy use and oil dependency (Eurostat, 2016), in building performance gaps (Bordass and Leaman, 2013), in the lack of sustainable buildings which go beyond tepid 'greening' (Irish Green Building Council, 2012) and in the lack of robust sustainability confidence in architects (NBS, 2012).

This paper suggests therefore that importance should not be placed solely on architects gaining possession of sustainability knowledge, but rather improving their skills in the *application and adoption* of it within the design process. The focus of this paper is therefore the review of available sustainable design guidance in the form of processes,

methods or tools and the effective implementation of same by architects. It examines to what extent guidance might better support a more successful realisation of sustainable design. The focus stage is early stage design guidance - as these early stages are most influential, and the focus consultant is inexperienced sustainable design architects in Ireland who are interested in these issues but unclear how and when to implement them.

Therefore, this paper seeks to firstly briefly summarise through literature review what current guidance is available. These broad findings are further discussed and verified by the findings of a design charrette conducted by the author which evaluated how current guidance is being utilised, and offers suggestions on how sustainable design guidance should be offered in the future in terms of a guidance framework which would enable architects to not only develop sustainable design skills and ability but to implement same.

### **Existing Design Guidance**

A literature review was undertaken to examine the effectiveness of current sustainable design guidance in the Irish early design context. There is currently sustainable design guidance available in the form of processes, (e.g. RIBA overlay) [environmental assessment] methods (e.g. LEED) and tools (software and manual). This guidance is an attempt to give some structure to a problem and to organise decision making sequences to help reduce design waste (Magent et al., 2009).

Current design **process** guidance does not address definition, realisation or sequencing of sustainable design ideas and standards. Instead, it offers a design process in which sustainability, where pursued, is added as an additional aspect to existing linear processes, manifesting in a 'DESIGN PROCESS plus SUSTAINABILITY' whereas what is called for is a SUSTAINABLE DESIGN PROCESS which incorporates sustainability within the design process. Current **method** guidance helps to set the [aspirational] goals of sustainable design – the definition - but not the means to achieve them - the realisation and sequencing is not addressed. They are primarily intended as assessment methods, and as such are unable to guide design (Cole, 2012). Current **tools** guidance are of some use in realisation of sustainability. Essentially, tools are useful to measure progress and though early design tools are available, tools appear to be of more value at a later design stage - the 'early' sequencing is therefore not fully addressed by tools, or these tools are in the wrong format. Most tools are of a technical nature and relate to outcomes that can be clearly measured, meaning many tools are used to assess not to inform decisions (Schweber, 2013).

It seems that while the body of knowledge on the theory of 'sustainable development/building/design' is growing - along with an associated increase in software, internet tools, methods and publications to act as design guidance in manipulating this theory - there still remains a consistent dearth of sustainable building both globally and specific to Ireland at present, and robust green building practices are yet to develop (Korkmaz et al., 2010). The technologies, products and guidance for sustainable building are available, but they are not successfully exploited in design (Häkkinen and Belloni, 2011). The current guidance interface is not meeting this need fully as guidance rarely addresses sequencing issues, and often issues are divided by topic or profession, and interdependencies between issues or professions are not highlighted (Lombardi, 2011). It is further suggested by the literature that as a support for sustainable design, existing sustainable design guidance such as methods and tools are useful and equally as important as process guidance but which are structured to be used at a later stage in the design process for a much more developed design, and as such process guidance is best poised to offer most assistance to inexperienced

sustainable design architects in early stage sustainable design. This calls for existing sustainable design process guidance to be questioned and perhaps enlivened to deal with the practicalities of delivering sustainable buildings.

### Design Charrette

The next phase was a design charrette, which was constructed as a “small scale experiment” involving a single test with a small number of groups (Cash et al, 2012 cited in Vallet et al., 2012); with both quantitative and qualitative aspects in its design and analysis of results. It provided an opportunity to observe design process in practice (Austin et al., 2001) and to test the applicability and validity of existing design guidance in form of process, methods and tools. It could be analogous of actual practice and process (Edwards, 2009) in order to enable characterisation of participants in relation to larger population (Vallet et al., 2012).

30 participants took part in design charrettes held over two days. Two of these participants were experienced sustainable designers recruited from an earlier interview research phase and the remaining participants were selected through an advertised open call for architects inexperienced in sustainable design. In the main participants worked on a variety of projects, were from small practices and had less than fourteen years’ experience. The participants were split into 5 groups and were given the same small group design task. Each group was given additional guidance in the form of either process, method and tool guidance, with one control and one inexperienced group given no guidance - Table 1.

Table 1. Charrette participant detail

GROUP	NO. IN GROUP	EXPERIENCE	GUIDANCE PROVIDED	FORMAT PROVIDED
Control (C)	7	Inexperienced	None	N/A
Tools (T)	6	Inexperienced	Variety of 8 software tools appropriate for early stage design regarding site ('climate consultant'), fabric (u value calculator, materials ('BEES'), comfort ('freerunner', 'designadvisor' and daylight factor calculator), energy ('design advisor') - all freely available and advertised as not requiring previous experience.	On 2 laptops with internet access, with instructions
Process (P)	7	Inexperienced	RIBA Green Overlay .This relates to UK design stages, and are mainly similar to the Irish RIAI stages. It gives sus issues to consider at each design stage.	Paper format, with instructions
Method (M)	8	Inexperienced	BREEAM 2008 for Offices - a sustainability accreditation checklist of sustainable topics and issues to consider in checklist format.	Paper and digital format, with instructions
Experts (E)	2	Experienced	None	N/A

Two surveys recorded the attitudes of participant’s pre and post design task, and were compared to annotated observations made by the author during the task. It is recognised for increased confidence in the generalizability of these findings a larger sample size would be required, however the sample size was deemed to be in line with previous studies of a similar nature (Cash et al., 2013) and appropriate for the investigative nature of this research.

The limitations to studying in this way all the design processes undergone by an architect are acknowledged; it is still a “synthetic experiment that does not carry weight equivalent to a natural experiment” (Clayton et al., 1998). However it is an approximation of process which reveals elements of real world practice which can inform and direct current sustainable design guidance and future research in these areas.

Participants were asked questions on the particular design guidance used by their group in terms of: 1) how useful it was to aid knowledge and understanding and meet sustainability targets 2) how effective it was to help to direct the design process, 3) practically how useable and understandable it was and 4) how likely participants are to use the guidance in the future. The main conclusions are summarised below.

## **Knowledge and understanding and sustainability targets**

It should be noted that pre-task the majority of the participants expressed generally that their knowledge and skill level to be 'average' or 'below average'. Participants found the process guidance most useful and the tools least useful in terms of the ability of the guidance to aid understanding and consideration of the design targets/brief. Post-task participants expressed their knowledge of sustainable design had improved, signifying that when a design process is framed with a sustainable design brief and approached from this viewpoint that sustainable design knowledge of participants can be enhanced. These findings correlate with literature findings in terms of the need for improvement in sustainable design knowledge and suggests that when the knowledge is there it can remain dormant and requires additional activation to bridge the gap between theory and its implementation in the design process.

## **Directing the design process and effect of guidance on design process**

Participants found the tools guidance least successful at aiding integration of sustainability into the design process and in aiding coordination of design activity – Figure 1. The process and method guidance are observed to be of equal success in this regard.

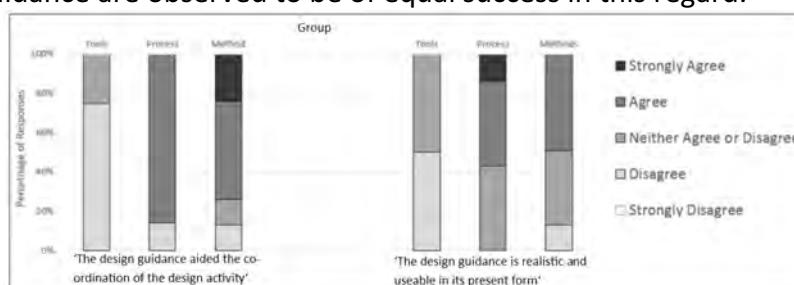

Figure 1. Responses of relevant charrette groups to given statements

Whilst on the whole the inexperienced groups P,T and M showed no major differences in terms of design activities engaged with or time spent on each design activity, there were some differences – particularly in relation to engagement with design activities (Table 2) which suggests this is in part linked to the guidance each group used, and that therefore perhaps the process guidance was more successful in eliciting a better design process response from participants than either of the Tools or Method guidance.

Table 2. Total percentage of design activities engaged with per charrette group

Group	Total % design activities engaged with (as indicated by participants)
C	62%
M	66%
T	70%
P	81%
E	75%

## **Practically useful or understandable**

The tools guidance was least understood with similar proportions understanding both the method and process guidance. Tools and method guidance is found to be the least straightforward to use by participants. Tools guidance is found to be least useable and realistic, and Process the most - Figure 1. Tools guidance is least successful in directing the design process and least relatable to existing design processes, with method and process similar.

## **Potential Future Use**

Participants were willing to use all guidance on a future project, with participants most willing to use the method guidance, then the process guidance, and then the tools. Participants expressed more strongly that the process guidance would be implemented more easily than the method, followed by the tools guidance. However, participants expressed they still

required additional guidance on how to implement sustainable design into their process. This indicates that although the design guidance used was useful in improving knowledge and skills, none of the given guidance was completely effective to enable successful implementation of sustainability and there is still the capacity and the need for a more developed or different form of sustainable design guidance for architects of this demographic in terms of *applying* sustainable design theory.

### **Where participants received no guidance**

In terms of the participants who *did not receive any additional guidance*, the Expert Group E is ambiguous in their attitudes to potential additional guidance though they are in clear agreement is in their willingness to use additional guidance. The Control Group C participants agree that potential additional guidance would be useful. Both of these findings indicates an openness and readiness that could be found amongst all participants to use and integrate sustainable design guidance into working design processes – either by inexperienced sustainable designers to enable a more effective sustainable design process or, to a lesser extent by experienced designers to advance their existing sustainable design processes.

### **Summary of design charrette findings**

In terms of the participants who *used some form of design guidance* during the task, the tools guidance was the least successful in all aspects as expressed by participants. Whilst there are a few aspects where method guidance is more successful than the process guidance these aspects are mainly related to design process management and administration issues. The process guidance is more successful than method guidance with regard to: considering design targets, effective team working, being useable, realistic and straightforward and ease of future implementation in practice; and marginally more successful in terms of understanding the guidance, having the potential to be clearer if the participants had had more time to use it and improving the process of sustainable design undertaken by architects. As such in this study it can be seen that the process guidance is most successful overall, particularly for aspects which have more weight in terms of enabling an effective sustainable design process (e.g. knowledge, understanding and practical use).

### **Proposed Process Guidance Framework**

From the research findings, the author proposes the form, content, structure, sequencing and use of guidance – Table 3. This is an initial framework to what guidance should respond to and contain and provides a basis for further research, testing and refinement. Table 3 shows an example of the framework for stage 1 of the design process 'inception'. It gives design criteria gathered from four sources for two headline issues (water and management). Please note this is a snapshot as the framework currently exists as interactive spreadsheet which covers expanded issues and design stages.

Table 3. Proposed guidance framework Stage 1; simplified

Sustainable Design Factors Headline Issues	Sustainable Design Factors Sub-Headline Issues	Design Process Stages (From RIAI workstages)			
		1. INCEPTION AND GENERAL SERVICES Sources for detail of sustainable design criteria			
		Openhouse indicators	Established and published literature and guidance for the Irish context	Interviews	RIBA Green overlay
WATER	Water efficiency		WATER: 1. Assess if the client will consider water-saving sanitary fittings - cisterns, controls and taps 2. Discuss the levels of water re-use possible - 'green', 'grey' , and 'black' water.		
	Rain Water Harvesting				
MANAGEMENT	Management				Client to consider formal adoption of soft landings approach to the project

### ***Proposed form and structure of Guidance Framework***

The author suggests the proposed sustainable design guidance should take the form of a framework which is based on a known process model structure (e.g. for Irish context - the RIAI workstages) which has a familiar structure and known context to inexperienced sustainable design architects and which could potentially be easily adjusted to other European design stages which are largely similar. Often existing guidance has been created with the transfer to industry expected to function as a self-evident automation. However, the use of the framework within or alongside a familiar structure would help to enable the assimilation of the new knowledge rather than it being an adjunct to the existing process; looking to make existing processes more sustainable instead of developing a new process (Heiskanen and Jalas, 2003 in Coley and Lemon, 2009).

The charrette findings suggest basing a guidance framework on a process model has the most potential to be successful. Using process workstages as the guidance framework basis has the potential to succeed as many practitioners refer to these workstages within their everyday design process. The purpose of the framework is therefore not to introduce new ideas but to improve and refine existing processes. Design processes evolve and change over time and a guidance framework related to the existing design process could be a trigger for this change in helping to integrate sustainable design into mainstream design process.

### ***Proposed Content and sequencing of Guidance Framework***

It is suggested the framework guidance should map the *whole* spectrum of potential sustainability goals. It is proposed this map is derived, compared and assimilated both from previous research (e.g. Openhouse indicators) and from published literature and guidance for the Irish context- Table 3. In this way many facets of sustainability could be assimilated into one area which relates very specifically to the Irish context but which would also be capable of being related easily to others. As such it would represent a more robust and holistic definition of sustainability than currently exists and enable a wider range of factors to be considered from the beginning –avoiding abortive work. The framework would ask designers and stakeholders to define and discuss project sustainability goals to help make clear any value judgements, worldviews, or ways of thinking (Wahl and Baxter, 2008) about sustainability that might otherwise go unheard and negatively influence the design process.

The charrette findings indicate that the current interface of existing processes, methods and tools guidance rarely addresses sequencing of issues, and often issues are divided by topic or profession; and therefore interdependencies between issues or professions are not highlighted; as various facets of sustainability can be affected by one design aspect; these interrelationships should be made evident (Lombardi, 2011).

Firstly sequencing of the issues should be mapped by relating the issues to *when* they should be considered in a design process (based on workstages as above) and secondly relationships between issues should be addressed by indicating which issues affect and influence other issues. In this way the framework would help a designer to translate a design process to a sustainable design process through specific actions and sequencing. As such the proposed guidance framework is intended be both comprehensive and practical to use (Schweber, 2013).

### ***Proposed use of Guidance Framework***

The framework is intended to form a guide to a better pattern of activities, not to prescribe a sequence of activities which must be performed. It is not intended as a ‘one size fits all’ – it

must be aligned to user and client needs and assembled by the designer for that particular project. By default the proposed guidance framework would indicate all the potential sustainable design factors to be considered at all stages which the design team could then refine. This is particularly useful in increasingly interdisciplinary design processes as the guidance framework can give a defined approach to enable teams to work successfully together towards shared goals which can be nurtured from the bottom up. This also reinforces the difference between this proposed guidance framework and other existing guidance interfaces in that it does not force a strict procedure, but can be adapted to suit a particular team and/or project. As the framework is directed at inexperienced sustainable designer it is expected these designers would use it only when experience is not sufficient to design a satisfying solution. Indeed, as the charrette findings have shown once architects move from inexperienced to experienced sustainable designers, i.e. towards a *sustainable* design process their need for a framework, such as this, diminishes.

The proposed framework is not intended as an assessment tool but to be a kick-start for sustainable design – an early design decision support tool to help to bridge gap between theory and practice (Magent et al., 2009). It enables architects to address a barrier in their individual control instead of waiting for bigger picture barriers to catch up (Figure 3). Even in integrated design processes, known to be best in delivering sustainability, a supportive framework could be of benefit to enable more sustainable solutions (Coley and Lemon, 2009).

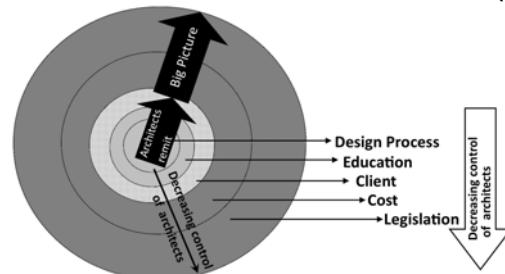

Figure 3. Levels of barriers to sustainable design implementation

## Conclusion

The aim of this paper was to explore current sustainable design guidance and propose the form it should take to enable more successful implementation of sustainable design. The intention of this study is to move the discussion forward with a focus on the *application* of sustainable design by architects in the Irish context, with a focus on early stage design.

Literature findings revealed limitations to the existing guidance available which was further established by the charrette findings. The charrette studied the importance of understanding how to *apply* sustainable design knowledge to working design practice and revealed existing guidance is not absolutely successful in achieving this - post-task participants expressed they still required additional guidance on how to implement sustainable design into their process. This indicates existing sustainable design guidance is not completely effective in its current form to enable successful implementation of sustainability within early stage design by inexperienced sustainable design architects. It was found there is still the need for sustainable design guidance for architects of this demographic which could apply to the greater population of inexperienced designers.

Notwithstanding this, charrette findings suggested the process guidance was most useful guidance overall, particularly for aspects related to knowledge, understanding and practical use and that overall, of the guidance available, design process guidance has the most potential to be successfully developed to more effectively implement sustainable design.

From this a guidance framework is proposed with the intention to assist in moving the design process of inexperienced sustainable designers towards a sustainable design process, and its proposed form, content, structure and use is based on the findings of literature and the charrette research phases. As such it is intended to respond to deficiencies highlighted within current sustainable design guidance to enable more effective implementation of sustainable design. As such it is hoped these findings will not only serve as a reference to practitioners but will aid the development of further understanding of the nature of this gap between theory and practice, and that the recommended guidance framework can give improved understanding and act as a stimulus to a more effective, useable and relevant form of sustainable design guidance for inexperienced sustainable designers than currently exists.

### **Future Work**

The proposed framework exists currently as a spreadsheet and requires further development and refinement to test its usefulness and appropriateness. Additionally the charrette findings could be further tested on larger numbers of the desired sample population.

# PLEA 2017 EDINBURGH

*Design to Thrive*

## Norway's electric vehicle deployment success and PLEA

**Harald N. Røstvik**

Professor,

University of Stavanger, Norway. harald.n.rostvik@uis.no

**Abstract:** The huge Norwegian hydropower capacity delivering 99% of its electric energy has been the backbone of the argument for the introduction of electric vehicles since 1988. This had led to the design and implementation of the world's most generous incentives for battery electric vehicles (BEV) from 1994, an act that later led to soaring sales. In 2012, 3% of all cars sold in Norway were BEVs and Norway was the World's 5th largest volume market for BEVs. By the end of 2016 there were over 101 000 BEVs and by 2020 it is forecasted that every second car sold will be electric. However, in addition to the BEV sales, the sales of Plug in Hybrid Electric Vehicles (PHEV) have soared. In the first two months of 2017, 49% of all sold personal cars, not vans and buses, in Norway were BEVs and PHEVs. The goal is an all-electric vehicle fleet. The paper responds to three questions: 1. How did this success come about? 2. What is the link between electric vehicles and buildings? 3. What can case studies teach us?

**Keywords:** Battery electric vehicles, incentives, buildings.

### Introduction

The discourse on sustainable urbanism is often centred on densification. Dense cities generally score well in terms of greenhouse gas emissions per person. Short distances between work, home and social arenas, well-developed public transport systems and compact housing has generally been considered advantageous. Urban areas like Hong Kong, New York, Vancouver, Tokyo and London can hence show average CO<sub>2</sub> emissions per person per year below 7 tons, while more rural areas, because of the need for more transport over large distances, score less well. The USA at large is above 15 tons CO<sub>2</sub> per capita per year (Global Carbon Atlas, 2016).

Norway, scores well on Human Development Indexes every year and topped the global statistics in 2014 (HDI, 2014). But the relatively non-dense cities, and the life style results in average CO<sub>2</sub> emissions above 10 tons per person per year. This does not tell the full story of a country generally considered to be happy, social democratic, equal and rich. As an oil exporter, most of Norway's oil is burnt abroad. This is not registered on the average Norwegian's annual per person emissions. To show this full picture, in addition to the 10 tons normally shown one must add another 149 tons CO<sub>2</sub> per person per year. In this paper I will concentrate on the 10 tons and discuss how BEVs and PHEVs can play a considerable role at reducing CO<sub>2</sub> emissions.

## Densification or technology

Densification of cities takes time and the effect cannot be noticed within a decade or two in the same manner as technology shifts can. This was also the conclusion of the 2005 Low Emission Report (Randers, 2006). It showed clearly that during a 45-year time span, densification will not have much effect, while technology shift in the transport sector will. As shown in Figure 1 densification leading to reduced need for transportation (Transportredusjon) only showed the potential for marginal reductions up to 2050.

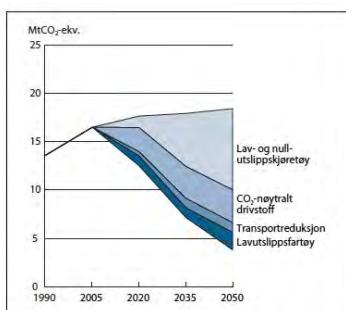

Figure 1. The Low Emission Report concluded that it would be much easier to reduce emissions through technological improvements than through densification (Transportredusjon).

The construction of new buildings also takes time. Although there are strong upcoming regulations regarding energy efficiency and the use of renewable energy leading to a new energy paradigm as shown in the new EU Directive (ED, 2010) stating that all new buildings from 2020 have to adhere to the Net Zero Energy Building level (NZEB), it will take decades to reduce the energy need in existing buildings. This is because buildings, as opposed to vehicles, have a very long life and are constantly adjusted. They last from 40 to 150 years at least, while a vehicle fleet is normally completely shifted, scrapped, recycled in less than 20 years. The current vehicle fleet in Norway is now 10,5 years old. This is relatively old compared to other European countries and a result of extremely high taxes on cars making them very expensive. The EU vehicle life average is much younger, only 7,4 years. Norwegian vehicles are on average scrapped or recycled after 19 years (VG, 2017 p12).

Replacing the existing fleet's oldest and very polluting cars is hence a strategy that can be implemented relatively fast, compared to replacing polluting buildings with new ones. This paper will hence concentrate on studying the shift with the biggest impact up to 2050, namely technological improvements of the vehicle fleet exemplified through the case of Norway. The paper will look at three main issues:

- How did the Norwegian BEV success come about?
- What is the link between electric vehicles and buildings?
- What can case studies teach us?

### How did the Norwegian BEV success come about?

In 1987, the UN World Commission on Environment and Development, headed by the Norwegian Prime Minister Gro Harlem Brundtland released its report "Our Common Future". Its conclusions were clear and recommended action to be taken to stop damaging the environment. But instead of becoming a fine example, Norway started to intensify its oil exploration and exports grew.

In 1988, and as a reaction to the double standards, a small group of Norwegians consisting of an energy- and transport expert, an environmentalist and a famous singer joined forces and decided to design a strategy to force the Norwegian Government to introduce strong incentives for electric vehicles to test their ability and willingness to put the UN report into practice and show the direction forward.

As a step one, they travelled to Switzerland to watch the annual solar electric vehicle race over the Alps, the “Tour de Sol”, after which they visited the race-related solar electric vehicle exhibition in Bern. Until then it had been difficult to get media attention for electric vehicles in Norway and the expert that initiated the “expedition” had hence decided to join forces with the two others. This worked well. Suddenly all the major Norwegian media, nationwide TV and national newspapers wanted to come along, since a celebrity singer was inviting and the event was thoroughly media covered. This led to growing electric vehicle curiosity in Norway. When the three-person group the year after in 1989 bought and imported the first electric vehicle to Norway the same media covered the event and the planned step two was accomplished. Step three of the plan was to drive the vehicle in the toll roads around Oslo, the capital, without paying toll road passings.

As the famous face of the pop star and by now, the famous face of the environmentalist, appeared on TV because of refusal to pay toll road passing, people felt it was a developing story like a series with unknown outcome. When the unpaid bills piled up, step four was unavoidable. The state secured their debt by taking the electric car into custody and it was sold at a public auction. The media was there and embarrassed the state officials. The auction resulted in a bid from a person sympathetic to the environmental cause. He bought the car and gave it back to the group and it continued to drive through the toll road passing without paying. Months later, the same procedure occurred, the state took the vehicle and sold it. Someone bought it and gave it back. After several rounds of this over a couple of years and always with the press up front in the audience, the group’s demands were granted.

When one of Europe’s first modern energy autonomous housing projects was completed at the Building for the Future exhibition in Stavanger, Norway in 1988, the imported vehicle was filmed while it connected to the solar PV system of the house, to charge its battery. The world’s best BEV incentives were thereafter one by one implemented. The BEV incentives were introduced one by one always following a fight and today they still remain more or less as composed back in the 1990s. They have led to a situation where BEVs are fully cost competitive with other cars. The first electric bus in regular traffic in Scandinavia was put into operation in 1994 (Figure 2).

The list of incentives and the year they were implemented are shown below:

- 1990: Temporary abolishment of import tax.
- 1996: Reduced annual electric vehicle registration tax.
- 1996: Permanent abolishment of import tax.
- 1997: Exemption from road toll.
- 2000: Reduced company car tax.
- 2001: Zero VAT, a reduction from the former 25% VAT.
- 2005: Access to bus lane nationwide.
- 2009: Free access to road ferries.

Figure 2. Trying an electric vehicle in Bern (left). The bought one, a Fiat Larag electric being charged at one of Europe's first modern energy autonomous housing projects in 1989. In 1994 Scandinavia's first electric bus in regular traffic was introduced in Stavanger (right). It had interchangeable batteries.

### The current situation

Norway has the 19<sup>th</sup> highest national car ownership in the world with 498 cars per 1 000 population (The Economist, 2017). With its five million inhabitants it is viewed as one of the most important countries for electric vehicles and a laboratory for research and testing out incentives, new models and driving modes. Norway is long; from its Southern tip to the Northern one is similar to the distance from Oslo to Rome. There are hills and flat land, rugged roads and motorways and the climate varies considerable from area to area. There are freezing inland mountain areas where frostbites occur as temperatures occasionally drop to extremely cold minus 35 C, while simultaneously the coastal areas are mild and above zero.

There are now more than 101 126 BEVs in Norway. More than 25 000 BEVs were sold each year during 2015 and 2016. In 2016, 15,7% of all sold vehicles were battery electric and the sale of hybrid vehicles rose to or 13,4%. In sum 29,1% or 154 603 vehicles of all sold vehicles in 2016 were BEVs and PHEVs (OVE, 2016). The comparable sum figures for Denmark is only 4% and Sweden 8%.

The data for the start of 2017 show that 48% of all new vehicles sold in Norway during January and February were BEVs and PHEVs. A silent and dramatic shift has taken place and a worry among owners of diesel and petrol fuelled cars that they might not be able to find a second hand market soon, if this development continues, is spreading.

While the existing total fleet of vehicles in Norway today has an average emission of 188 grams CO<sub>2</sub> per vehicle kilometre, the average of all sold vehicles in January 2017 were only 84 grams (VG, 2017 p66). There are now PHEVs on the market that have emissions as low as 21 grams CO<sub>2</sub> per vehicle kilometre (Toyota, 2017).

### What is the link between electric vehicles and buildings?

The tremendously fast and positive development in battery technology for the electric vehicle sector has resulted in side effects that could have a considerable impact on the building sector. Charging of BEVs and PHEVs take place both at home, at work and in the urban landscape. When vehicles connect to buildings the possibility of sharing electric storage space occurs. With all the battery packages now available for vehicle charging a new energy storage option is made available in buildings. This offers a completely new possibility for utilizing the battery in the vehicle and/or a stationary battery bank as energy storage.

There is, however, a condition for making this realistic: The energy need in the building has to be lowered. This can be achieved through the classical passive and low energy measures like designing buildings so they use as much daylight as possible to save the use of electric light, use natural ventilation whenever and wherever possible, use passive solar heating without overheating. By lowering the need for bought energy, the

application of new, renewable energy becomes more realistic because it becomes less costly when the energy system size is reduced. Passive methods, energy efficiency and the use of new renewable energy is hence the very foundation necessary to bring in vehicle sector battery storage sharing as an option, simply because the need for energy in buildings becomes so small that the battery size becomes realistic.

An advantage of limited size battery storage is that it combines cost effectiveness with the possibility of evening out morning (breakfast time) and afternoon (dinner time) energy peaks. This helps the electric utility to plan ahead with more rational systems, eliminating costly capacity peaks. Such building/vehicle battery sharing solutions can be extended to become neighbourhood solutions connecting with local decentralised new renewable energy systems like solar and wind on building facades, roof and in the surrounding landscape as well as combining the energy from them with geothermal heat pumps.

Whether the approach of forcing authorities to go in a certain direction as regards incentives as described for the BEV sector can be applied to the architecture and planning sector is hard to answer. Certainly, sometimes, a more outspoken and action orientated profession might manage to question cemented truths and authorities, than an obedient profession. But at other times the outcome is the opposite, so there does not seem to be a golden rule or learning experience from the BEV case that can be transferred to another sector. What certainly can work though is to strengthen the architectural profession so that it makes use of its ability to convince clients to move in a more sustainable direction. There are also several ethical issues related to this and it can be argued that it is a moral obligation for the profession to work for more sustainable solutions, given the dramatic and negative consequences of climate change leading to millions of humans suffering and a general degrading of the human condition on Earth.

### **What can case studies teach us?**

Freiburg is often described as the environmental capital of Germany. Architects, planners and technologists go there to study the technical gadgets of its solar buildings and its transport systems. But few ask how Freiburg managed to achieve its sustainability goals. Was it technology alone? Not at all! It was a holistic approach that started in the 1970s and 80s by environmental activists that were fighting against the construction of a new nuclear power plant in the region. There was also the Fraunhofer Institute and the solar architecture of German architect Rolf Disch and the environmentally conscious inhabitants in the region. They made it possible to develop Freiburg to what it has become. They were receptive to new environmental ideas and this pushed politicians in a green direction that led to the introduction of the sustainability policies that were later implemented. In a study asking which factors are important in Freiburg for sustainable urban development, many factors were scoring well, but the highest score with 70% of respondents ticking off this box, was *Conscious population* (Muller-Eie et al, 2016).

In another case, this one in Norway at Madla Revheim in Stavanger, a new city-part for 10 000 people is being developed using the method of public participation (Figure 3). The planning process has been concentrating on involving both people in the area, potential contractors, housing corporations and industry actors in order to try to create an environmental-positivism years before the actual building will start. It is all about public participation. The energy strategy is also developed and based on trying to communicate a goal to the public. At the core of the strategy are energy efficiency, new renewable energy and an all electric vehicle and bus fleet. The study so far shows that such an all-electric

approach is possible technically and it is viable economically, provided energy efficiency is at its base, but the people must also be brought in and informed about the visions and the consequences of implementing it.

While this study was carried out, we became aware of hundreds of other cases with similar content. The architectural, engineering, mobility and scientific literature frequently carries reports and essays on the issue of the link between an all electric vehicle fleet and buildings. In a recent book that came about as a result of IEA Task 40 "Towards Net Zero Energy Solar Buildings", feedback from thirty built cases of NZEBs were described (Garde et al, 2017). The solution sets described all had the possibility to link the mobility sector with the buildings sector through sharing of electric energy, in much the same way as the Madla Revheim project proposed. The tremendous development in battery technology happening as a result of advances in the electric mobility sector, where not only road vehicles but also electric boats and planes are being developed, planners and architects must make sure they stay updated and see the potential. Buildings have a long life and cannot easily change. It is hence crucial that planners have a time-perspective catering for several kinds of possible changes.

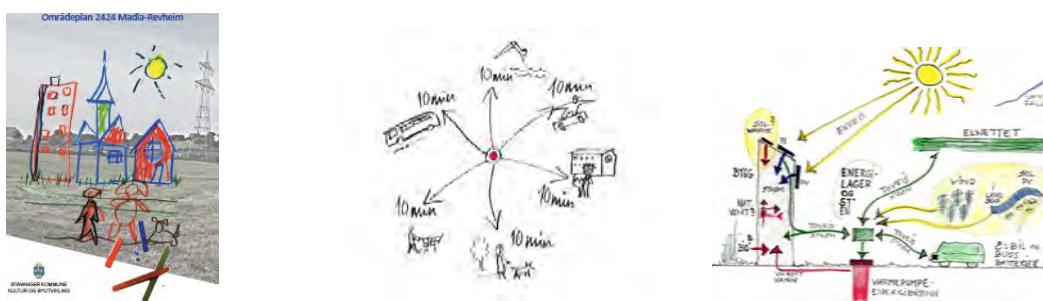

Figure 3. Madla Revheim, Norway. A new part of the city Stavanger for 10 000 people plus schools, commercial and social activity is designed around a strategy of passive and low energy. Measures and new renewable energy connecting buildings and vehicles.

## Conclusions

The Norwegian electric vehicle incentives are a success story. They came about through radical actions by an unusual mix of people that managed to achieve sympathy for the cause among the average man and this led to the Government bending over and granting all demands. Later this success story has been further strengthened by a national plan to deploy fast charging station throughout the country so that one can drive practically anywhere without losing time. The national network of fast charging stations is now under construction. In addition stringent regulations are put in place through the National Transport Plan 2018-2029 (NTP) to promote and provide incentives for electric goods vehicles, boats and ferries. The experience from the vehicle sector can and is applied to the building sector as vehicles and buildings are finally beginning to "talk" together and to share each other's stored energy.

To bridge the gap between the mobility sector and the building sector requires an understanding of the other sector. This expansion of the understanding of another sector than one's own will become important in the process of developing a more holistic environmental thinking among planners and architects as well as mobility actors. Such an expansion must happen early in life, during the education in the different fields, to avoid the growth of cemented "truths" that limit the ability to see new exciting possibilities.

## Application of LCA results in the early design phase of environmental-friendly buildings

Toktam Bashirzadeh Tabizi<sup>1</sup>, Glen Hill<sup>1</sup>, Mathew Aitchison<sup>1</sup>

<sup>1</sup> Faculty of Architecture, Design and Planning, University of Sydney  
toktam.tabrizi@sydney.edu.au

**Abstract:** Buildings are responsible for a significant impact on the environment during their life cycle. For the design of an “environmental-friendly” building, the environmental impacts of aspects including the manufacturing of construction materials, operation and maintenance, demolition and disposal, and related transportation should be analysed from “cradle to grave”. A variety of models have been developed to calculate the life cycle environmental impacts of buildings. However, attempts to find common criteria or principles for design decision making from the results of previous studies is problematic because different studies determine life cycle assessment (LCA) results using a varying series of assumptions and a variety of different parameters. Because of their complexity, LCA quantification methods are not generally employed by building designers at the early design stages when they may be of most benefit. The aim of this study is to elaborate the difficulty of generalising results from previous LCA studies and therefore the difficulty of developing elementary heuristic principles to assist designers, by highlighting the complexity of LCA tool and providing examples of life cycle energy assessment in residential buildings. The results highlight the main problems designers would encounter trying to use the LCA method at the early design stages, and the need to develop heuristic guidelines for designers to allow them to understand the most effective design variables on the building life cycle performance.

**Keywords:** LCA; environmental impact; early stage design; rules of thumb; material selection.

### Introduction

Minimizing impacts on the environment is an important goal for the building sector. Energy is generally one of the most important resources consumed by buildings over their lifetime (Thormark., 2001). If no action is taken to improve energy efficiency, energy demand in the building sector is expected to rise by 50% by 2050 largely because of the rapid growth in the number of households, increasing building floor areas, higher ownership rates for existing electricity-consuming devices and increasing demand for new energy consuming products (IEA, 2013).

Buildings not only impact the environment through energy consumption and greenhouse gas emissions, they also negatively impact aspects such as water use, waste generation and resource depletion (Stephan et al., 2013). Rapid urbanization in developed and developing countries is expected to increase demand for new housing and more comfortable living environments and therefore further exacerbate these impacts (Ortiz et al., 2009).

Because buildings consume materials and energy across their whole life, they need to be analysed in terms of their life cycle. Construction and occupation are the two main

phases of a building's life cycle. Life cycle assessment quantifies potential environmental effects of a building during its life cycle, starting from extraction of raw materials to its demolition and waste management.

Many attempts have been made to quantify the total environmental impacts associated with buildings through their life cycle. However, quantification methods are not generally employed by building designers at the early design stages when they may be of most benefit. The aim of this study is to elaborate the difficulty of generalising results from previous LCA studies and therefore the difficulty of developing elementary heuristic principles to assist designers, by highlighting the complexity of LCA tool and providing examples from 18 case studies of life cycle energy assessment in residential buildings. The results highlight the main problems designers would encounter trying to use the LCA method at the early design stages, and the need to develop heuristic guidelines for designers to allow them to understand the most effective design variables on the building life cycle performance.

### **LCA and the features**

LCA is a tool for systematically analysing environmental impacts of the products or processes over their life cycle. LCA is often considered a "cradle to grave" approach to the evaluation of environmental performance and includes all important phases of LCA of a product, particularly the extraction of raw materials from the natural resources, materials' production, the final outputs, their use, waste removal/recycling, and all related transportation (Cabeza et al., 2014, Klöpffer, 2014).

Different LCA approaches have different emphases when determining environmental impacts. Life cycle energy analysis (LCEA), for example, focuses on energy and accounts for all energy inputs to a product. This not only includes direct energy inputs during manufacture, but also all energy inputs for producing components, materials and services needed for the manufacturing processes. Life cycle cost assessment (LCCA) of buildings, on the other hand, measures impacts in terms of cost. LCCA thus analyses the total cost of facility ownership, including all costs of acquiring, owning and disposing of a building or building system (Cabeza et al., 2014). Another approach, life cycle environmental impact (LCEI) assessment measures environmental impacts that include pollutant emissions.

The International Organisation for Standardisation (ISO14040, 1997) highlight four steps for all these LCA approaches: goal and scope definition; life cycle inventory (LCI); impact assessment; and interpretation of results. Goal and scope definition explain the purposes, audiences, and system boundaries; the LCI engages with data collection and calculation to calibrate materials and energy inputs and outputs of a system; the potential environmental impacts, based on the LCI, are appraised by impact assessment (Ramesh et al., 2010).

### ***Life cycle energy analysis (LCEA) of Buildings***

For this paper, LCEA has been chosen as the basis for discussion, both because it uses the simple quantifiable measure of energy appropriate to this brief paper, and because it is commonly used for building LCA. The significant consideration of LCEA is the formulation of strategies for reducing a buildings' primary energy use and thereby controlling emissions (Ramesh et al., 2010). Life cycle inventory (LCI) as one of the four phases of LCA, including LCEA, requires a methodical approach for collecting the necessary data. Three main methods of LCI can be applied to quantifying the various inputs and outputs of products or

processes: process analysis, input-output analysis and hybrid analysis. Process analysis, based on data related to specific processes or products in a given location, quantifies the inputs and outputs and the resulted environmental impacts through the life cycle of these processes or products. Today, many countries, including Australia, Europe (e.g. Swiss EcoInvent® database), Japan, the USA and Canada (e.g. Athena Institute® database), provide databases of detailed process data for a large array of products. However, using this data is problematic because of lack of simplicity and accuracy, and the incompleteness of the system (Stephan, 2013). Input-output analysis (I-O analysis) uses national average data for each sector of the economy. It is a complete description of the system at a whole sector scale. I-O analysis can potentially solve the main weakness of the process analysis method, however it fails to provide accurate figures for specific processes or products. Hybrid Analysis is a combination of process and input-output analysis intended to minimise the limitations of both (Stephan, 2013, Crawford, 2008).

### ***Main life cycle energy demands of buildings***

When calculating LCEA, most recent studies determine the life cycle energy demand of buildings using the following phases (Stephan, 2013, Dixit et al., 2010, Ramesh et al., 2010):

*Embodied energy (EE)* is the amount of energy required during all processes of production, on-site construction, and final demolition and disposal. The overall energy sequestered in buildings and building materials has two primary components: direct and indirect energy. Direct energy is the energy consumed in on-site and off-site operations such as construction, prefabrication, assembly, transportation and administration. Indirect energy is responsible for energy consumed in manufacturing the building materials, and in renovation, refurbishment and demolition processes of the building. These comprise initial embodied energy, recurrent embodied energy and demolition energy.

*Initial embodied energy (IEE)* is all the consumed energy during the production of materials and components and including raw material procurement, building material manufacturing and finished product delivery (transportation) to the construction site. This energy can vary to a large extent between various building assemblies designed for the same function.

*Recurrent embodied energy (REE)* is the energy used in all maintenance and refurbishment processes during the useful life of a building. During a building's use phase, the components with a shorter lifespan than the building's useful life will need to be replaced (because of programmed differential lifespans, poor design or poor maintenance regimes).

*Demolition energy (DE)* is energy used in the processes of a building's demolition and disposal of building materials. Several studies have ignored this in the LCEA as studies (Crowther, 1999) have shown that it may only be responsible for 1% of the total life cycle energy.

*Operational energy (OE)* is expended in maintaining the indoor environment and is usually consumed by heating/cooling the building, mechanical ventilation, domestic hot water, lighting, appliances and cooking. Annual operational energy is primarily influenced by user behaviour, location, and the type of power of the systems. Life cycle energy is the sum of each of the above energy consumption components through the building life time (Ramesh et al., 2010).

## **Case studies review**

Review of the case studies aims to highlight the difficulty of generalising the LCA results from previous studies. For consistency all case studies reviewed have used LCEA and are residential buildings as they have the most significant environmental impacts (U.N.H.S Programme, 2009). The case studies selected use LCEA to consider the effect on energy demand of material selection for different building's elements. Table 1 presents 18 case study buildings. The influential factors affecting the amount of operational and embodied energy in these cases are classified as follows: Building location (country/ city); building type and net indoor floor space; structural typology; building lifetime; and energy calculation method. The different materials employed for roof, façade and the ground are all specified for each case but for brevity are not listed on the table.

## **Discussion**

The LCA of buildings is a complicated and time/cost-consuming procedure. The following section firstly discusses the LCA process generally in terms of the limitations for transforming it into a tool that could be employed at the early phase of designing, and secondly discusses the reviews of the case studies and the insights they contribute to understanding the limitations for transforming LCA into a tool that could be employed at the early phase of designing.

### ***Limitations arising from analysis of the LCA process generally:***

- The first step of LCA — goal and scope definition — has the potential to make previous studies incomparable and therefore inhibit the development of the sort of generalised advice that would be useful at the early design phase. Beginning the analysis using different functional units, reference flows and system boundaries complicate the possibility of having comparable data.
- Because the databases that are used as the bases for calculating LCA may not be comprehensive and may be different for different countries, the findings from case studies are not always readily compatible.
- The environmental inputs and outputs of each design combination are classified using a range of quite different impact assessment that might include energy usage, cost, CO<sub>2</sub> emissions, pollutants, and material toxicity. This makes the development of comparable impact unfeasable .
- Interpretation, which is the last step in the LCA methodology, presents results, limitations and recommendations. But because the first three steps significantly affect this last step and the first three steps as discussed may already have incomparable outcomes, any attempt to generalise in the last step is made problematic.
- Reliable and consistent results depend on a comprehensive LCA which include all life cycle phases. However, this requires the assessment of many different materials, components and processes for which information is not always available. Exacerbating this is evidence from a previous small study by the author (Bashirzadeh Tabrizi et al., 2016a) that indicates the level of complexity and certainty/uncertainty is different in each LCA phase.

### ***Limitations arising from analysis of the case studies***

- Defining the relative importance of operational and embodied energy in a building's life cycle is still not clear. Some previous studies show that embodied impacts (raw material extraction, processing, manufacture, transportation and construction) can be as significant as operational energy. However, there is limited consistent and comprehensive information available for building designers to make informed decision in this area. Comparing case studies 11,12,16,17 and 18 which analysed IEE and REE to other cases shows the ratio of EE and OE in the building's LCEA is not consistent.
- Improvements to operational efficiency and thermal performance and efficiency of appliances and systems within buildings are typically the centre of attention of environmental decision-making during the building design process, so the results are not comprehensive. For example, in case 16, if only the amount of operational energy was analysed the building's total energy demand would lead to an incorrect result for the passive house. In this case, EE significantly affects the building's total life cycle energy demand.
- Additional criteria throughout the comprehensive LCA could significantly affect the results. For instance, in cases 6, 7 and 8, the 100 years of building lifetime means most of the materials would need to be substituted and this would significantly change the EE results. Moreover, the compatibility of the building and materials lifetimes and maintenance requirements and methods should be considered when the recurrent embodied energy is assessed. However, different estimations and assumptions for the components' embodied energy in various studies alter the results between studies (Building's lifetime/materials' service life).
- The quality of results from operational and embodied energy assessments are not reliable because the influential factors are unclear and vary greatly. For instance, considering energy demands for heating, cooling, hot water and appliances affects the

OE proportion of the building LCEA. So the interpretation of quantitative results of case studies 6, 7 and 9 would be dramatically different to others. (It is important to notice what types of energy consumptions were included for operational energy assessment.)

- It is not possible to identify the most effective parameters on the buildings' life cycle energy demands by reviewing these cases as there is no classification or prioritization of effective variables.

## Conclusions

While significant research has been conducted on the environmental impact of buildings, the knowledge about the type and quantity of information from quantitative LCA models is still limited. This information is not available when the designers make strategic design decisions in the early stages which will influence the whole lifetime environmental cost of the building. This study elaborates the difficulty of generalising results from previous LCA studies and therefore the difficulty of developing elementary heuristic principles to assist designers at the early design stages. Reviewing the LCA tool, its features and the results from selected analysed case studies in which the LCA were applied as the assessment tool, it can be concluded that:

- Life cycle energy assessment process is complex, and the existing analyses found in research are all case studies of one or a few buildings. The applicability of their results to other buildings in other areas is not clear. Comparing these studies is also complicated due to the difficulties and variability in their analysed data. For instance, the calculation method plays a crucial role in these results and applying different analysis techniques or/and different life cycle phases is primarily responsible for the imperfections of previous studies of the LCEA of the buildings.
- Moreover, building envelopes are known by researchers as a responsible for more than half of the embodied energy distribution and the total heat gain in residential buildings. However, it is still not clear which variables have more impacts. Therefore the individual effect of each variable on energy performance and dependencies between them must be defined clearly for designers in the early design stages.
- There is still a lack of accurate data on the embodied energy and the environmental parameters of the materials and manufacturing processes applied in different countries. Thus, international and well known databases used by many current LCA studies may lead to unreliable results for any national assessment.
- Most of the published studies yield the ranges of embodied energy of buildings or components by applying data from primary material sources, transportation, manufacturing processes and their own estimations and assumptions which differ from case to case.

Overall, interpretations and comparisons of previous study's results are not readily usable in the early decision-making stage by building designers. This small study thus indicates that there may be potential value in developing simple guidelines to help designers to consider the most effective parameters on the life cycle environmentally friendly building design in terms of the individual character of each project.

## REALISING INTENTIONS: An evaluation of green building rating tools for Australian buildings

Leena Thomas<sup>1</sup> and PC Thomas<sup>2</sup>

<sup>1</sup> School of Architecture, Faculty of Design Architecture and Building, University of Technology Sydney, Australia; email Leena.Thomas@uts.edu.au

<sup>2</sup> Team Catalyst Pty Ltd, Sydney, Australia; email pcthomas@teamcatalyst.com.au

**Abstract:** With growing concerns for enhancing sustainability, much attention has been paid to benchmarking performance in buildings. This paper evaluates the effectiveness of three rating systems that have been widely adopted for over a decade in Australia namely: (i) mandatory compliance under Section J (Energy Efficiency provisions) in the National Construction Code of Australia (NCC), (ii) a voluntary design rating tool - Green Star, and (iii) a voluntary operational rating tool-National Australian Building Environmental Rating Scheme (NABERS). The paper builds on the authors' experience in building performance simulation, rating tool design, practice consultancy and post occupancy evaluations of buildings. It presents a detailed analysis of the rating tools with respect to the alignment between what is being assessed, how it is assessed and administered and the impact on design process and performance outcomes in buildings. The paper assesses the successes and shortcomings of the rating tools to demonstrate the potential for design and post occupancy rating tools to influence market behaviour and building performance and argues for increasingly stringent approaches to get to net zero emissions.

**Keywords:** rating tools, design targets, actual performance, resilience

### Introduction

To meet the Paris 2C target, human greenhouse emissions need to halve each decade for the next three decades (Rockström et al 2017). The US EPA (2008) estimates that buildings are responsible for 38% of all human GHG emissions (20% residential, 18% commercial). The Intergovernmental Panel on Climate Change (IPCC, 2007) states that this sector presents the most cost effective opportunities for GHG reductions, ie., that buildings represent the low hanging fruit. This paper evaluates the effectiveness of three rating systems that have been widely adopted for over a decade in Australia namely: (i) mandatory compliance under Section J (Energy Efficiency provisions) in the National Construction Code of Australia (NCC), (ii) a voluntary design rating tool - Green Star, and (iii) a voluntary operational rating tool-National Australian Building Environmental Rating Scheme (NABERS).

Our emphasis is mainly with respect to questions of mitigation of greenhouse gas emissions and the intersection of these aspects with the ambition of resilience and thriving cities. Consequently this paper goes beyond direct questions of energy consumption in buildings to consider indoor environmental quality and location and transport effects as well as outcomes for occupants. On the other hand this paper does not extend analysis to materials, water, waste and landscape ecology dimensions of thriving cities. The paper builds on the authors' experience in building performance simulation, design, review and

application of rating tools, practice consultancy and post occupancy evaluations of buildings. It presents a detailed analysis of the selected rating tools with respect to the alignment between what is being assessed, how it is assessed and administered and the impact on design process and performance outcomes in buildings. Following an overview of the key rating tools, we present a thematic review of their successes and shortcomings.

## **Overview of Rating Tools**

### ***Section-J (Energy Efficiency provisions) of the National Construction Code (NCC) of Australia***

These provisions cover minimum mandatory energy efficiency provisions for all buildings. The stringency limits and choice of measures for the deemed-to-satisfy (DTS) prescriptions were determined through detailed life cycle benefit cost analysis to weigh compliance costs against energy savings. This approach prioritises the efficiency of the building envelope (thermal mass, insulation, glazing and shading) given it typically outlasts changes to services and internal systems. For commercial buildings, compliance can also be achieved using energy simulation to compare with a reference building model (JV3) to give designers some flexibility in trading between different building envelope elements. In the case of residential buildings, the DTS requirements are also hard-coded into the CheNath thermal simulation program. Compliance requires all house designs to meet a minimum level of performance (unconstrained heating and cooling energy) based on the climatic location of the house.

The state of New South Wales is an interesting case in that it requires compliance with the BASIX (Building Sustainability Index) system, which goes beyond Section-J requirements for the building envelope (assessed as thermal comfort) to legislate for reductions in potable water and assess energy efficiency of installed appliances – (air-conditioning system, washing machine, hotwater) and extent of reliance on rainwater collection and on site renewable energy generation. BASIX targets for detached houses require new construction to deliver 40% reduction in potable water consumption and 40% reduction in greenhouse gas emissions compared to the state average consumption of 3,292 kg of CO<sub>2</sub> per person per year. Interestingly the targets for apartments were set at 25% reduction in greenhouse gas emissions as a benefit cost analysis revealed “that unit dwellings have higher per capita greenhouse emissions than houses and were therefore likely to incur significant additional costs to meet a 40% reduction in emissions” NSW Department of Planning, 2011)

### ***Green Star***

Green Star was first introduced to the Australian market in 2003 as a rating system for integrated design of office buildings. Administered by the Green Building Council of Australia, credits in different categories are totalled up achieve 4, 5 and 6 Star building design ratings. It is similar to LEED, sharing the same Intellectual Property and being one of eight national councils which helped to found the World Green Building Council. The rating tools have undergone significant evolution over the years, to encompass more building types such as educational, retail, residential and public and to improve outcomes. There are nine sustainability categories that are rated for Green Star certification: Management, IEQ, Energy, Transport, Water, Materials, Land Use and Ecology, Emissions and Innovation. Currently, there are three Green Star rating tools available, Design & As Built (to certify design & construction), Interiors (to certify interior fit-out), and Communities (to certify plans for precinct level development) that allow developers to ratify projects as they are developed and delivered for occupancy.

A fourth tool Green Star Performance (to certify operational performance), was piloted in 2015 and formally introduced in 2016. Green Star Performance aims to close the loop on performance and allows existing buildings to be rated actual performance against targets for sustainability across similar categories to the As Built Rating tools.

### ***The National Australian Building Environmental Rating Scheme (NABERS)***

Developed in 1999 as the Australian Building Greenhouse Rating (ABGR), the scheme adopted the philosophy that the largest quantum of greenhouse emissions were produced by the existing stock of buildings in developed economies like Australia, and that operational ratings for these buildings were the most effective means of benchmarking and reducing emissions. The rating is “attribute neutral”, and does not consider any design features. Inputs towards the rating process are utility bills, leased area, weekly hours of operations, and a correction for climate (postcode) to benchmark the greenhouse gas emissions (Scope 1 and 2 equivalent CO<sub>2</sub>/m<sup>2</sup>.annum). Subsequently NABERS added Water, Indoor Environmental Quality (IEQ) and Waste benchmarks to its rating suite. The energy and water benchmarks were extended to Shopping Centres and Hotels. Energy benchmarks were also introduced for Data Centres.

The IEQ rating is the most complex and assesses thermal comfort, air quality, acoustic comfort, lighting and office layout through physical measurements for air temperature, mean radiant temperature humidity, air speed ventilation effectiveness, indoor pollutants sound level horizontal light levels and also uses surveys to occupant satisfaction.

## **Outcomes of Rating Tools in Australia**

### ***The role of minimum performance requirements***

Mandatory minimum performance requirements as embedded in the NCC have the best opportunity for capturing the bulk of new building stock; as it is developed or refurbished. In order to operationalise reduction of GHG – the current approach emphasises the thermal performance of the building envelope, rather than to drive innovative approaches with respect to building form, layout, alternate environmental control system or even the extent of reliance on HVAC systems for comfort, or push for an absolute target. Starting from a very low baseline in the early 2000’s, the energy efficiency provisions have served to lift the thermal performance and ensure that all buildings include basic insulation, thermally efficient glazing and comply to a minimum light power density and system efficiency and have served to educate the building industry on these benefits.

Since its introduction, there have been a number of reviews (Pitt and Sherry 2016) based on revised benefit cost ratios arising from lowering of compliance costs thanks to improvements in technology and best practice standards. These included a shift from 5 star level (equivalent to a thermal energy load of 66 MJ/m<sup>2</sup>.annum for Sydney) in 2006 to a 6 star in 2010 (51 MJ/m<sup>2</sup>.annum) for residential and an increase in building envelope stringencies for commercial buildings. Based on our experience in practice, a DTS compliant office building in Sydney is equivalent to a 4 star NABERS rating (193 kgCO<sub>2</sub>/m<sup>2</sup> pa – whole building). However as discussed later in this paper, these levels in themselves are unlikely to lead to deep and significant cuts in greenhouse gas emissions.

In the absence of mandatory reporting of post occupancy emissions it remains difficult to gain proper accounts as to actual savings in energy and greenhouse gas emissions as a consequence of the code. Typically simulation models for compliance use idealised conditions and estimated outcomes are optimistic. Moreover isolation of the NCC regulated attributes (building envelope, installed heating and cooling systems and equipment from

other plug loads during the actual monitoring of houses is incredibly difficult. This is compounded by variation in occupancy (schedule and area) as well as occupant behaviour and appliance efficiency. Even in commercial buildings where more detailed monitoring of end uses is available, our experience suggests that the simulation conducted for purposes of compliance are rarely comparable with the reality of operation.

### ***Incentivisation of the top end buildings through voluntary design based tools***

Since its introduction in 2003, the Green Star tool has been used to rate over 1500 buildings served to embed the conversation around green buildings and sustainability within the major players of the building industry. A large number of developers and building owners use the tool to validate their flagship projects and others committing to achieve minimum 5 Star Green Star – Design & As Built ratings for all new industrial, commercial and retail projects.

The tool is also called up in the design brief of many projects and used by industry as a surrogate for ensuring design quality and environmental design. Its emphasis on the occupant comfort, well-being and broader questions of sustainability as meant that well versed good design practices such as access to views, daylight and increased access to fresh air, used of forest certified timber, low VOCs and no PVC, access to public transport are entrenched in the tool as attributes that can be rewarded with scoreable points. While the Green Star tool adopts fairly ambitious targets under all categories, it allows industry stakeholders to gain credibility for good practice measures even if the ultimate goal is not reached. For example, in the case of greenhouse gas emissions the minimum compliance is set above industry benchmarks at a 4.5 star (equivalent to 164 kg CO<sub>2</sub>/m<sup>2</sup>.annum in Sydney) NABERS equivalent simulated rating with rewards for progressive reduction from this baseline. However, maximum points (20/20) are only achievable for a net zero emissions. This is in contrast to tools such as Living Building Challenge, where compliance requires a pass or fail for the top level target that demands net positive energy and on energy storage for resiliency.

### ***Incentivisation of the top end buildings through Commitment to Performance***

The attribute neutral report cards offered under NABERS prioritises performance and real outcomes. In a science target hungry property market, this has caused a number of assets holders to report their historical operational performance for energy/greenhouse emissions, water consumption, IEQ and waste. Within this framework it must be said that Water and Energy have gained early and wider adoption as these are easy to assess being a single metric, whereas ratings for Indoor Environmental Quality and Waste that require measurement of multiple attributes and include aspects perceived to be intrusive such as occupant surveys are adopted only by a smaller group of buildings.

Table 1: Average reduction in energy intensity over multiple consecutive NABERS Energy star ratings for office buildings (source: NSW Office of Energy and Heritage)

Repeat number of NABERS Energy ratings	Average reduction in energy intensity
2	7%
4	16%
6	24%
8	29%

It can be argued that the requirement to ensure and maintain a minimum, monitored, operational performance for energy/GHG via NABERS, has improved the performance of the stock of office buildings impacted. Table 1 shows the impact of ongoing monitoring where, on average, office buildings captured under the NABERS scheme have been shown to reduce

energy use by 7% on their second rating and 29% by the eighth rating. It is important to note that this is not the performance improvement for a small number of non-representative top performers, but the average improvement of hundreds of buildings in the NABERS database.

The ability to benchmark their asset portfolio over a wider range of categories for sustainability is also gaining traction. The success of Green Star at the top end of the property market (<http://www.architectureanddesign.com.au/news/gbca-ends-the-year-on-a-high-with-80-more-green-st>) where ratings increased from 223 projects in 2015 to 401 in 2016 was attributed to a sharp uptake of the Green Star Performance tool. However at this stage, that tool is in its infancy and its impact in influencing change is not easy to assess as yet.

### ***Policy measures that influence market behaviour and performance***

Figure 1 documents the take up of NABERS Energy (Greenhouse) Star ratings in Australia. There was little uptake until 2003 when the NSW State Government mandated that all their buildings were to be rated for annual performance. Further increases in uptake can be seen in 2006 and 2007 when Federal and then State Governments introduced requirements that buildings owned or leased office spaces be 4.5 stars, and again in 2010 when the Commercial Building Disclosure (CBD) Act requiring all office buildings with more than 2,000 m<sup>2</sup> to report their emissions at the time of lease or sale was introduced by the Commonwealth.

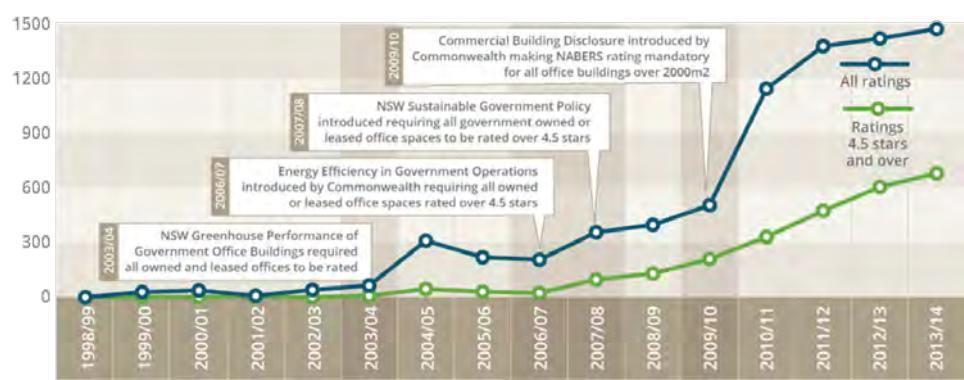

Figure 1: Take up of NABERS Energy Star ratings in Australia

Figure 1 also points to a significant increase in the number of annual ratings at 4.5 star or better after the 2010 CBD Act. This can be traced to a number of factors. The NABERS energy/GHG rating scale originally comprised 5 stars. At the inception of the scheme the top 5 star level, was expected to only ever be achieved by 5% of the target building population. However, once governments mandated a 4.5 star level performance for base buildings (landlord operation equivalent to 87 kg CO<sub>2</sub>/m<sup>2</sup>.annum in Sydney), industry quickly rose to the challenge. By 2010 almost every new building was committing to (and achieving) NABERS Energy 4.5 star, and more than 5% were performing at or above 5 stars (base building equivalent to 71 kg CO<sub>2</sub>/m<sup>2</sup>.annum in Sydney). This led to a review of NABERS Energy benchmarks (RMS and Team Catalyst, 2010) which proposed an extension to the scale to 6 or even 7 stars (net zero). A sixth star was added in 2012. Equivalent to 72 kg CO<sub>2</sub>/m<sup>2</sup>.annum whole building and 35 kg CO<sub>2</sub>/m<sup>2</sup>.annum base building in Sydney, a 6 star level is a 50% reduction in GHG emissions compared to 5 star performance. Adding a seventh star to the NABERS scale offers a ready-made mechanism for zero carbon performance.

Interestingly, Federal and State governments have not reviewed their 4.5 NABERS Energy star performance criterion for the buildings they own or lease. Consequently, the 4.5 star level continues to be the de facto minimum performance standard for all office buildings greater than 2,000m<sup>2</sup> NLA.

### ***Risk and responsibility driving performance, choices and outcomes***

The emphasis on actual performance has resulted in a number of market behaviours.

The speculative nature of the Australian building market contributes to an industry practice that attributes and isolates responsibility for performance to different end users. To accommodate this the NABERS tools offer separate ratings for base building (landlord) and tenancy in addition to whole building ratings (base building+tenancy). However the separate ratings do not portray the full story of the building performance. In the area of IEQ for example, the base building is assessed by measurement of physical attributes of IEQ. Even though the building shell (base building) also has a significant impact on the quality of occupant experience, responsibility of occupant satisfaction ratings for IEQ is isolated only to the tenancy rating. In the case of energy, the base building ratings of many large office buildings and shopping centres do not reflect the energy use of the tenants - for instance many larger stores often run independent HVAC systems separate from the base building.

The Commitment Agreement process is an interesting mechanism established within NABERS to enable developers to market the future performance of the building before commencing construction. It requires the developer to legally commit to achieving a post construction performance target at development application stage. The developer is given a specific time period, usually 18 months after start of normal operation, to have an independent assessor confirm the level of performance. If the committed target is not achieved, a series of mitigation steps may be instigated, following which, all signed up tenants are informed and the non-conformance is reported on a public website.

In a number of building developments we have observed that all cost saving measures, alternate specifications, system configurations are carefully assessed by independent assessors to ensure the commitment agreement is not at risk. As discussed elsewhere (Thomas and Hall, 2004) the goal for a 5 star performance ensured that advanced ventilation system via solar chimneys was not deleted in the face of mid project value engineering in Building A. On the other hand, the push back of capital costs where buildings are developed only to aspirational targets is also noteworthy. In Building B, the use of an HVAC air distribution component designed to improve airflow in low load situations was initially refused by the project manager as it was thrice the cost of the standard product. This was until the electrical contractor realised that installation of this newer device would not require electrical wiring and reheat coils. At this point the displaced capital cost enabled the newer device to be incorporated to capture the GHG savings.

A large number of office buildings are delivered via a design and construct mechanism based around least cost tenders. In our practice, we have observed the risk of demonstrating the initial NABERS Energy performance as per the Commitment Agreement is increasingly being passed onto the head contractor. Legal contracts are being written around "builder retentions", where a percentage of the head contractor fees are retained by the owner/developer until the NABERS Energy star performance is proven within a stipulated time frame.

### **Questions of long term resilience**

The mandatory energy efficiency provisions of the NCC do not go beyond the emphasis on greenhouse gas mitigation to questions of energy sources, or reliance on energy based systems. In the past, the use of simulated performance of heating and cooling was predominantly used as a surrogate measure for the thermal energy load in residential buildings. However, the reality is that more and more residential buildings are actually resorting to air-conditioning for their heating and cooling needs - thanks to increased

expectations for standardised comfort conditions and further compounded by poor designs of apartment buildings where deep plans and poor ventilation make buildings uncomfortable fairly quickly. This situation is further exacerbated during heat waves such as the recent hottest summer of 2016-2017 which resulted in city wide shortages of pedestal fans and air-conditioning units for sale. These aspects further emphasise the need for higher stringency within existing mandatory measures but also highlight the need to ensure aspects such as natural ventilation and passive operability continue to be maintained in residential buildings.

Another area that needs to be tackled is the manner in which the metric for efficiency emphasises unit area meter is masking the total consumption or the consumption per capita of many of these houses (see Thomas and Thomas, 2001) – especially as the average Australia house at over 200m<sup>2</sup> or 90m<sup>2</sup>/person is one of the largest in the world (Wilson, 2014).

In the context of increased potential for energy brownouts and blackouts in the face of extreme weather events and grid stress, measures such as switching off non-essential loads, and/or relaxing comfort tolerances and further attention to on-site generation and storage becomes crucial in both residential and non-residential buildings. Some of these aspects fold into requirements for a Climate Change Adaptation Plan that gains credits under Green Star. While this paper tackles the measures at building level, the opportunities for precinct wide strategies in this respect are gaining attention through tools such as Green Star Communities.

Most non-residential buildings are designed to very narrow temperature conditions (20-24°C) which reinforces the assumption of year round air-conditioning. Under normal conditions, targets for 4.5 and 5 star performance are routinely achieved using energy efficient buildings that are sealed and air-conditioned all year round. Under current rating tools, moving performance of such buildings towards zero carbon could be achieved through a techno-centric focus through huge arrays of PV panels. However a more cost effective and arguably resilient approach could come from a philosophical shift to building comfort that questions standard reliance on year round air-conditioning, and seeks to reinstate mixed mode conditioning through spatial and temporal diversity in buildings (Thomas, 2107).

### **Conclusions – A regulatory pathway towards zero carbon**

As discussed in this paper, Australia has seen a number of effective regulatory and voluntary initiatives to improve the sustainability of buildings with particular emphasis to mitigate greenhouse gas emissions in the past decade. These tools have been primarily developed to influence and work with market forces, and have brought these questions to the front and centre of building practice. The findings above demonstrate the value of setting aspirational targets within Green Star and the value of setting operational targets that are annually assessed under the Commitment Agreement protocols of NABERS to shift the performance of the office building sector. Furthermore as discussed, the use of design ratings and commitment agreements have encouraged the market to mature and rise to the challenge and actually deliver buildings to meet ambitious targets.

However in terms of new buildings, the only regulatory framework that covers GHG of ALL buildings is the NCC. We argue that currently the NCC is not stringent enough and remains a market oriented framework where planetary costs are not driving the stringency limits. In contrast, if we consider these from the perspective of keeping Australia's commitments to get to no more than 2 degree global warming by 2050, as discussed above, we need to halve our emissions every decade and get to zero carbon in three decades (Rockström et al, 2017). While this is in keeping with the commitments of three of the states (NSW Victoria and South Australia), in the country, buildings will need to play their part.

In the case of new commercial buildings we contend that the mandatory target for all buildings (not just government owned or leased) would need to rise from 4.5 star NABERS to 5 star in the next decade and then to the 6 star level in the following decade and zero carbon in the decade after. Such deep cuts and commitments to actual performance would need to extend beyond office buildings to include retail, industrial buildings, and mandate whole building ratings rather than only base-building or tenancy ratings to ensure no potentials for mitigating GHG are lost. The relatively lenient energy targets in the residential sector must also shift towards zero carbon emissions by 2050 especially in multi residential apartment buildings, given the increase in the construction of apartment buildings coupled with the concerns for resilience of such buildings as discussed above. Similar to commercial buildings, these should include some mechanism for commitment operational performance between the developer/contractor and tenant association.

The bulk of the buildings that will exist in 2050 are already with us. Increasing heatwaves are causing a sharp uptake of air-conditioning over summer and exacerbating energy use in these existing buildings - an aspect that is completely escaping the attention of the building monitoring or regulations in place. Based on the success of the building disclosure in office buildings (CBD), we recommend that similar schemes to reveal and document actual performance need to be mandated for all existing building types, in conjunction with incentives to retrofit and improve performance.

The regulatory frameworks and ratings tools in Australia offer the necessary mechanisms to bring about the change. That said, increased stringencies and significantly more ambitious targets and a commitment to performance rating is required to ensure buildings play their role in meeting the Paris 2C GHG emission reduction targets.

## **`Learning from 'horror' stories: a plan of work to reduce the performance gap in deep retrofit**

**Abstract:** Over the past 20 years efforts have been made to bridge the performance gap by developing design guidance and reports to raise awareness and increase construction quality of the delivery and handover stages; as well as improving tools and prediction methods by validating them with real data comparing anticipated performance with achieved energy use. The complexity of the gap ‘problem’ increases in deep, low-carbon refurbishment processes. Both the scale and quality of construction work need to be increased if challenging emission reduction targets are to be met. Established professional work plan frameworks (e.g. RIBA and Soft Landings) have been designed mainly with new build in mind without explicitly capturing important stages of a retrofit project that close the loop from in-use to design and back to in-use. The Appraisal (or Strategic) stage misses important diagnostic actions for evaluating client/occupant past experience and assessing existing building energy performance and Indoor Environmental Quality. Similarly although Project roles are described, they do not include the skills/knowledge that individuals (or teams) need; or the tools/ methods that can be used to manage and reduce unforeseen risks related to the existing building condition. This paper presents a modified version of the RIBA Plan of Work, which shows existing and additional workstages for deep refurbishments in a continuous cycle, linking roles to skills, knowledge and tools. Drawing upon evidence from pioneering empirical studies in deep refurbishment in the UK, the notion of ‘failures’ and key lessons from previous ‘horror’ and ‘learning’ retrofitting stories are used here to highlight problems and risks in each of the proposed work stages; and to address the major changes needed in traditional processes to reduce the retrofit performance gap.

**Keywords:** performance gap, domestic retrofit, deep refurbishment, low-carbon technologies, skills and knowledge

### **Introduction**

It has long been recognised by both industry and policymakers that buildings are not only the most significant consumers of energy but they also represent the largest untapped potential for energy savings and reductions in greenhouse gas emissions. There were 28.1 million homes in the UK in 2014 (ONS 2016) at least 87% (over 24 million) of these will still be standing and be in use by 2050 (Power, 2008). The 1% of new build added yearly into the existing stock is small percentage compared to the 99% of buildings that are already built and are responsible for over a quarter of all UK carbon emissions (Power, 2008). However, in the UK under current policies, CO<sub>2</sub> emissions from buildings by 2030 are estimated to be

reduced only by 12% below the business as usual levels, and not the 30% targeted (Galvin and Sunikka-Blank, 2017).

Energy policy debates emphasise the physical, technical and economic side of building retrofits, formulating ‘hero stories’ of works that individuals have undertaken to achieve success (Janda and Topouzi, 2015). These stories, and their content, rely on modelling technical potential rather than understanding the actual social capacity to support change that is held in collaborative professional practices, knowledge and skills. In buildings the performance gap - between what energy-efficiency design standards and modelling promise to deliver and what happens in practice - also rests on the different types of the stories that can be told, and the ways such stories are communicated to different actors (e.g. policy makers to building industry, design team to users, construction team to clients). Previous work by Janda and Topouzi (2015) identifies three different type of stories: hero stories, learning stories and horror stories, describing how different types of narratives in energy storytelling may encompass different qualities of reality, fiction and interpretation, either creating policy gaps or helping to solve them. ‘Hero’ stories are taking place in the ‘imaginary’ world of estimates and forecasts while the ‘learning’ and ‘horror’ stories are in the real world. Energy hero stories in building retrofit take place in non-ideal existing environments so that, although experiencing difficulties during the process, there is always positive heroic input to achieve (or transcend) design performance targets. ‘Learning’ stories lie between the technical potential and what is achieved in practice. The narrative of a retrofit learning story is what the diagnosis of existing building condition and the experience of commissioning tell us, and what the post-construction reality checks and post-occupancy monitoring reveals. Janda and Topouzi (2015), in examining the implications of storytelling in energy policies, suggest that every hero story has at least one learning story in it (or associated with it). When the surface of the hero story is scratched then the learning story can be uncovered. In this transition from ‘hero’ to learning story there is also an intermediate stage of something ‘failing’ in practice, - this is the ‘horror’ story.

In this paper ‘hero’ stories are deliberately not discussed, as the ‘hero’ in these narratives tends to be a technology or a set of technologies rather than the person or group providing them (Janda and Topouzi, 2015). The main focus here is on the intermediate set of narratives that involve a story of failure, fear of failure or risk of failure, of technologies that did not perform as promised or processes that did not occur as planned (e.g. InstituteforSustainability, 2012a, InstituteforSustainability, 2012b, Gupta et al., 2015, Fedoruk et al., 2015). Adding a learning story to the hero story and turning the ‘failure’ into an educational opportunity with broader possible outcomes means that ‘horror’ tales from the real world start to be told. In retrofitting existing buildings there is an unseen presence of risks and failures that are not apparent until works have started. The “plan of work” proposed in this paper looks the complex socio-technical system – building retrofit – and the relationships between people, stages, roles and skills, rather than simplifying it to a technical-only system.

### **Performance gap in low-carbon retrofits**

Previous studies explored performance gap discrepancies focusing on technical and non-technical factors related to: thermal performance of the building fabric, energy performance of the services, occupancy and operation. From a technical perspective a considerable number of studies investigated the mismatch between design, construction and operation, looking at how people use design tools, computer models, certificates and monitoring

techniques. This paper explores the performance gap issues as they evolve within the retrofit process work stages in different housing sectors (social and private owned). Our analysis uses evidence from large scale retrofit projects, pioneering housing retrofit networks in the UK and 'grey' literature (e.g. EST, 2007, NEF, 2014, ZeroCarbonHub, 2014a, ZeroCarbonHub, 2014b, Fawcett and Killip, 2014, Dollard and Edwards, 2015, Dollard and Edwards, 2016, Topouzi, 2015). A review explored established Plan of Work frameworks like Royal Institution of British Architects (RIBA) and how such frameworks are used in retrofits and how they are used by different actors. The paper draws out a retrofit-specific Plan of Work, adapting the RIBA procedure. It discusses how non-technical horror story causes of the design-performance gap (lack of technical knowledge; poor communication among project teams; unclear boundaries or roles and responsibilities) within different workstages emerge and what role the proposed feedback loops in the plan can play.

### Retrofit process and plan of work frameworks

For over a half century in the UK, the Royal Institute of British Architects (RIBA) Plan of Work has been the model building design and construction process providing a framework for organising and managing building projects for both new and existing buildings (RIBA, 2013). It is a process map and a management tool that organises important processes in a building project of briefing, designing, constructing, maintaining and operating. In 2012, the Government Soft Landing policy was driven by the UK Government Construction Board as an opportunity to incorporate principles of the Soft Landings framework (SLF) (2009) for both new construction and refurbishment. An integration of the RIBA work stages and SLF project key activities are summarised in the latest version Soft Landings and Government Soft Landings (BSRIA, 2015). A major strength of this integration for a retrofit project is that it underlines important procedures to progress a project in a rationalised and structured order from commencement to completion and beyond. However, these frameworks are mainly designed with new build in mind and are not detailed or aligned with the tasks, objectives and key issues encountered in a retrofit process. Four specific issues can be identified where the RIBA Plan of Work does not align well with the nature of retrofit projects:

- Missing important diagnostic actions for evaluating client/occupant past experience and assessing existing building energy performance and indoor environmental quality;
- Overlooking differences in the types of retrofits (deep, typical, shallow) and size (individual or repeated/area-based);
- Usability considerations from different actors (e.g. design teams, homeowner or builders);
- Lacking guidance on the tools and methods that can be used to manage and reduce unforeseen risks or the skills/knowledge different roles need to for retrofitting existing buildings.

All four of these are related to the fact that a retrofit project starts with a building in use rather than a blank building site. The design and construction process needs to negotiate a loop from an initial 'in-use' condition into a design phase, and then round to 'in-use' again.

## **Horror and learning stories**

Drawing upon the evidence from academic and grey literature review, and given the abundance of 'hero' stories, this paper explores the underplayed and less told 'horror' and 'learning' stories. Accepting that learning stories occur in the 'real world' (Janda and Topouzi, 2015, table 1, p.528) of construction and, post-construction, of use of the building when it is occupied, this section gives examples of the source and causes of these two types of stories.

### ***Retrofit 'Horror' stories***

Evidence suggests that the cause of 'horror' stories often arises from a lack of technical knowledge, poor communication and unclear boundaries of roles and responsibilities that generally occur during four main stages: preparation/appraisal, design/specification, construction/ delivery and in-use/ maintenance. Much of the discussion that follows has to do with the relationship of these causes in the 'real' world.

#### *HS1 Lack of technical knowledge and skills*

Evaluation of an existing building's energy performance requires a combination of three things: theoretical knowledge of applied building physics (e.g. the relationship between temperature and relative humidity), skills in design and construction; and skills in understanding the interaction of buildings and their users. In many cases the tools used to diagnose the existing situation of technical and in-use performance do not reveal the full story. For instance, Energy Performance Certificate assessments may offer a technical estimate of the energy performance based on assumptions about the impact of individual building elements on performance. However, these impact calculations are dependent on non-technical issues that are either based on standardised assumptions about occupancy, heating patterns or not even considered (like control and usage). It is a story of failure, of the inadequacy of the tools that are used as a result of the lack of knowledge and skills in Post Occupancy Evaluation (POE) and Building Performance Evaluation. In this case, the risk is of the central character (client, occupant or builder) being unable to deal with a real project and deciding to leave requirements unsatisfied (or partly satisfied). This in turn leads to risks for policy-makers as they contemplate possible interventions in retrofit markets. Over the life-time of a building the different retrofit interventions (deep or shallow) need to be seen as a hybrid of old and new materials/technologies; and old and new skills (Chan and Dainty 2007, p378), that need to be evaluated and evolve over time under a 'whole-house' perspective. As Fedoruk et al. (2015) put it: "knowing what works and where the big risks lie so that care and attention are paid to the things that make a big difference to the outcome" (performance).

#### *HS2 Poor communication*

In this arena, most horror stories are between the design and construction stages; and between handover and use. The complexity of deep refurbishment projects inevitably involves unpredictable issues appearing as work progresses. This is the time when the imaginary world of design aspirations (e.g. standardised 'one solution fits all', complicated modelling solutions lacking technical details, design for a default user disregarding occupants' lifestyles) meets the real world and there is a need for communication between multiple actors (client, design and construction teams). It is a story of failure when high cost, low-carbon specified technologies did not perform as promised because of insufficient

ways to communicate to the users all aspects of a retrofit process. For instance, at the pre-refurbishment stage, not entirely explaining design target/standards and design options; low-carbon measures and technologies; as well as the project timeline. At the post-refurbishment stage, not providing personalised information; not providing training by a knowledgeable demonstrator for the specific combined and individual systems, at a time appropriate for the user; and not ensuring aftercare support. Communication problems prevent the creation of feedback loops which would allow individuals and teams to accumulate experience of ‘failure narratives’ from different actors and stages. Such failure narratives may be technological (e.g. a system with a CHP boiler, solar thermal collector and no integrated control system). Alternatively, the failure may be more socio-technical (e.g. a lack of handover and user training leading to the risk of inefficient operational practices).

### *HS3 Unclear boundaries for roles and responsibilities*

Low-carbon standards and combined systems require coordination and collaboration between professional groups (e.g. architects, engineers, energy consultants, constructors, builders, technicians). The horror story emerging from the construction and handover stages is when members from these groups play their part without taking responsibility for the whole-house energy performance targets. Taking responsibility would involve practices like reality checks in the delivery/handover stage that test the performance of the building-system as a whole, rather than testing the performance of individual measures, allocated by individual trade responsibilities. Taking part or full responsibility for integrated solutions is widely seen as a risky thing to do, precisely because it relies on others playing their part fully and competently. For roles and responsibilities to be clear, there needs to be an overarching role for team and project management, which is typically not present. Such coordination is crucial for retrofit at many levels: for on-site problem solving; to intervening in crucial environmental and energy decisions; to identifying and communicating issues of misalignment between design intent and implementation. In certain types of projects when managing design in construction, there is a distinct separation of ‘doing’ from ‘managing’ (as Gray et al. (1994) cited in Hughes and Murdoch, 2001, p13), as is often followed by horror stories.

### **Proposed work plan**

The Plan of Work proposed by this paper integrates additional stages into the existing BSRIA (2014), (BSRIA, 2015) framework. These additional stages are , developed explicitly for retrofits, creating a continuous cycle with feedback loops between stages (Figure 1 below). The scope of this work plan is to bring together key issues related to different roles and responsibilities, communication and tools in order to enable horror stories provide a learning outcome. The continuous cycle of retrofit stages ‘begins’ and ‘ends’ in the ‘real’ world with the appraisal of existing condition through to the repair and maintenance. Within this cycle only the four stages (stage1 to 4) of design occur in the ‘imaginary’ world.

Figure 1 illustrates the main connections provided by twelve feedback loops. Each of these loops between stages can be repeated several times during the retrofit process to accumulate implementation outputs and to phase out fear.

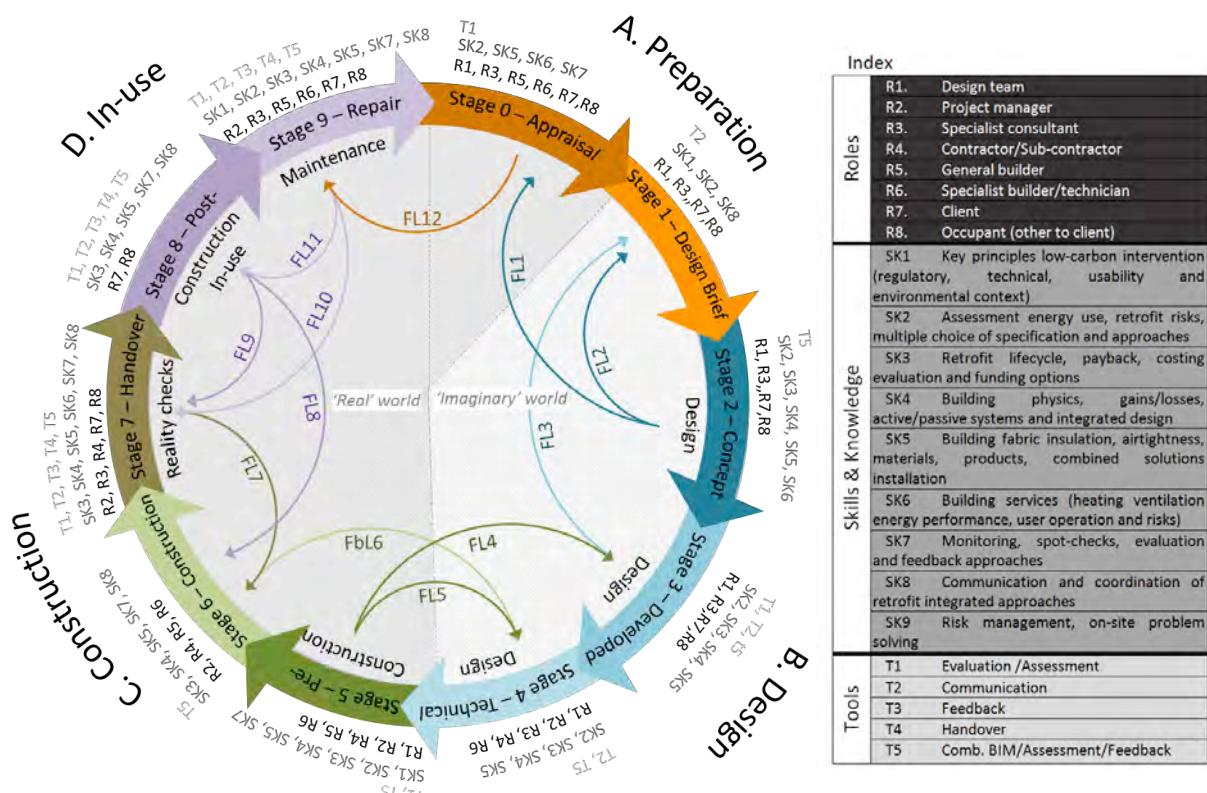

Figure 1. Proposed outline of main work stages in a retrofit process and feedback loops (FL) (based on sources (RIBA 2013, BSRIA 2014), related to roles, skills and knowledge, and tools.

### Retrofit ‘Learning stories’

To reduce the distance between imaginary world (design intent) and real world (construction/in-use) (Janda and Topouzi, 2015), more learning stories need to be added in the energy toolkit to move beyond binary hero-horror or success/failure frames. The proposed work of plan in this paper aims to bridge the gaps that the transition between the two ‘worlds’ (imaginary and real) creates. Away from the individualistic perspective of hero stories the horror/learning stories aim to transform existing systems in retrofit process. The feedback loop is used as a tool to turn the causes of horror stories (lack of knowledge and skills; poor communication; and unclear roles and responsibilities) into accumulated learnings. These causes can be found in all stages and in different practices during a retrofit process. Here the discourse in the following examples is of feedback loops and learning outcomes in relation to the horror stories as discussed earlier.

**Feedback Loop 1 (FL1) and HS1:** FL1 is the only feedback loop in the proposed circle which allows design aspirations, evaluation frameworks and monitoring performance techniques from the ‘imaginary’ world can be explored in the ‘real’ world; while insights and learning capacities from the real world back can also feedback to inform the design. The technical skills and knowledge of building performance evaluation become an in-situ exercise for the design team, evaluator or builder, to explore not only technical issues but include the overlooked occupancy and usage related factors. Feedback Loop 4 (FL4) and HS2: The complexity of retrofit projects makes the use of design practices and heuristics based on previous learning and experience with low carbon-standards and systems unavoidable. The loops from pre-construction to developed design can help the design team, the construction teams and clients to re-evaluate and inform often overoptimistic design aspirations. This

loop allows problem-solving to be communicated to (and amongst) different actors (designers, contractors and users), using frequent reviews of design-build problems at early stage before problems become irreversible and cannot be treated. This review is the learning of which options are not realistic on site for the specific property and users, information which can help shape other design stages and transmitting learning between projects.

**Feedback Loop 8 (FL8) and HS3:** A feedback loop between the post-construction/in-use and handover/reality checks can offer continuity in roles and responsibilities to single people or teams at a crucial stage of delivery where users are often left with no aftercare support. The learning process in this loop evaluates the implementation of the technical and non-technical issues and the performance outcome of the building system as a whole beyond individual perspectives, using instead an evaluation of a collective team work. Finding causes of misalignment between construction and in-use can help to reduce the gap between ‘doing’ and ‘managing’ and to define the roles that roles and responsibilities for the next stages of repair and maintenance.

## Conclusions

Undertaking deep retrofit of existing buildings requires a major shift in how design teams, constructions teams and users share information and knowledge in order to achieve consistently high quality, low carbon outcomes. From a ‘constructive pessimism’ starting point, learning stories bring up the contingencies of things that are not going to work as expected and planned. This paper proposes a cyclical work-plan for retrofits, developed from the accepted industry standard framework and tested by RIBA over decades, which codifies feedback loops in order to support this concept this and change from assessing individual measures to evaluating whole building system performance. Critical to achieving this transformation is the need to cross boundaries – the boundaries between professions, the boundaries between the design, construction and use, boundaries between building components.

In exploring how to blur the boundary between the imagined world of design and the real world of construction and use, we identify how narratives play a vital role in how individuals and teams develop understanding of their project experience. While technology-focussed ‘hero stories’ of individuals battling against the odds appear to dominate much of the discussion in energy policy and practice, we argue that paying attention to ‘horror stories’, and the fears that such horror stories are founded upon, actually help to identify the positive ‘learning stories’ that could, if routinely discussed and shared, increase the capacity of the construction industry to deliver deep retrofit at the pace and scale required.

The proposed revision to the RIBA Plan of Work explores the transition between stages from ‘imaginary world’ to ‘real world’, looking the causes of horror stories from lack of technical knowledge, poor communication and unclear boundaries of roles and responsibilities within each of these. It highlights a new task – that of appraising an existing building in use, which requires technical and socio-technical understanding. This has far-reaching implications for education and training in construction. Equally, the feedback loops identified in Figure 1 make new connections between not just stages of design, but also between the design and construction phases of a project. If these connections are to be made in a systematic way, the education of design professionals and construction trades will need to be more closely aligned, with insights from each group being respected and

taken on board by the other. Integrating feedback loop mechanisms during a building's lifecycle can increase significantly the continuity of a learning process. Such a joined-up approach may be a long way challenging for current practices, but it is badly needed if learning stories are to be heeded and climate change targets are to be met.

## Zero-Energy Me - The Struggle for Individual Energy Neutrality

Andy van den Dobbelaer<sup>1</sup>, Craig Lee Martin<sup>1</sup> and Greg Keeffe<sup>2</sup>

<sup>1</sup> Faculty of Architecture and the Built Environment, Delft University of Technology, the Netherlands, correspondence: a.a.j.f.vandendobbelaer@tudelft.nl

<sup>2</sup> School of Natural and Built Environment, Queen's University Belfast, United Kingdom

**Abstract:** The strife for zero-energy buildings and carbon-neutral developments is – however noble and benevolent – mostly aimed at an abstract target, such as a design in architecture school, a house still to be built, an urban plan under development. It is mostly dealing with there, then and them, rather than here, now and us. A sustainable, climate-, carbon- or energy-neutral society implies that each individual needs to be sustainable, climate- or carbon-neutral. Acknowledging this, the main author started to keep track of his performance in energy use, travel and food habits, and during lectures he presented about this openly to his students. Over a period of 7 years, the detailed tracking of energy, travel and food, and, more so, consecutive actions taken, have led to a lower energy consumption and hence carbon footprint. In the author's private life, we should say, because in the meantime his professional international career took off and so had many flights across the globe. They once more demonstrated that we, even when living low-carbon consciously, often are penny-wise, pound-foolish. This individual research clarified the greatest challenges and most effective strategies of living in a modern, dense city, with abundant access to unsustainable food and with easy opportunities to travel unsustainably for little money. As it held a mirror to the author, it will do too to a greater audience.

**Keywords:** net zero-energy, carbon neutrality, accommodation, transportation, food

### Introduction

If we want to stay beneath a 2-degrees temperature increase – widely considered a maximum level to avoid runaway climate change with unpredictable outcome - the world needs to reduce its carbon emissions by 80% in the year 2050 [IPCC 2014]. For a sustainable situation on the longer term, climate neutrality or carbon neutrality is essential, creating a balance between the greenhouse gases emitted on the one hand and chemically binding or sequestering of these gases on the other.

### Society's great energy challenge

The predominant part of achieving this goal, as agreed upon in the Paris treaty of 2015, is to be achieved by becoming independent from fossil fuels, the greatest contributor to greenhouse gases as methane, CO<sub>2</sub> and NOx. Therefore, the term 'fossil free' was introduced in various European projects already since 2006 [e.g. Roggema et al. 2011], after Al Gore's 'An Inconvenient Truth' came out [Gore 2006]. Fossil free simply means that no fossil fuels (coal, mineral oil and natural gas) are used anywhere in the system considered. With our fossil society this is an ambitious goal to achieve, and it may take a lot of time to get there. In the meantime, becoming 'net zero-energy' already is a big step. This ambition, often also described as 'energy-neutral', means that in a year's time one is not to use more energy than one can generate oneself. It implies acceptance of fossil fuels as long as this quantity of energy

is compensated for by self-generated renewable energy. In its Energy Performance for Buildings Decree (EPBD), the EU prescribes that as of 2020 all new buildings need to be ‘nearly zero-energy’. The word ‘nearly’ of course leaves space for interpretation, but it is clear that designing fully zero-energy buildings will put architects on the safe side for a building permit.

### ***Individual energy-neutrality***

The strife for zero-energy buildings and carbon-neutral development is noble and benevolent for future generations to follow. However, it is usually aimed at an abstract target, such as the design of a building in architecture school, a house still to be built, an urban plan under development. It is mostly dealing with there, then and them, rather than here, now and us. A sustainable, energy- or carbon-neutral society will not be possible if people themselves on average are not sustainable, climate-adaptive, carbon-neutral in their own way of living. It is easy to point at others and not achieving these goals oneself. People who understand the importance of striving for a sustainable world, must set the example by becoming net zero-energy in their habits. Acknowledging this, the main author started to keep track of his performance in energy use, and during lectures he presented about this openly to his students. This paper gives an account for the measurements and calculations done in the period of 2010-2016.

### **Boundary conditions and starting-points**

#### ***Sources of energy use considered and unconsidered***

Energy neutrality may be considered for many parts of our lives.

Perhaps most trivial is the energy used at home, including building-related energy (for lighting, heating, ventilation, pumps etc.), user-related energy (for use of equipment, devices, lifts etc.), and also the ‘embodied energy’ of building materials (for winning, transport, production etc.). The latter we usually do not consider because we usually do not have data thereof.

Other forms of energy use are related to our own living: mobility (private travel, commuter travel etc.), water (energy needed for producing drinking water, for pumps, for the purification of waste water, etc.), food (energy needed for growth, transport, storage and production of food), clothes (energy needed for the resources, transport and production of clothes), stuff (energy needed for the resources, transport and production of stuff), and again, the embodied energy of packaging and materials of previous products.

Least obvious, yet an essential part of everyone’s life is the (embodied) energy use of everything we use outside ourselves: infrastructure (roads, bridges, piping, wiring, sewage, etc.), utilities and facilities (for electricity, drinking water, waste water treatment, etc.), public objects (public buildings, street furniture, etc.), commercial objects (factories, offices, retail, etc.), and so on.

For practical reasons this research was limited to the building-related and user-related energy at home, mobility and food. Based on estimates that around 30-40% of carbon emissions result from the built environment (buildings) and 20-30% from transportation, the authors assume that thereby they have covered over half the energy individuals use, at least a part they can influence.

## **Method**

Over a period of 7 years the main author's energy use and travel was tracked in detail, linked to annual energy bills. Since the main author moved house in December 2009, with a baseline measurement done, account was made on the 1<sup>st</sup> of January every year. 2010 was the reference year, with little to no adjustments made to the house, after which various consecutive measures were taken and their effect measured.

Next to this private part of life, a professional career defines the use of energy; also with the individual considered. Working in an office most of the time, the energy consumed at the office is important but has to be divided by all who use it. Business travel can be an even more decisive factor. In the case of the authors this is certainly true, reason for which to keep track of business trips, both by car, train and plane.

## **Basics of energy**

Repetition of some figures is useful before we present energy data in the section to come. For conversion to a general energy value only two conversion factors are relevant (actually only one): 1 kWh = 3.6 MJ; and 1 MJ = 0.278 kWh. Besides, the energy content of common energy sources is important. Table 1 gives an overview of this. Notice that all fossil fuels as well as biotic oil and fat have an energy content of around 36 MJ i.e. 10 kWh per unit.

Table 1. Energy sources and energy content per unit

<b>Energy source</b>	<b>Unit</b>	<b>Energy content</b>	
Natural gas	1 m <sup>3</sup> nge (natural gas equivalent)	35.2 MJ	9.8 kWh
Petrol	1 l (litre)	32.4 MJ	9.0 kWh
Diesel	1 l	35.8 MJ	10.0 kWh
Kerosine	1 l	37.4 MJ	10.4 kWh
Oil and fat	1 kg vegetable/animal	37.0 MJ	10.3 kWh
LPG	1 m <sup>3</sup>	26.0 MJ	7.2 kWh
Coal	1 kg	24.0 MJ	6.7 kWh

Related to the energy mix of electricity the Netherlands has an average efficiency of around 45%, which implies – unless one uses electricity from renewable sources – we have to multiply the use of electricity by 2.2, in order to get to the amount of primary energy.

Furthermore, note that one flame (either a flame of a candle, oil lamp or gas burner) has a heat power of around 100 W [Hermans 2011]. Gas boilers and geysers often used to have ten rows of ten gas flames, giving them a heat power of 10 kW. One flame burning one hour long has produced  $100 \times 1 = 100$  Wh (watt-hour). Someone taking a shower for 15 minutes has used  $10,000 \times 0.25 = 2,500$  Wh or 2.5 kWh. Taking an efficiency of 100%, this is the equivalent of 0.25 m<sup>3</sup> of gas, or 250 ml ('a longdrink glass') of petrol.

## **Local energy habits**

In the Netherlands, the main author's home country, inhabitants typically have access to electricity, natural gas, drinking water, sewage, and other utilities that are centrally provided by public or private service companies. Recently, there is a shift towards dwellings free of natural gas, but the large majority of the building stock still relies on it (for both heating and hot water). Cars mostly use petrol or diesel, and airplanes kerosene. Electricity comes from centralised, regional power plants, which run on natural gas, coal or a small share of biomass. In North-Western Europe electricity is not bound to country borders and some of the energy produced in the Netherlands is exported while a small amount of nuclear power is imported from Belgium or France. The Netherlands are positioned second to last on the European table

of renewable energy (a share of around 5%) [Eurostat 2016]. So the energy mix is diverse, with dominance of natural gas.

### ***Energy use of Dutch households***

For their house, Dutch households on average use 1,400 m<sup>3</sup> of gas (13.6 MWh thermal) and 3,500 kWh (7.7 MWh of primary energy). In total this is 21.3 MWh<sub>prim</sub> (76.7 GJ). Ignoring public transport and bikes, for their mobility the Dutch drive on average 13,300 km per year. With 8 l/100 km this is around a thousand litre of diesel or petrol, or 36 GJ or 10 MWh<sub>prim</sub>. Hence, for living and private travel the total energy demand of a Dutch household is 31.3 MWh<sub>prim</sub>. Households on average contain 2.2 persons [CBS], so the individual energy use is 14.2 MWh<sub>prim</sub>. This is nearly 30% of the total energy the Netherlands used in the year 2015: 49.9 MWh per inhabitant [PBL 2017]. The private use of energy requires a continuous power of 3.56 kW, of which 2.43 kW for the house.

### **Domestic energy consumption**

#### ***Energy system of the house***

The terraced house under scrutiny is positioned in the inner-city of Delft, the Netherlands. Officially it is an apartment, squeezed in between two neighbours and a cinema at the back, with shops underneath and a parking garage below these. It therefore has an uncommon wide and shallow floor plan, with one open façade. Total gross floor area is 165 m<sup>2</sup>, with approximately 460 m<sup>3</sup> of space. The house is inhabited by a family of four: two parents and two teenage children.

The multifunctional urban complex the house is part of was delivered in 2005. Compliant with the energy codes of that time it has HR+/HR++ windows ( $U = 1.0\text{-}1.3 \text{ W/m}^2\text{K}$ ) and, compared to the Dutch average, good thermal insulation ( $R_c = 3.0 \text{ m}^2\text{K/W}$ ). For energy-efficient ventilation the house has so-called balanced ventilation with heat recovery, which can be switched to three speeds; filters for incoming and outgoing air need to be regularly replaced by the house owner. The complex has a shared heat-pump system that is connected to a collector of tubes that exchange heat with the underground. The heat extracted from the soil pre-heats warm water used for floor heating and hot water. For hot water (used in the bathroom) it needs to be electrically after-heated in a boiler tank. The house's kitchen contains small electric close-in boilers, one for boiling water, one for normal hot water from the tap.

### ***Energy use in 2010, the reference year***

After a year of use and only minor adjustments (replacing broke lightbulbs with more energy-efficient ones, the energy use measured was:

- Electricity 5,622 kWh
- Heat 36 GJ heat (from the heat-pump system)
- Total 56 GJ or 15.6 MWh

The total energy use come down to 1.77 kW of permanent power (in this case fully electric). This is already 27% less than the Dutch average house. So although the consumption of electricity is higher than average, the use of heat from a heat pump is so much lower than the usual use of gas, that the house could be called energy-efficient already.

### ***Measures taken since 2010***

Since 2010, all lighting has been replaced by LED and energy-saving fluorescent lighting. Based on calculation of sufficient levels of fresh air for a family of four, standard ventilation rates were brought down from 50 to 20% of full power, which also reduced noise levels indoors. The boiler temperature was reduced from 65 to 55°C, a level that safe enough against Legionella bacteria with short piping circuits. In August 2011, 5 m<sup>2</sup> of mono-crystalline PV was installed on the small flat roof of the house (15%, 550 W<sub>peak</sub> ~ 600 kWh/a). As a measure of effective flexible thermal insulation during winter evenings and nights, in November 2011 thick curtains were hung behind the large windows of the second floor. As a technical measure to fix the floor heating system, a much more energy-efficient water pump (from hundreds of Watts to 10 W on average) was installed in early 2013. Finally, and not unimportantly, the residents switched off boilers and electrical equipment when they were away for at least two days.

### ***Energy use since 2010***

Table 2 gives values for energy use figures, measured between 2010 and 2016. All values have been converted to 365 days, and heat values were calibrated according to degree days.

Table 2. Energy sources and energy content per unit

Date	Electricity	Savings	Heat	Savings	Total	Permanent	Savings
02-10-2011	4,676 kWh	17%	36.0 GJ		56 GJ / 15.6 MWh	1.77 kW	
31-10-2012	4,338 kWh	23%	25.6 GJ	29%	42 GJ / 11.8 MWh	1.35 kW	24%
16-11-2013	3,946 kWh	30%	74.7 GJ*	-108%	89 GJ / 24.7 MWh	1.82 kW	-56%
08-11-2014	3,822 kWh	32%	28.9 GJ	20%	43 GJ / 11.9 MWh	1.36 kW	24%
07-11-2015	3,739 kWh	33%	24.3 GJ	21%	38 GJ / 10.5 MWh	1.20 kW	26%

\* In 2013 a very odd measurement was done by an official of the energy company. Although no fraud by the official could be proven, the energy company returned the extra costs of 2013 in the years after, when the dwellers had proved the falseness. So this measurement can be ignored.

Converting the results of Table 2 to the main author only, taking the two kids as one adult, the personal use after these years of savings turns out to be 12.6 GJ or 3.5 MWh, 400 W permanent. This is 55% less than the average Dutch person. For this use of electric energy renewable power is purchased off an organic farmer with PV on his stables, via energy company Vandebron (literally ‘from the source’). So the house considered is not energy-neutral – it does not produce all of its own energy – but it is carbon neutral – all energy it uses is from renewable sources.

### ***Further savings***

Following the New Stepped Strategy [Dobbelsteen 2008], further reuse of waste heat (step 2) is difficult since heat from exhaust air is already recovered and installing heat recovery systems on waste water from the shower and bath is practically impossible.

That leaves the following measures for reducing the energy demand (step 1) still to be taken: achieving better airtightness by foam strips (executed in the winter of 2016), applying curtains in all rooms (still to be done), and using external sun-shading (see next).

A greater production of renewables (step 3) could be achieved by a solar collector, but in combination with the heat pump system already installed, the added value is very limited, and extra expenses disproportional. Adding more PV is only possible on the facades, for which approval is necessary of the house owners' society and municipal architectural committee. More interesting would be to combine external sun-shading with PV strips (louvres) on the south façade next to the roof terrace (a big source of undesired heat in summer). This is currently explored. Adding a small wind turbine next to the PV on the upper roof (for instance the Windleaf, by Windchallenge) is spatially possible but with a projected annual yield of around 800 kWh and an investment of more than 3000 euro, return on investment still takes about 20 years. It is however considered seriously.

It appears, as with many dwellings in dense inner-city locations, possibilities for personal production of renewable energy (and hence, becoming net-zero energy) is limited, leaving the sustainable procurement as a good option.

### **Personal transportation and commuter travel**

#### ***Situation before and after 1 January 2010***

In December 2009 the main author, following his appointment as full professor at TU Delft, moved from Amsterdam to Delft, changing his modal split from riding the train and cycling to and from stations to cycling directly to his faculty building. Regardless of this commuter transport there of course also is personal transport, which will be elaborated shortly here.

#### ***Cycling and walking***

Cycling costs approximately 60 kJ/km (per person). Energy for this comes from food. Before 2010, the main author cycled 5 days a week, 10 km a day, which comes down to 2,300 km a year. In energy this equals 138 MJ. After 2010 the cycling distance halved to a maximum of 5 km a day, 5 days a week, entailing an energy use of 79 MJ.

#### ***Public transport: train rides***

Trains use 80 Wh/p.km of electricity, based on average occupancies in Dutch trains. Before 2010 for his commuter transport the main author travelled 5 days a week over a distance of 72 km, a total annual distance of 33,000 km. The electric energy needed for this was 2600 kWh (9.36 GJ). After 2010 this dropped to an average of train business trips of 80 km a week, a total annual distance of 3,700 km. This implies an energy use of 294 kWh (1.06 GJ), 90% saved.

#### ***Private car use***

The main author has a private car, a Volkswagen Transporter T4 camper van with Transfalia infill. It has a 2.4-litre diesel engine, and it uses one litre for 11 kilometres on average. Hardly energy-efficient but seldomly used and a sustainable means of combining travelling with holidays on campsites in summer. The car is used for the whole family, two adults and two teens, which we count as 3 persons, so the individual share for the main author is one third.

Before 2010 the main author used the car for 12,000 km a year, using 1,090 l of diesel, which equals 36,3 GJ. Divided by three this means a personal use of 12.1 GJ. After 2010 care use dropped to 9,000 km a year, implying a use of 750 l of diesel with the energetic equivalent of 27,3 GJ. The main author's personal use therefore is 9.1 GJ.

### **Conclusion**

Seeing the figures for transportation one noticed the big difference of energy used for cycling, riding trains and driving cars. The car, even with a smaller distance covered than the train uses by far the most energy per person. For the main author's private travel the total energy use went from 21.6 GJ in 2010, to 10.2 GJ (2.8 MWh) after that year, an energy saving of 53%.

Since 2017 the Dutch railways ride on 100% of renewable energy (wind power) after one year of 50% of renewables. So the only real problem to become carbon neutral is the main-author's diesel-fuelled car, with a share of 41% of his total energy use, including the house.

### **Other factors of individual energy**

#### ***Business travel and the energy of flying***

Based on energy data of air travel the main author has kept track of his business trips since 2011, consisting of train rides in the Netherlands and neighbouring countries (Belgium, Germany, UK), some distances covered by car and flights. The energy use of airplanes strongly relies on the distance covered, the airplane itself and the occupancy.

Based on the distance and mode of transport, 2011 showed a relatively modest energy use of 3.2 MWh (11.5 GJ), 90% of the personal use of energy for the house. 2012 saw 3 intercontinental flights and 3 continental flights, which led to a total energy use of 47.6 MWh (171 GJ), seven times more than the energy used for house and personal travel. In 2013 business travel reduced to 42.7 MWh (154 GJ), in 2014 to 32.6 MWh (115 GJ), but thanks to the success of European research projects and international collaboration the energy consumed for business trips in 2015 and 2016 was greater than 50 MWh.

#### ***The energy of food***

As already introduced, food is an important factor for energy consumption. The term of 'food miles' indicates the distance that food has to travel to arrive in the supermarket; also the means of transport and necessity of frozen or chilled storage plays an important factor. Not to forget the production of food in greenhouses, under optimised conditions, requiring heating in winter, to mention one aspect. Meat and fish cost more energy than other foods; meat is the killer when considering greenhouse gas emissions [[www.landshare.org](http://www.landshare.org)]. So becoming energy-efficient and low-carbon requires a conscious lifestyle that includes wise selection of food. The authors made a calculation of average eating patterns and compared these to vegetarians or vegans, which made a big difference when taking an American lifestyle as the basis [US Department of Agriculture] and less so when looking at a continental European [RIVM]. In general, eating seasonally fitting food avoids a lot of energy for transport and storage. Most effective is eating less meat.

#### ***Other sources of individual energy use, not assessed***

There are many more elements of life that cost energy and that have not been assessed for this paper. For instance, pumping out rainwater, producing drinking water and processing wastewater all cost energy. Furthermore, the extraction, transport and processing of resources requires energy that can be considered as 'embodied energy' of materials and

products. A particular kind of products are clothes and what we may call stuff. Almost impossible to assess all of these, they form a part of everyone's life and choices, hence have an important influence on the environment.

## Conclusion

In total, in the year 2015, the individual considered used 22,8 GJ or 6,3 MWh for his house and personal travel. This is 41% less than the reference year and 49% less than the average Dutchman. The actions taken by the main author clearly led to a lower footprint. Of the energy used, 60% is carbon-neutral, the diesel van being the main problem to be solved. Net-zero energy living is possible but difficult when considering dense urban circumstances, but everyone can be carbon neutral when energy is procured from renewable sources. For mobility, unless one can fully use human-powered or public transport, becoming energy- and carbon-neutral is more of a challenge, and this particularly holds true for flying. The calculation of energy for flying goes to show that painstaking efforts to reduce the energy used at home to carbon-neutral and nearly zero-energy are terrifically over-compensated when flying for business (or for private goals).

If all energy used at work were to be accounted to employees, we would have to include many more sources of energy use: the office, ancillary company utilities, the conference for which this paper was written... Perhaps all of these factors should be included. After all, in the near future we will all have a carbon budget that cannot be exceeded, produced at home or at work does not matter then. Therefore, one of the next steps is to convert all energy use related to the university to all of its employees and students. Including these factors will increase the individual influence one can have on the national energy use from 30 to at least 50%.

This individual research clarified the greatest challenges and most effective strategies of living in a modern, dense city, with abundant access to unsustainable food and with easy opportunities to travel unsustainably for little money. As it held a mirror before the author, it will hopefully do as well before a greater audience.

## Users in context: actions and practices in low energy buildings

Gabriela Zapata-Lancaster<sup>1</sup> and Chris Tweed<sup>1</sup>

<sup>1</sup> Welsh School of Architecture, Cardiff University, Cardiff, United Kingdom,  
zapatag@cardiff.ac.uk

**Abstract:** One of the key challenges of the building industry is to achieve the expected performance in buildings in-use. The literature shows significant gaps between the as-designed and in-use building performance. There is a pervasive assumption among design practitioners and facilities managers that the occupants and their actions in buildings are a primary source of these 'performance gaps'. This paper contests two misleading notions that underlie that assumption: 1) the view that the user is a 'passive agent' in the built environment; and, 2) the view that there is a 'typical' user that can be applied universally. This paper presents a study that investigated the occupants' actions in four BREEAM certified buildings, comparing their as-designed and in-use performance. The study applied post occupancy evaluation techniques and user studies to investigate occupants' practices to provide explanatory detail to monitored environmental and energy consumption data. The paper focuses on occupants' actions and facilities management practices enacted in the everyday operation of buildings: what users do to achieve comfort, which include reconfiguration within spaces, adaptation through clothing, and operating building technologies; and, the facilities management strategies to operate the building. All of these take place against a background of institutional policies and norms. The observed actions and reported practices bring challenges to the typical representation of users and facilities management practices embedded in as-designed models of building performance. Therefore, an in-depth understanding of the context of building use considering different stakeholders' perspectives is deemed valuable to inform effective design strategies for building performance as well as to develop interventions to reduce the energy consumption of existing buildings.

**Keywords:** in-use building performance, building user, energy consumption, comfort, post occupancy evaluation

### Introduction

The building industry is facing increasing demands to create energy efficiency buildings and reduce the carbon emissions of the building sector. The non-domestic building sector accounts for 20 per cent of carbon emissions in the UK. Therefore, attention is centred to improve the performance of existing non-domestic buildings. A review of the energy performance gap in the non-domestic sector suggests that 10-80% of the performance gap found in operation could be attributable to occupants' actions (van Dronkelaar et al., 2016). Typically, approaches to reduce energy consumption during operation have emphasised control strategies that restrict the actions of the users as a means to prevent their inconvenient and inefficient energy behaviour. However, building performance is the result of design features and their effectiveness to meet the expectations of occupants (Cole et al., 2010). Occupants' actions and any resulting performance gap could originate in how the occupants' expectations are met (or not) in the everyday use of buildings. There is a need to understand the actions and behaviours of everyday use and operation of buildings as a way to inform strategies for the efficient operation and management of existing buildings and

for the building industry to learn from real buildings in operation and improve future building design (Janda, 2011, Fedoruk et al., 2015). The literature highlights that building occupants do not operate in a vacuum. The occupants have and exert agency to achieve desired conditions and to develop the actions in the daily occupation of buildings. In the context of non-domestic buildings, the individual and group agency of occupants could also be shaped by the social and cultural context (Lorch, 2008, Inalhan et al., 2010). Human agency manifests in the social context of use (Krippendorff, 2006). Krippendorff argues that the user should be regarded as 'knowledgeable agent whose actions are not arbitrary' (Krippendorff, 2006). Building upon the literature, this paper presents a research that investigated the users' actions and management practices relevant for thermal comfort in the light of the organisational culture and policies of four BREEAM certified buildings.

## Methodology

The study applied post occupancy evaluation techniques and user surveys to identify occupants' satisfaction with and actions to modify indoor environmental conditions (thermal, lighting, acoustics) in four case studies. The purpose of the study was to identify how the social and organisational aspects encouraged (or discouraged) the occupants to modify the indoor environmental conditions and informed the management and the operation of the buildings. This paper focuses on the findings related to thermal aspects, referring, as relevant, to other indoor environmental conditions to highlight the nexus between thermal, lighting and acoustic conditions in providing the conditions for the satisfactory use of buildings as perceived by the research participants. The case studies were four BREEAM Excellent buildings: two schools and two offices buildings, certified to BREEAM 2006 version. Table 1 summarises the key performance aspects of the case studies.

The indoor environmental conditions (temperature, CO<sub>2</sub> levels and relative humidity) and the electricity and gas consumption were monitored for a year. The user studies were carried out across four visits (one per season) and comprised semi-structured interviews, questionnaires and walkthroughs. The studies collected qualitative data about actions and perceived satisfaction with energy and indoor environmental conditions (thermal, lighting and acoustics). They included an additional spot monitoring exercise that recorded the indoor environment parameters (internal air temperature, mean radiant –globe-temperature, relative humidity, illuminance levels and ambient noise level) to link users' satisfaction and actions to the monitored conditions on the day of the visit.

### ***User studies—Instruments***

During the user studies (one visit per season), the environmental conditions were monitored at 10-minute intervals, recording the internal air temperature (°C), mean radiant (globe) temperature (°C), relative humidity (%), illuminance levels (lux) and ambient noise levels (dBEqA). A morning and an afternoon reading of external air temperature were recorded on the day of the visit. The equipment used for monitoring the conditions during the visits were: (1) Testo 435 anemometer to record the air speed and the temperature; (2) Digital impulse sound level meter Dave D14-22C and calibrator Serial # 3742070; and, (3) Eltek squirrer data logger 1000 server to record the globe temperature, lux and relative humidity.

### ***User studies—qualitative study***

The user studies investigated the occupants' actions and management practices in the buildings. Questionnaires were administered to students and employees in the case studies. The questionnaires included questions about the perceptions, satisfaction levels, knowledge of systems and controls, actions taken to achieve comfort. Three questionnaires were administered per seasonal visit: one general questionnaire and perceptions/actions in the day repeated in the morning and in the afternoon of the seasonal visit. The general questionnaire included questions about the building in general. The repeated questionnaires focused on reporting about the space where the respondent is based. The repeated questionnaires data were analysed in the light of the indoor environmental data monitored on the day. In addition to the questionnaires, semi-structured interviews with open-ended questions were conducted to facilities managers and different user representatives (teacher, employees in the office, head teacher and office manager). The mix of participants enabled to depict multiple perspectives with regards to how the buildings were used: the end-user engagement in everyday use of building (ie. data from employees), the medium-long term management of facilities (ie. data from facilities manager), the corporate norms and impact on the building management activities (ie. data from the head teacher, office manager). The length of the each interview was between 45 and 60 minutes. Documents such as the Operation and maintenance manual and the BREEAM reports were analysed to identify the as-designed energy and environmental performance intentions.

## **Findings**

The users in all of the case studies expressed their willingness to take action to modify their immediate indoor environment to achieve comfort when the indoor conditions were not

satisfactory. The main reason for dissatisfaction in the buildings was overheating, which was reported at different times of the year as shown in Table 2.

Table 2 Temperature recorded during seasonal visit (Tmp °C) and percentage of occupant's complaints due to overheating (Ovht %)

Seasons	CS 1	CS 1	CS 2	CS2	CS3	CS3	CS4	CS4
	Tmp °C	Ovht %	Tmp °C	Ovht %	Tmp °C	Ovht %	Tmp °C	Ovht %
Summer	24-25.6	71.43	23.2- 24.4	85.71	24.5-28	66.70	27-31.8	100.0

Spring	24-25.4	14.29	22-24.5	14.29	24.8- 25.5	60.00	19.8- 21.5	77.78

The types of action taken by the research participants to improve their thermal comfort were: reconfiguration of spaces to match the location of workstations to individual thermal preferences (those who tend to feel hot next to windows, those who tend to be cold next to radiators); personal adaptation (i.e. adding/removing layers of clothes and taking hot/cold drinks); operation of windows and doors; use of fans and fan heaters.

Occupants in Case Study 1 (office building) were encouraged by the management team to exert adaptation strategies to achieve comfort: flexible dress code, relocation of workstations in the office and the use of personal fans and lamps in the workstations. The location of the workstations for individual employees is based on their thermal preferences. Employees working on the second floor, an open plan office area, chose the location of their desks (next to a window, in the core of the space, on the perimeter of the office by a radiator):

*Interviewee CS1: 'We have had people who specifically asked to move desks to somewhere else because they were hot or cold. One of our girls used to sit near the window but she is really cold so when other of the staff wanted the window opened, she was not happy. But of course, the ones in the middle wanted to get a bit of flow of air so she moved away from the window and near the radiator so in the winter she would have the radiator. So people have said I don't like it here, it's too hot, too cold and moved appropriately to a better position.... still you can't please everybody but we've tried the best we can to sit people in a position that make them in a more comfortable environment.'*

A personal fan and fan heater are used in 75% of the individual workstations. The support provided at corporate level to the employees in Case Study 1 to be comfortable is motivated by the desire of the company to enhance the employee's productivity by increased comfort.

The research participants in all the case studies expressed their willingness to modify the thermal conditions of the spaces that they occupy. This was manifested by adaptation actions exerted at personal level and at building/technology level. The typical actions at building/technology level included the operation of windows and doors and the use of fans. However, some building features and control strategies in the case studies did not support adaptation despite the design intentions. For example in Case Study 4, the teachers expressed their desire to use windows and doors to improve the ventilation in the

classrooms for thermal comfort and for fresh air. However, these actions were restricted by the layout of the school. The manually operable classroom windows in the first floor open to a buffer ventilation area. The ventilation area was originally designed for minimum occupancy, as a play area when the weather conditions did not allow the use of outdoor play area. The buffer area is a double-height space connected to the nursery area on the ground floor and adjacent to classrooms with manually operable windows on the first floor. The buffer area has been converted to a permanent play area for nursery children on the ground floor due to lack of spaces, restricting the use of the operable windows of the classroom in the first floor. When the windows in the classrooms are open, the noise from the nursery disturbs the classroom activities (78dBC). While the doors of the classrooms could be open for ventilation, the teachers prefer to keep the doors closed to avoid noise from the corridor (113.4dBC). When the building overheats, the teachers tend to switch off the lights in the classrooms to limit the lighting heat gain. This action in turn compromises the lighting levels in the classrooms (267-305lux). These classrooms also have windows at ceiling height that are automatically controlled on the basis of CO<sub>2</sub> levels. These windows open to the exterior but cannot be manually operated because they are out of reach (approximately 2.60m high). The caretaker in Case Study 4 reported that the CO<sub>2</sub> levels that trigger the operation of the windows are changed seasonally so that the automatic windows open more frequently in summer (to reduce overheating) than in winter (to prevent incoming cold air). The CO<sub>2</sub> levels that trigger the opening of windows in winter is 1250-1750ppm. In summer season, the CO<sub>2</sub> level trigger point is 750-1550ppm. This strategy, however, is problematic when the CO<sub>2</sub> levels rise and there is rain, cold air or drafts due to outdoor weather conditions and during autumn and spring. It should be noted that CO<sub>2</sub> levels can build up to unadvisable levels in winter; yet, the windows remain closed. Another criticism of the automatic windows was the noise and disruption created when they open during teaching activities that required concentration. In Case Study 4, the occupants wanted to modify the immediate environment (which in turn could increase their perceived satisfaction in the building); however, there were limited opportunities for the occupants to use effectively the building features (windows, doors) to support adaptation.

A similar situation was reported in Case Study 3. The research participants expressed their desire to exert a range of adaptation actions: personal (clothing according to the season) and to operate the building technologies in the spaces that they occupy (windows, doors, blinds). However, at organisational level, some school policies limited the adaptive opportunities available to occupants. In terms of personal actions, the dress code for employees strongly recommends suits and ties to be worn all year round to present a professional image to the students and parents. Occupants were not allowed to wear lighter clothing in summer. For the operation of building technologies, there was a policy to not operate windows or blinds in the spaces adjacent to the main façade. The intention was to maintain the uniformity of the main façade to avoid that this facade '*looks as if it is missing some teeth*' when some windows/blinds were open while others remained closed. The use of windows in upper level floors was also restricted due to safety concerns.

The facilities manager in Case Study 3 reinforced this view by expressing his discontent with the corporate expectations about his role. He felt that there was little support for him to promote activities to reduce the energy consumption. He thought that he was expected to focus on the provision of the physical conditions of classrooms (sufficient space, number of computers, chairs and resources for teaching) rather than the management of indoor environmental conditions and energy performance. He felt that the actions to manage the

indoor environmental conditions were supported at corporate level if triggered by unexpected problems in the classrooms rather than as a planned programme of management and maintenance. It should be noted that this was the only case study with onsite availability to BMS data. However, there were problems with the metering and possible data corruption. Yet, there had been no support to fix the BMS problem which prevented the facilities manager from having robust recorded energy and environmental data that could inform medium and long-term plans for performance management.

The data indicate that the organisational policies shape the management practices and actions available to the occupants to achieve thermal comfort in the case studies. For example, in Case Study 2, the facilities management role was fulfilled by a team offsite. Case Study 2 is a building that belongs to an institution with its main headquarters in a different location. The Estates department deals with the energy management of the building, including the automated building controls and the access to the monitored data by the BMS. There is limited control directly available to the building occupants in Case Study 2 to modify their indoor environment. The windows operate automatically on the basis of CO<sub>2</sub> (like Case Study 4) although the occupants can override the system and operate the windows manually. There is no dedicated facilities manager in this building. When a problem arises in Case Study 2, a technician whose role includes 'facilities management tasks' contacts the Estates department. The Estates department is perceived to be helpful although they are unable to respond immediately to the problems in Case Study 2. One source of dissatisfaction is the automatic operation of windows. Windows open in weather adverse conditions (rain/draft/cold) and interfere with activities in the office. The technician felt that the building management activities should take place onsite for a more efficient operation of the building. Table 3 summarises the key findings concerning facilities management aspects and institutional policies and norms that enabled (or discouraged) the adaptation actions.

Table 3 Summary of facilities management aspects and corporate support to initiatives

Case Study	1	2	3	4
BMS	No BMS	BMS off-site, by internal organisation	BMS onsite, problems-data corruption	BMS off-site, by external organisation
FM's role	No FM/office manager	FM Off-site, technician onsite troubleshooting	FM on site, troubleshooting	No caretaker, FM/troubleshooting
*Corp. comfort	Yes, productivity	Neutral	No: reputation, aesthetics, safety	Neutral
**Corporate pro-EneEffic.	No	Reduction of electricity use	No	Reduction of electricity use

\*Corporate norms/policies that supported initiatives to achieve comfort; \*\*Corporate norms/policies that supported initiatives to reduce energy consumption

## Discussion and conclusions

The research data suggest that occupants are willing to modify their thermal conditions through personal adaptation and by using building technologies/features (windows/doors). This is manifest in the following strategies: (1) rearrangement of the space (dynamic use and location of workstations in relation to individual thermal preferences in Case Study 1); and, (2) Adaptation actions observed in all of the case studies, in alignment to the thermal

comfort theory (Brager and De Dear, 1998). However, the data also suggest that corporate policies could support (and discourage) the adaptive opportunities available to occupants. In Case Study 1, the company supported actions to achieve comfort to enhance employees' productivity. In Case Study 3, corporate norms limited adaptation: restricted dress code, restricted operation of windows/blinds. In Case Study 4, the opportunities to operate the windows were restricted by the change of use in a space originally designed as a ventilation area. The organisational context, therefore, could potentially have an effect on the scope of individual and adaptation actions available to building occupants. In other words, the actions for comfort and the operational practices at facilities management level (and alike-i.e. caretaker) took place against a background of institutional policies and norms. The range of the actions available to different stakeholders (occupants, facilities managers) seemed to vary in relation to the institutional context. It should be noted that the management and the operation practices were not driven by energy and environmental targets in the case studies. Case Study 3 had a facilities manager onsite who did not exert direct actions for energy and environmental management. In one case study, the facilities manager was located offsite and in two case studies there were no facilities managers in house. There was a general opinion that facilities management was a reactive rather than the proactive role needed to enhance the energy and indoor environmental performance or to foster the efficient operation of the buildings.

This work has provided insights into occupants' actions and facilities management practices in relation to institutional norms and policies. The results draw attention to the complex context of building use and operation and question the simplistic notions that regard the user as a passive agent and the stereotypical user as a standard 'concept'. Ultimately, the paper advocates a more sophisticated understanding and more nuanced representations of users, in contradiction to the typical 'one size fits all approach' to inform energy efficiency interventions and strategies to improve the operational performance of existing buildings. Such a need is already recognised by service design approaches for the design of many new buildings, when the concept of 'personas' prevalent in user-centred product and technological system design is used to explore possible interactions between different types of users and the managed buildings they will inhabit. The acknowledgement of the agency, the knowledge and the non-arbitrary actions of building occupants within the context of organisational norms and policies are key propositions to analyse the 'counterintuitive' and 'inefficient' occupant behaviour. That stance puts inhabitants at the centre of the debate to achieve energy and environmental performance targets in existing buildings. Their different perspectives could inform interventions guided by the concerns and needs that are relevant to the users with a view to enhance the energy and environmental performance of existing buildings.

Further research will examine how corporate goals and individual goals could be linked to energy efficient intentions. For example, it is widely recognised that good indoor environments have positive effects on occupants' health and wellbeing: increased productivity, reduced absenteeism, better educational attainment. These aspects are likely to be relevant to occupants' concerns and corporate goals and could be nudging points to motivate the proactive and efficient management of building performance. The energy efficiency initiatives in non-domestic buildings seem to sit within three layers of action: building occupants, facilities management and the organisation/corporate level. Aligning the different visions of these stakeholders may result in more effective ways of operating

buildings. This could provide feedback to designers to enhance their understanding of operational performance and to inform the design representations of occupants.

### **Limitations**

The user studies aimed to explore the indoor environment variations experienced in the buildings throughout the year and within the day of the visit (morning and afternoon) by investigating the participants' responses in relation to the specific indoor environment conditions of the day of the visit. They are not representative of the season. The user studies investigated the occupants' actions and facilities management practices that take place within the organisational policies; aspects that are relevant to the achievement of energy and environmental performance targets in existing non-domestic buildings.

**Abstract:** This study evaluates occupants' comfort, summertime and wintertime temperatures in a timber dwelling unit located in Milton Keynes, UK. The study was conducted in July, 2012 for the summer survey and from January-February 2013 for the winter survey. The study employed a combination of thermal comfort survey and on-site measurement of parameters (temperature and relative humidity). The findings revealed the occupants feel warm in summer but thermally satisfied in summer and winter. The monitoring results using the static and adaptive comfort models showed summertime overheating occurs in the living room (7.0% each time above the 28°C and the BSEN15251 Category II upper indicators) and the bedroom (18% and 15% each time above the 26°C and the BSEN15251 Category II upper limit respectively). Higher neutral temperatures (summer – 1.8°C; winter – 0.8°C), preferred temperatures (summer – 1.1°C; winter – 2.6°C), and mean temperatures (summer – 0.5°C; winter – 1.3°C) are reported in the bedroom than the living area. The results showed the ability of occupants to have higher adaptation to the thermal environment in bedrooms than living rooms. Finally, the results revealed the ability of timber dwellings to provide more comfortable indoor conditions to occupants in winter than summer.

**Keywords:** Thermal comfort, summertime and wintertime temperatures, thermal comfort survey and on-site measurement, thermal comfort models, prefabricated structural timber dwelling.

### Introduction

There are various studies that have investigated thermal comfort of occupants in residential buildings [1-6]; a few studies on thermal comfort of occupants have addressed occupants' comfort in dwellings [4-5]. Generally, the primary needs for people to survive in any climate include food, clothing, and dwelling. Of these three basic needs, people aspire and have preference for dwellings with favourable and comfortable conditions in summer and winter due to harsh external weather conditions aggravated by climate change. Most people want to acquire and live in dwellings with acceptable comfort condition but acquiring dwellings tend to be the most critical and in many instances the highest expenditure item in people's lifetime. These further contribute to why most people have preference for dwellings that provide the most comfortable conditions [7]. In recent decades, more sustainable dwellings are constructed with materials that have low-carbon footprints. Investigations on thermal comfort of occupants in energy-efficient dwellings and the ones built with green materials such as bamboo, structural timber are important to understand occupants' adaptation and behavioural actions [4] as well as to reduce overall energy used in dwellings. As mentioned

in existing studies, energy used in dwellings accounts for about 29% of the total energy consumed in the UK in 2015 [8]; while it accounts for almost 40% of the total energy consumed in the US in the same year [9].

As reported in previous research, thermal comfort of occupants is one of the most crucial parameters evaluated in order to understand the thermal environment of various dwellings [7]. A recent study stated that investigations on thermal comfort of occupants can provide a better understanding of a range of temperatures at which occupants prefer no change as well as feel neither warm nor cold in summer and winter [4]. Existing studies have evaluated occupants' comfort in UK dwellings [1-6]. These studies considered short-term [1,5] and long-term assessments of occupants' comfort in summer [3-4,6]. A few studies addressed occupants' comfort in wintertime [1,5]. On-site measurements of buildings built with heavyweight materials such as concrete, bricks are also investigated [2-3] while measurements of timber buildings in summertime are considered in some studies [1,4-6]. To date, only a few studies on occupants' comfort in UK timber dwellings have been conducted due to the limited number of timber dwellings in the nation [10] when compared to the number of timber dwellings in the United States and Scandinavia [11].

Existing studies have revealed that overheating occurs in UK dwellings, especially in dwellings located in the warmest regions [1-3]. The climate (UK's climate) is considered to be wet and mild in summer [5] and cold in winter [11]. Research has also been conducted to investigate overheating in dwellings located in UK cold regions [6]. A study conducted in 282 UK homes [3], and another investigation [2] revealed high temperatures are observed in UK dwellings in summer. However, these studies [2-3] only considered on-site measurements of dwellings with limited or no information on subject votes in summer. A recent study showed that overheating occurs in timber dwellings in Scotland [6]. The study was conducted on timber frame buildings since they are common in Scotland and stated various causes of overheating in timber dwellings [6]. Summertime overheating has been evaluated in previous studies using different comfort models [3-4]. The two most widely used thermal comfort models for evaluating risk of overheating include the CIBSE 'static' model [12-13], and the adaptive comfort model [14]. Existing studies have highlighted that UK dwellings are prone to summertime overheating with a different degree of overheating reported in different studies [4]. Subject votes were also collected and analysed in various dwellings [1,4-5]. Attention was however paid to thermal comfort of occupants and summertime temperatures [2-5] with limited or no information on wintertime temperatures.

Past studies have also considered post-occupancy evaluation (POE) to investigate occupants' comfort in summertime [4-5]. An existing study has presented its findings on occupants' comfort in spring, summer, autumn, and winter [1]. The study explored a combination of subject votes and on-site measurements as the research methodology. The study [1] considered comfort temperatures in summer and winter with limited information on neutral and preferred temperatures. The study however evaluated mean temperatures and presented the mean votes on thermal sensation and thermal satisfaction during the field study [1]. From the literature, it is clear that additional studies are required to understand occupants' comfort and the performance of timber dwellings in summer and winter [4]. Also, timber is increasingly used for construction of dwellings in recent years in many parts of the world due to its green credentials, aesthetic appearance, cost, workability, ease of transport, speed of erection, and ability to capture carbon as long as it exists [4,10].

Based on the gaps identified from literature, this study investigates thermal comfort of occupants, summertime and wintertime temperatures in a single prefabricated timber

dwelling. Existing studies have mentioned that dwellings built with structural insulated panels (SIPs) are likely to be prone to overheating than dwellings built with cross laminated timber (CLT) panels [4,11]. As a result, it is important to understand occupants' comfort in summer and winter in dwellings built with SIPs. Moreover, this study aims to understand mean, neutral, and preferred temperatures in the living area and bedroom of the case study dwelling. The study also intends to understand if the outcomes of the research align with findings from existing studies on bedrooms being warmer than living areas [4,15]. This study aims to contribute to recent and on-going studies on thermal comfort of occupants in timber dwellings. The paper provides a better understanding of occupants' comfort in structural timber dwellings.

## Methodology

The research study employed a combination of thermal comfort survey using subjective questionnaire and on-site measurements. The parameters (temperature and relative humidity) were measured every hour. The study was conducted from Jul 24-31, 2012 for the summer survey and from Jan. 28-Feb. 8, 2013 for the winter survey. The HOBO and TinyTag data loggers were used for the on-site measurements. The parameters were measured at 1.1m above the floor level as specified by the ASHRAE [16]. The questionnaire was completed three times a day. The outdoor weather data for the same periods (summer and winter) were collected from Luton Airport weather station. The subject votes using 7-point scale (from cold to hot) for thermal sensation and 5-point scale for thermal preference (from much cooler to much warmer) were considered (Fig. 1) and analysed while the measured indoor and outdoor weather data were plotted in charts.

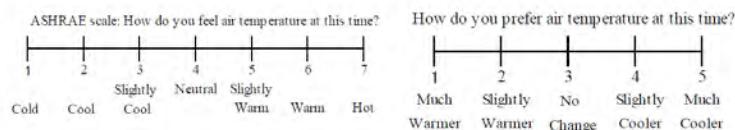

Figure 1: Examples of 7-point ASHRAE thermal sensation (left) and 5-point thermal preference scales (right)

The questionnaire was developed in a simple format for participants to easily understand and tested before it was distributed. Subject votes were analysed using the appropriate statistical software (SPSS and Excel) to find mean values, plot histograms and different charts including regression, as well as establish correlations between various parameters examined. Thermal comfort models (the CIBSE and the adaptive models) were employed to understand summertime temperatures since the dwelling is considered to be naturally ventilated in summertime. The CIBSE model was considered for evaluation of comfort temperature in wintertime and the adaptive model was not considered due to heating required in the season. For the CIBSE model, this study examined number and percentage of hours of temperature above the indicators (1% > 28°C for living area; 1% > 26°C for bedroom) [12-13]. Regarding the adaptive thermal comfort evaluation, the Category II '*acceptable conditions for newly built and refurbished dwelling*' was considered. The evaluation of comfort temperature focused on number/percentage of hours (5% of hours above the Category II upper thermal comfort envelope) to establish warm discomfort and (5% of hours below the Category II lower level) to identify cold discomfort [14].

## Case Study

The dwelling is an end-terraced unit and one of the completed 116 dwelling units located in Milton Keynes, UK. The housing development has won various awards due to the material

used for its construction and green credentials. The dwelling unit consists of living area, dining/kitchen on the ground floor while two bedrooms and study area are located on the upper floor (Fig. 2). The unit is occupied by a family of four (two adults and two young people). One of them works from home which revealed the dwelling is occupied nearly every time while the second adult works from home but not on a regular basis. The floor area of the unit is 76.8m<sup>2</sup>, and floor-to-ceiling height is 2.35m. The floor areas of the spaces monitored include living area (20.9m<sup>2</sup>) - southwest orientation and bedroom (12.2m<sup>2</sup>) - southeast orientation. The dwelling is constructed with building components that have low U-values: walls – 0.12W/m<sup>2</sup>K; roof - 0.17W/m<sup>2</sup>K; and windows - 1.7W/m<sup>2</sup>K.

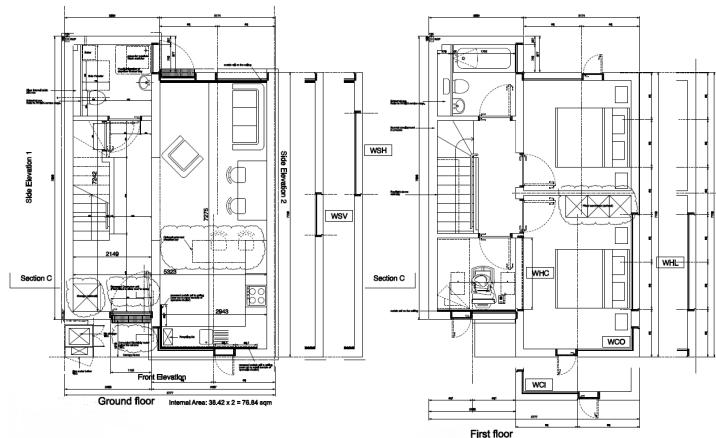

Figure 2: The ground floor plan (left) and the first floor plan (right) of the dwelling unit (RSHP Architects)

## Analysis

The analysis showed external temperature was between 8.0°C (minimum temperature) and 27.0°C (maximum temperature). The average external temperature was 16.6°C. The indoor temperature was from 19.8°C - 30.0°C in the living area and between 20.5°C and 28.8°C in the bedroom in summer. In winter, the external temperature was from -1.0°C to 13.0°C. The mean external temperature was 5.1°C. Table 1 below provides a summary of the measured temperatures in the living area and the bedroom in summer and winter. The analysis showed the external temperature was below 18.0°C for more than 50% of the time in summer. Likewise, temperature was within the comfort range (22.0°C – 25.0°C) in wintertime (Fig. 3). In addition, humidity was within 40%-60% in the summer; while it was within a wider range of 30%-80% in the winter. Table 2 provides summary of the subject votes in the living area and the bedroom.

Table 1. Summary of the measured internal and external temperatures including running mean temperature

Space	Summer Temp. [°C]			Winter Temp. [°C]		
	Mean Temp.	Max. Temp.	Min. Temp.	Mean Temp.	Max. Temp.	Min. Temp.
Living room	23.5	30.0	19.8	18.9	21.8	17.5
Bedroom	24.0	28.8	20.5	19.6	22.9	17.7
External temp.	16.6	8.0	27.0	5.1	13.0	-1.0
Running mean	17.8	18.9	15.9	NA	NA	NA

Table 2: Summary of the subject votes in the summer and winter

Space	Summer			Winter		
	Thermal sensation	Thermal preference	Thermal satisfaction	Thermal sensation	Thermal preference	Thermal satisfaction

Bedroom	5.4	2.9	6.3	4.0	3.4	6.2
Unit average	5.3	2.8	6.2	3.9	3.2	6.0

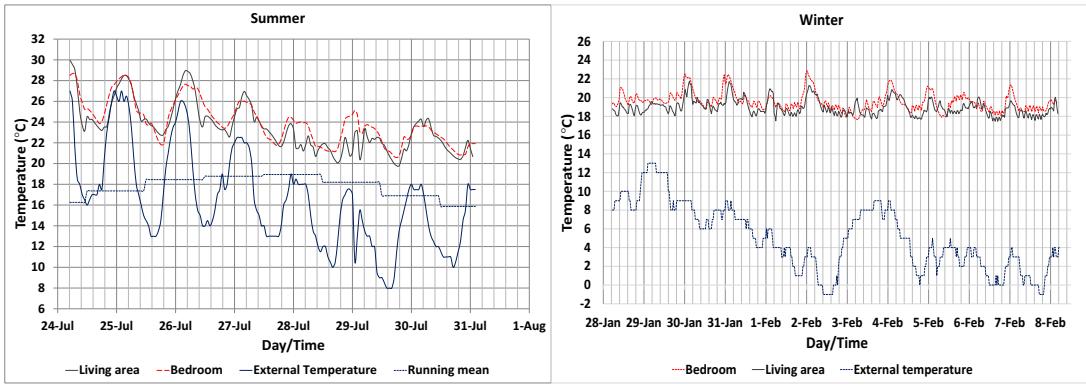

Figure 3: Measured temperatures in the living area and the bedroom

## Results and Discussions

The findings showed the monitoring period in summer was not an extreme summer period which could have contributed to high temperatures recorded in the living area and bedroom. However, the results revealed high temperatures were reported in the summer. The subject votes revealed the occupants feel warm in the summer and feel slightly cool in the winter (Table 2). The respondents prefer to be cooler than they were in the summer but prefer no change (that is, neutral) in the winter. However, the occupants are thermally satisfied with the thermal environment in both seasons. More than 80% of the votes revealed acceptability of the thermal environment in the summer and the winter. The result on thermal acceptability is in agreement with ASHRAE's recommendation [16] that at least 80% of the occupants must find the thermal environment acceptable.

Relationships exist between the internal and external temperatures in the living area and the bedroom. The bedroom is found to be warmer (about 1.0°C higher) than the living area in the summer and winter (Fig. 4). The floor layout of the dwelling unit may be a contributing factor to the bedroom being warmer than the living area due to the location of the bedrooms on the upper floor of the dwelling (Fig. 2). Since hot air rises, it is possible hot air moves from the lower floor to the upper floor where bedrooms are located. Temperature is also found to be within a higher range in the bedroom than the living area (Fig. 4). The result showed the possibility of higher temperatures to be frequent in the bedroom especially at night which may affect the quality of sleep during the period.

Using the CIBSE 'static' and adaptive comfort models to evaluate the risk of summertime temperatures in the living area and the bedrooms, the results showed summertime overheating occurs. The measured temperature rose above the 28°C indicator for over 12 hours (7%) during day-time (08:00am-10:00pm) out of 167 hours of monitoring and it rose above the BSEN15251 Cat. II upper indicator for more than 7% of the time in the living area. In the bedroom, the measured temperature rose above the 26°C indicator for over 18% of the time during the same period and it rose above the BSEN15251 Cat. II upper indicator for over 15% of the time (Fig. 5). The results showed the bedroom is prone to extreme summertime overheating and occupants are likely subject to warm discomfort in summer. In winter, the results showed the measured temperature did not rise above the 28°C indicator at any time in the living area and it was below the 26°C in the bedroom throughout the period of the survey.

Regarding the neutral temperature as well as the preferred temperature in the living area and the bedroom in the summer and winter, relationships exist between the variables especially in the summer (Fig. 6 and Fig. 7). The results showed higher neutral (at least 0.8°C, preferred (at least 1.1°C) and mean temperatures (at least 0.5°C) are recorded in the

bedroom than the living area in the summer and winter (Table 3). Preferred temperature is significantly higher by 2.6°C in the bedroom than the living area in the winter. This may be attributed to a change in use of space in summer and winter. Occupants that work from home preferred to work in the spaces on the upper floor of the dwelling unit in winter while the lower floor is preferred in the summer. The results showed higher adaptability of occupants to the thermal environment in the bedroom than living area. The mean, neutral and preferred temperatures in the summer and winter are presented in table 3 below.

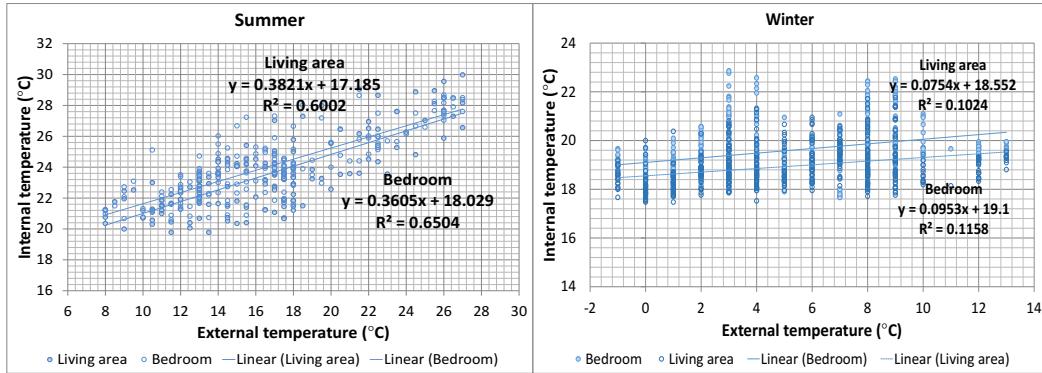

Figure 4: Relationship between measured temperatures in the living area and the bedroom

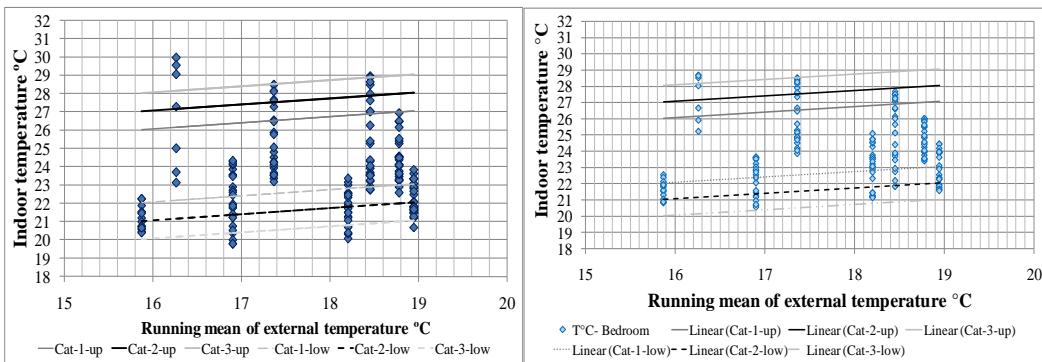

Figure 5: Temperatures in the living area (left) and bedroom (right) compared to the BSEN15251 levels.

Table 3. Summary of the neutral and the preferred temperatures in the summer and winter

Space	Summer Temp. [°C]			Winter Temp. [°C]		
	Neutral Temp.	Pref. Temp.	Mean. Temp.	Neutral Temp.	Pref. Temp.	Mean Temp.
Living room	22.1	22.2	23.5	17.6	20.8	18.9
Bedroom	23.9	23.3	24.0	18.4	23.4	19.6
Unit average	23.0	22.8	23.8	18.0	22.1	19.3

Comparing the results from this study with existing studies on summertime and wintertime temperatures, it is observed temperatures especially neutral and mean temperatures are slightly higher in this study than existing studies [1,17]. This study further validated findings of previous research [4] that prefabricated timber buildings are prone to high summertime temperatures while lower temperatures may also be observed in winter due to low thermal mass of structural timber materials. The table below provides summary of comparison of summertime and wintertime temperatures with existing research (Table 4).

Table 4. Summary of comparison of summertime and winter temperatures with existing research

Study	Summer Temperatures [°C]			Winter Temperatures [°C]		
	Neutral	Preferred	Mean	Neutral	Preferred	Mean
This study	23.0	22.8	23.8	18.0	22.1	19.3
Rijal et al [1]	22.9	NA	23.4	NA	NA	20.9
Hong et al [17]	20.4	NA	21.0	18.9-19.1	NA	17.1-19.0

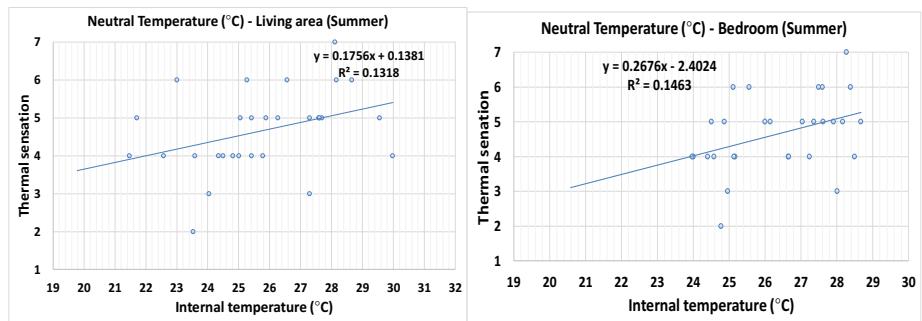

Figure 6: Relationship between thermal sensation and the internal temperature in the spaces in the summer

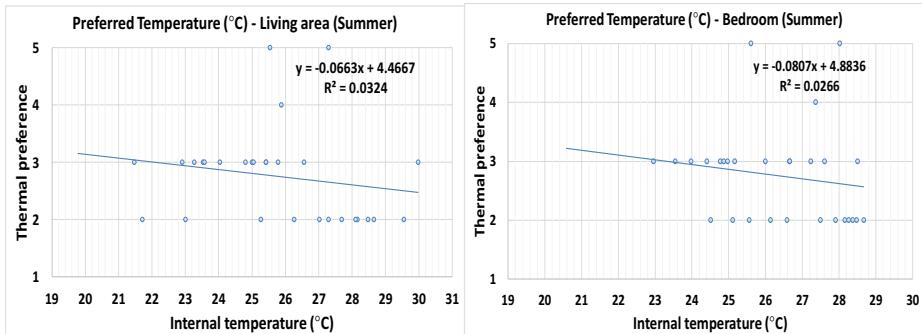

Figure 7: Relationship between thermal preference and the internal temperature in the spaces in the summer

### Possible causes and remedial measures to overheating

Since findings presented in this study revealed that overheating occurs in the dwelling, it is important to highlight possible causes and remedial measures to overheating. Some of the possible causes include reduced ceiling-to-floor height of the dwelling, reduced height and area of windows, and use of low performance windows in some of the spaces. Possible remedial measures include higher floor-to-ceiling height, use of high performance windows and doors, and application of passive cooling strategies. Also, improved thermal mass of building envelopes as mentioned in existing studies [4,11] and behavioural actions [6] can reduce overheating in dwellings. However, these remedial measures require further research to understand the extent the measures can reduce overheating in timber dwellings.

### Conclusions

This study evaluated occupant's comfort, summertime and wintertime temperatures in a timber dwelling. The study found that occupants feel warm in summer and slightly cool in winter. The subject votes revealed that the occupants prefer to be cooler in summer than they were with mean thermal preference votes in winter around thermal neutrality. However, occupants are thermally satisfied with the thermal environment. The results revealed over 80% of the respondents are comfortable within the thermal environment.

Higher mean (summer – 0.5°C, winter – 0.7°C), neutral (summer – 1.8°C, winter – 0.8°C) and preferred (summer – 1.1°C, winter – 2.6°C) temperatures are observed in the bedroom than the living area in the summer and winter. The mean temperatures are also higher than the mean temperature (19.1°C) recorded in a study conducted in UK dwellings in 2001 [18]. The bedroom is found to be warmer than the living area. This finding is in agreement with the finding presented in existing studies [4,15]. Comparing the findings from this study to existing research, temperatures especially neutral and mean temperatures are slightly higher than temperatures reported in existing studies. The findings showed timber buildings are prone to summertime temperatures and possibly

lower wintertime temperatures. Also, occupants living in timber dwellings are likely to develop higher adaptability to the thermal environment than those living in other dwellings.

Overheating is likely to occur at a frequent rate in the bedroom than the living area of the timber dwelling. Over 7% of the hours rose above the 28°C and the BSEN15251 Category II upper limit when measured temperatures are evaluated in the living area using the CIBSE and the adaptive comfort models. Extreme summertime temperatures (18% of the hours above the 26°C indicator) and warm discomfort (15% of the hours above the BSEN15251 Category II upper limit) are also reported in the bedroom.

Finally, this study revealed possibility of temperatures to be extreme in timber dwellings in summer. However, the findings showed occupants tend to be more comfortable with thermal environment and no overheating is reported in winter. From this study, it appears the occupants preferred higher temperatures in the summer and winter in the bedroom than the living area. This is a crucial finding that needs to be investigated in further research to understand occupants' comfort in the sleeping area since timber has low thermal mass which may affect or influence occupants' comfort in timber dwellings.

## The Environmental Performance of the Engineering Science and Learning Centre UK: An investigation of thermal and light benefits from an atrium covered by ETFE cushions

**Abdulquadri Ademakinwa<sup>1</sup>, Benson Lau<sup>2</sup> and Lucelia Rodrigues<sup>3</sup>**

<sup>1</sup> Department of Architecture and Built Environment, University of Nottingham, Nottingham, NG7 2RD, United Kingdom, abdulquadriademakinwa@gmail.com

<sup>3</sup> Department of Architecture and Built Environment, University of Nottingham, Nottingham, NG7 2RD, United Kingdom, Lucelia.Rodrigues@nottingham.ac.uk

**Abstract:** Nowadays, Ethylene-tetrafluoro-ethylene (ETFE) cushion roof is being used substantially for covering atrium as an alternative to glass roof. This paper examined the environmental performance of the Engineering and Science Learning Centre (ESLC) at a university campus, investigating the thermal and luminous environment and the environmental benefits of the atrium covered by ETFE cushions on the adjacent learning spaces in the building.

This study was undertaken by using different analytical tools, which include environmental design rule of thumbs, field work and selective computer aided simulations using IES VE for parametric analysis of the existing and improved luminous and thermal environment. The users' perceptions of the light and thermal conditions were critically evaluated by using questionnaire and the results were correlated with the theoretical data obtained from the quantitative studies.

The research results show that the learning spaces have insufficient daylight illuminance towards the far end of the lecture rooms and the high illuminance level in the ETFE covered atrium is not benefiting the adjacent spaces. In addition, the learning spaces are out of comfort zone and have high CO<sub>2</sub> concentration for most of the time during summer due to the ineffective ventilation strategy with inadequate effective opening size of the roof vents. This study proposed and tested the alternative daylighting solution by modifying the window profile to the walls of the learning spaces facing the atrium, and developed new summer ventilation strategies to improve the thermal performance of the learning spaces adjacent to the atrium.

### Introduction

Atrium is often used as a common architectural solution and environmental strategy to improve the internal conditions of buildings to bring more daylight into the inner space, transferring the light to the surrounding, acting as a buffer zone to prevent direct solar penetration and drive surplus heat (CIBSE, 2006). The building envelope has significant impacts on the indoor environmental conditions which can affect occupants' health and performance (Irene and Robert, 2007). Meanwhile, Glass has traditionally been used in atria to admit natural light and modify the indoor environment, but in recent years, ETFE has become an alternative to glass (Tanno, 1997).

A single ETFE foil transmits 94-97% of visible light, a higher percentage than the equivalent 89% of single glazing. A double layer ETFE transmits approximately 76% of visible light, which is similar to the amount of visible light transmitted by a typical double glazed unit (Robinson-Gayle et al., 2001). According to Tanno (1997), a standard 3 layer cushion has a U-value of around  $1.95 \text{ W/m}^2 \text{ }^\circ\text{K}$  which is considerably better than triple glazing when used horizontally.

This study examined the luminous and thermal environment of the ETFE enclosed atrium space of the Engineering and Science Learning Centre at the University of Nottingham and investigated how both daylight and thermal conditions in the atrium can be passively used to improve the indoor environmental conditions of the adjacent spaces. The atrium and two typical teaching spaces (Room B02, B13) on the first floor were chosen for detailed performative analysis and improvement.

## **Case Study and Seasonal Environmental Strategies**

### ***Engineering and Science Learning Centre***

The Engineering and Science Learning Centre (ESLC) is located at the north-east side of the University Park, University of Nottingham, UK. It is surrounded by the medium rise educational Buildings. It was designed by Hopkins Architects and completed in 2011. It is a  $3500\text{m}^2$  horseshoe-shaped, three-storey educational building accommodating students support office, graduate centre, offices, learning and teaching spaces and a multi-functional central atrium.

The ESLC atrium roof consists of three-layered ETFE cushions that bring top lighting into the atrium of the building and complimented by a glazed aperture on the southwest façade. On its south east elevation, it is cladded in horizontal aluminium louvers. Figure 1 and 2 show the building exterior and interior of the building.

Figure 1. Exterior views of ESLC

Figure 2. Interior views showing the atrium and ETFE roof

### ***Selected Studied Rooms***

The selected rooms are typical teaching spaces located on the first floor as shown in Table 1 and Figure 3.

Table 1. Geometric parameters of the selected rooms

Room	Orientation	Window area ( $\text{m}^2$ )	Floor area ( $\text{m}^2$ )	Window/floor ratio	Distance to nearby building
Room B02	Northwest	29	108	0.27	16m
Room B13	Southeast	15	54	0.27	9m

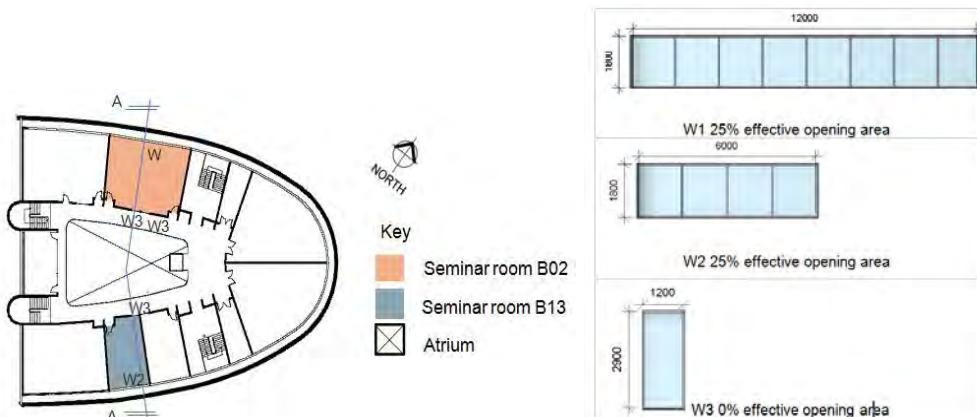

Figure 3. ESLC first floor plan showing the selected rooms and window schedule

### **Building Environmental Strategies**

The environmental control system for this building is a hybrid system, mechanical ventilation via AHU system provides cooling in summer, while in winter, closed loop ground source heat pump are used as a primary heat source with additional perimeter heating via fan coil units and under floor heating to the atrium area with reverse cycle for mechanical ventilation via AHU. The building environmental strategies are shown in Figure 4

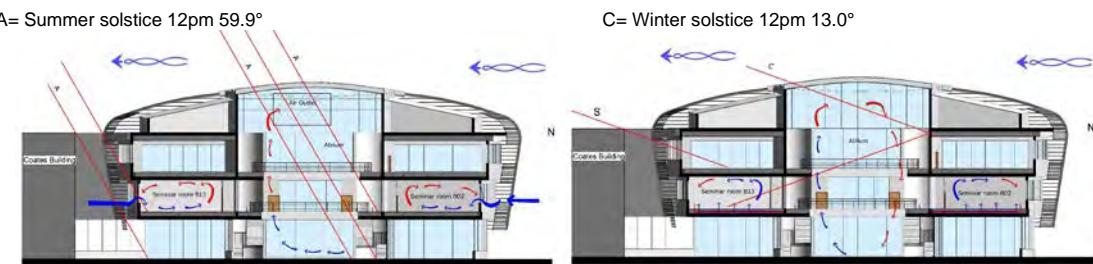

Figure 4. Summer and winter environmental strategy (Section A-A)

### **Building Users' Satisfaction**

The survey was conducted on site using 7 points scale questionnaire on 6th May, 2016 with outdoor temperature of 21°C. The questionnaire was answered by 18 students and their levels of satisfaction to the indoor environmental conditions were presented in Figure 5.

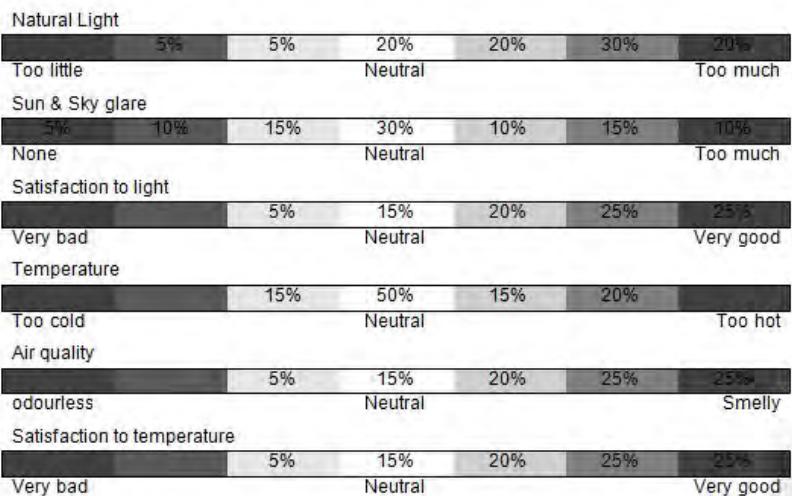

Figure 5. Building users indoor environmental conditions survey results

From the result of the survey, most participants, especially the ones in the atrium complained that there was too much light while users on the third floor of the atrium felt

that there was glare and the temperature was hot and air quality was neutral. The participants in the adjacent spaces were mostly neutral in their responses to natural light perception, but their view on the air quality was smelly.

## On-site Monitoring

### *Daylighting Performance Assessment*

The daylight spot measurements were carried out under sunny sky conditions by using an illuminance meter. The objective was to evaluate the daylighting performance in the atrium and to examine the daylight benefits from the atrium on the adjacent spaces.

### Results

The daylight illuminance in the central part of the atrium (Figure 6) was high and it decreased towards the atrium edges. The average internal illuminance at ground level was 12791 lux while the highest and the lowest value were 33180 lux and 4030 lux respectively compared to average external illuminance was 35698 lux. This indicated that the ETFE cushion transmitted about 93% of the outdoor illuminance into the atrium, which confirmed the abundance of daylight in the space.

The daylight illuminance in the learning spaces B02 and B14 were higher closer to external windows and reduced sharply from the window. In B02, the illuminance level decreased towards the atrium window, which indicated that the atrium did not benefit the luminous environment in the selected adjacent rooms (Figure 7).

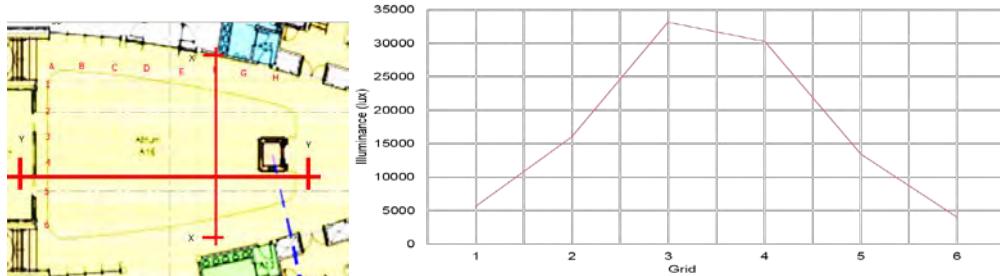

Figure 6. Atrium measurement grid plan and daylight illuminance distribution along Section x-x

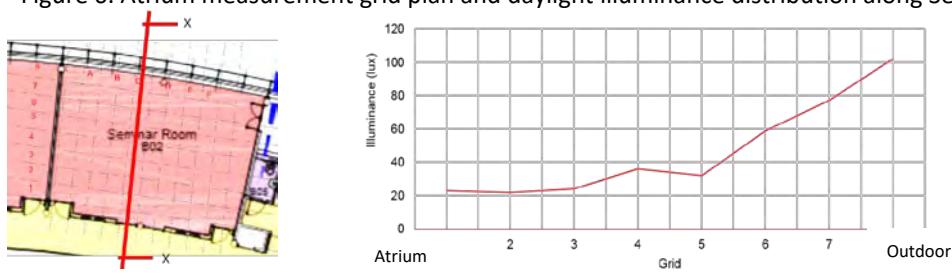

Figure 7. Room B02 measurement grid plan and illuminance distribution along Section x-x

### *Thermal Performance Evaluation*

The on-site monitoring was carried out to investigate the indoor thermal environment at each level of the atrium and the selected rooms. Temperature and CO<sub>2</sub> were taken simultaneously using tiny tag data logger while the surface temperatures were measured using Fluke infrared thermometer.

### *Results and Discussion*

The results of the thermal environment at different level of the atrium on Tuesday and Wednesday which are the days with full occupancy are shown in Table 2. The thermal image analysis of the atrium temperature variance is shown in Figure 8. During the day and night,

temperature stratification was observed in the atrium that is a potentially why the survey participants on the 3rd floor gave unsatisfactory remark on the temperature. The temperature and CO<sub>2</sub> concentration of the atrium space increased during the occupancy period and decreased at night as presented in Figure 9.

Figure 8. Thermal image of atrium showing temperature stratification

Table 2. Atrium temperature and relative humidity during the night and occupancy period (day)

Night (1 <sup>st</sup> March 2016, 22:00pm)					Day (2 <sup>nd</sup> March 2016, 12:00pm)			
Outdoor temperature=16°C			Relative Humidity 50%		Outdoor temperature=20.2°C			Relative Humidity 27%
Level	Space temp.(°C)	Wall (°C)	Floor (°C)	Ceiling (°C)	Space temp.(°C)	Wall (°C)	Floor (°C)	Ceiling (°C)
1	17.3	20	20.5	19.5	17.3	20	20.5	19.5
2	18.4	20.5	20.5	21	18.4	20.5	20.5	21
3	18.7	19.5	19.5	15.5	18.7	19.5	19.5	15.5

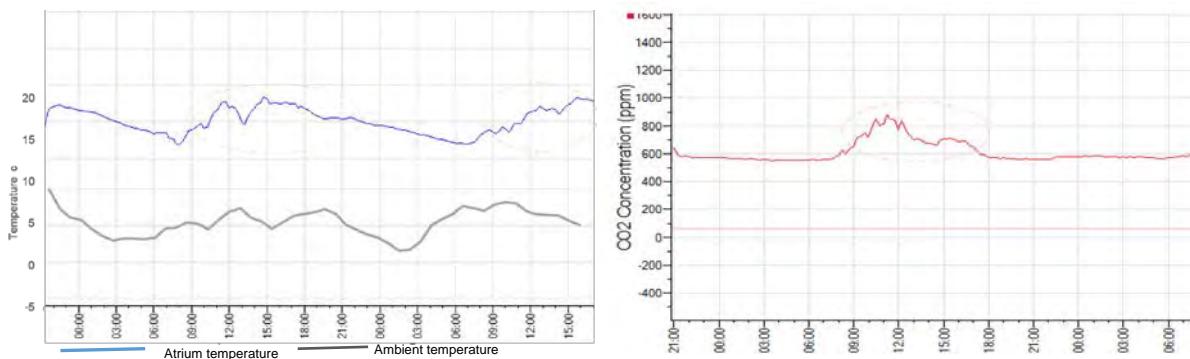

Figure 9. Atrium temperature and CO<sub>2</sub> concentration

It was observed from the result in Figure 10 that the indoor temperature of B02 is within comfort threshold during the occupied period. The CO<sub>2</sub> concentration reached 900ppm which is peak recommended level by the CIBSE to maintain comfort. The increase in occupancy level might result to the CO<sub>2</sub> concentration to rise more than the recommended level.

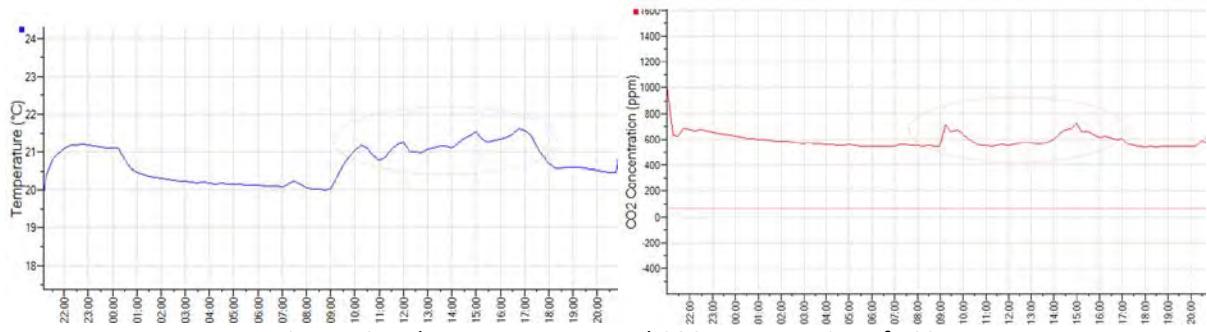

Figure 10. Indoor temperature and CO<sub>2</sub> concentration of B02

## Building Performance Predictions

### *Daylighting performance predictions*

The prediction of the luminous quality of the selected spaces was conducted with the objective of understanding the percentage of the time the learning spaces are naturally lit. This dynamic daylight simulation was undertaken by using IES VE with correct surfaces reflectance and the working plane was set at 850mm above finished floor level.

### *Results and Discussion*

The Spatial Daylight Autonomy (SDA) of this B02 showed that 51.23% of the floor area receives 300 lux for 50% of occupancy period. The SDA of B12 revealed that 18.24% of the floor area received 300 lux for 50% of occupancy hours (8:00-18:00) which is considerably low to IES benchmark of 50% floor area to admit 300Lux for 50% of occupancy time (IES,2012). The simulation results of B02 and B12 are presented in Table 3 and 4 respectively.

Table 3. Climate-based daylight prediction of B02

SDA: 300 lux 50 % (8:00-18:00)	DF for Overcast Sky	Annual Average Lux for DA	Annual UDI 100-300 Lux for DA
51.23%	Min. =0.6% Max. =16.4% Average =3.46% DF> 2% =44.12%	Min. =81.6 Max. =2251.2 Average =515.42	<25 =34.56% 25-50 =64.70% 50- 75 =0.74%

Table 4. Climate-based daylight prediction of B12

SDA: 300 lux 50 % (8:00-18:00)	DF for Overcast Sky	Annual Average Lux for DA	Annual UDI 100-300 Lux for DA
18.24%	Min. =1.4% Max. =12.4% Average =4.09% % DF > 2 =90.2%	Min. =182 Max. =1338.8 Average =508.32	<25 =17.65% 25-50 =82.35%

## Building Performance Improvements

### *Daylighting*

For improving the daylight benefit from the atrium to the adjacent rooms, three cases with three different window profiles were investigated. Figure 11 shows the window profiles, A is base case while B and C are the improved window profiles: case 1 and 2 respectively.

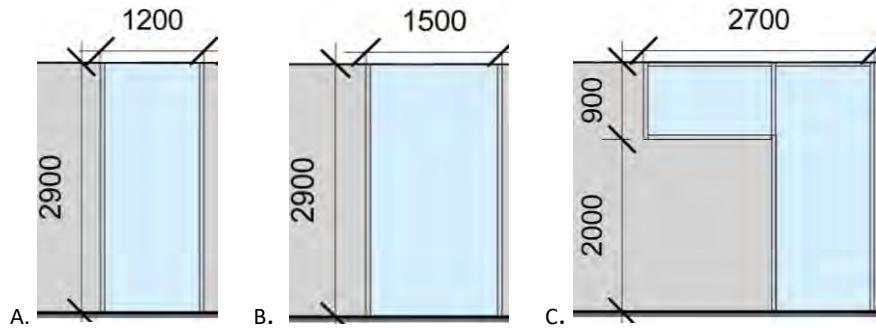

Figure 11. Window profiles for daylight improvements

### **Thermal and Air quality**

Using the internal windows facing the atrium as air outlets, cross ventilation of the adjacent rooms could be achieved as illustrated in Figure 12 and the simulation results are shown in Figure 13. Three cases of effective window opening were investigated to achieve good indoor environmental conditions. The following assumptions were made: Simulation period was in summer (May-August), occupancy period (8:00-18:00), occupancy density of 40 students, Laptop 15w/m<sup>2</sup>, projector 360w, light 2.2 w/m<sup>2</sup>, air exchange is natural ventilation with maximum flow of 10ACH, 30% air inlet and outlet effective opening (acoustic duct) is 30%.

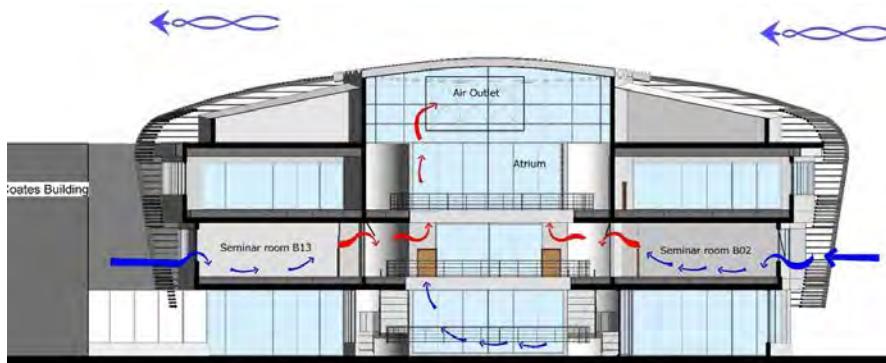

Figure 12: Summer strategy for thermal and air quality improvements

### **Results and Discussion**

In case 1 the percentage annual UDI of 100-300 Lux for DA of B02 increased by 6.15% while case 2 achieved 10.2% improvement to the existing condition. For Seminar Room B12, the percentage annual UDI of 100-300 Lux for DA increased by 2.7% for case 1 while case 2 resulted in 5.7% improvement to the UDI of the existing room. This implies the window profile C admits more daylight from the atrium space into B02. The day lighting improvement result is presented in Table 5 and Figure 13

Each simulation was presented in percentage of hours during summer when the temperature is within comfort band and CO<sub>2</sub> concentration is within 450ppm-650ppm. For B02, the percentage within comfort temperature increased to 69.5% in case 1 and 79.4% in case 2. Meanwhile the air quality improved from 44.5% to 80% for case 1 and 97.7% for the case 2. By adopting cross ventilation strategy, the atrium facilitated improvement in percentage of time within 450-650ppm by 35.6%. The air quality and the period within comfort level improved by 50.9% and 34.3% respectively for B12. The thermal improvement result is presented in Figure 14.

Table 5. Comparison of Percentage of annual UDI 100-300 Lux for Daylight Autonomy for all the cases

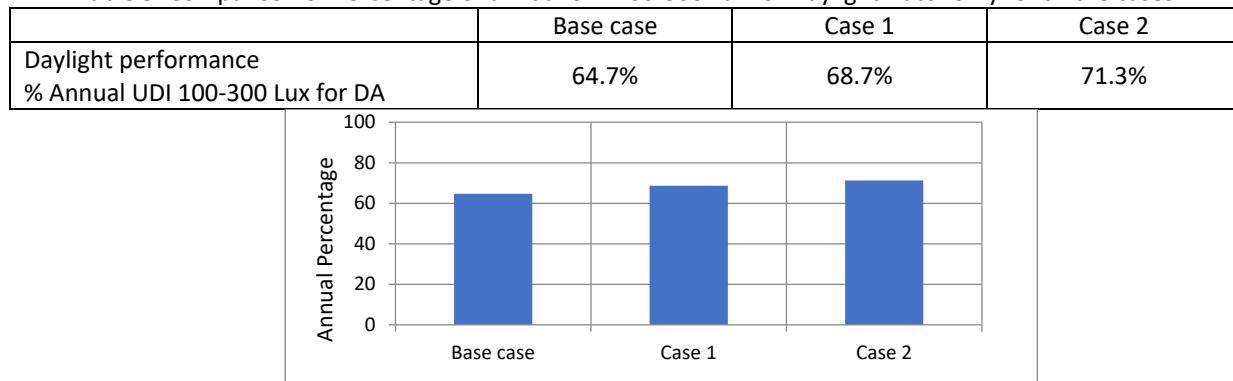

Figure 13. Percentage of annual UDI 100-300 Lux for Daylight Autonomy for all the cases

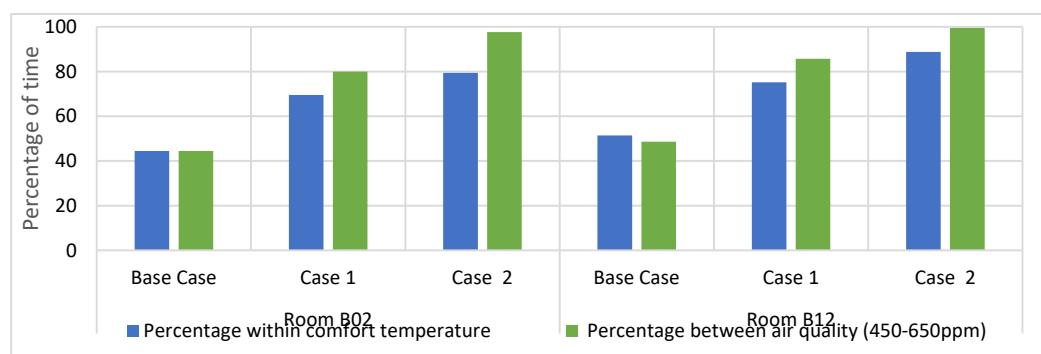

Figure 14. Percentage of time within comfort temperature and air quality

## Conclusion

In the current building, this study concluded that the atrium does not offer sufficient daylight benefits to the adjacent spaces. With proper window to wall ratio, the adjacent rooms could borrow light from the main atrium. There was temperature stratification in the atrium and occupancy density affected the temperature and air quality in the selected spaces.

The proposed atrium window options help improve the daylight level, the annual percentage of time within comfort temperature and desirable air quality. This paper concluded that through proper atrium window design, the thermal and luminous environment of the adjacent spaces facing the atrium can be significantly improved, and as a result, it is expected that overall energy consumption can be substantially reduced and the comfort conditions can be much improved.

## Evaluating indoor environmental performance of laboratories in a Northern Nigerian university

Sani Muhammad Ali<sup>1</sup>, David Brett Martinson<sup>2</sup> and Sura Almaiayah<sup>3</sup>

<sup>1</sup> PhD Candidate, School of Civil Engineering and Surveying, University of Portsmouth, UK.

<sup>2</sup> Senior Lecturer, School of Civil Engineering and Surveying, University of Portsmouth, UK.

<sup>3</sup> Senior Lecturer, Department of Architecture, University of Salford, UK.

**Abstract:** Poor environmental comfort in learning spaces can have an impact on the learning capacities of students. It is not unusual to find learning spaces in Nigerian higher institutions in which the indoor environmental qualities do not meet the occupants' requirements. Despite being in the tropics, where solar radiation is in abundance, Nigerian building industry professionals pay little attention to passive energy utilization. Knowing how buildings perform in the country may appeal to their consciousness in reconsidering this situation. This paper is part of an ongoing study on comfort in higher education facilities involving lecture theatres and laboratories in Bayero University, Kano, Nigeria. Objective and subjective assessments were undertaken during the wet-warm season of August 2016. It reports the assessment conducted on two laboratories, with a view to finding how they perform environmentally in comparison to occupants' preferences and international comfort standards. Although some of the measured and calculated physical parameters, have not met the thresholds specified by ASHRAE-55 and EN 15251, the respondents expressed their acceptance of the laboratories' situations subjectively. This is not surprising as these standards are often based on experiments implemented in developed countries, where the severity of the climatic conditions and the culture are dissimilar to sub Saharan Africa.

### Introduction

Indoor environmental quality (IEQ) investigations in several buildings, such as offices, hospitals, schools and shopping malls, have been on the increase since the middle of the last century. Such an increase in the studies could be attributed to the concern of the adverse effect poor IEQ has on people's comfort and wellbeing, which potentially affects their productivity and performance (Dias Pereira et al., 2014; Heath & Mendell, 2002). As vividly captured by Almeida (2014), that it is the combination of rising indoor occupancy levels, health requirements, environmental concern, new construction practices, rising occupants' expectations, development of new indoor finishes and the desire to cut down on energy costs that led to the need of the IEQ studies. Similarly, the need to contribute to the effort of decreasing global warming in reducing energy consumption from fossils sources has led to the rise in such types of studies.

Many studies have been evaluating IEQ and analysing indoor conditions through investigating the thermal, visual and aural environments as well as indoor air quality (IAQ) (Catalina & lordache, 2012; Frontczak et al., 2012; Nimlyat & Kandar, 2015). Frequently reported poor IEQ concerns include discomfort due to high or low temperatures and relative

humidity; high level of carbon dioxide concentration ( $\text{CO}_2$ ), carbon monoxide (CO), volatile organic compounds (VOCs) and PM; inappropriate lighting levels and presence of glare and occurrence of noise. Poor thermal environment affects occupants' mental performance as well as increasing stress and fatigue among them (Auliciems, 1972). Appropriate quality and quantity of light are important to building occupants' health and wellbeing, affecting their mood, emotion and mental alertness (Salonen, 2013). Acoustic discomfort is shown to cause fatigue, headaches, annoyance, changes in behavior and attitude leading to decrease in intellectual working ability and sleep disorders (Hodgson, 2000). High level of PM was reported to increase respiratory symptoms and acute lung diseases in schools (Rumchev, 2003). Raised concentrations of  $\text{CO}_2$  is also associated with morbidity, absenteeism in school children and office workers (Valavanidis & Vatista, 2006).

Although IEQ studies including those in higher education institutions are on the increase, most of the published works deal with buildings located in temperate climate zones and mainly situated in wealthier parts of the world, and not in Sub Saharan Africa. Some examples of researches conducted in higher education buildings include (Al-Maiyah et al., 2015; Mishra & Ramgopal, 2013; Ogbonna & Harris, 2008; Ugranli et al., 2015).

Furthermore, most of the studies in higher education facilities tend to concentrate on classrooms, lecture theatres, libraries, offices, students housing, and fewer works were done on laboratories (Rumchev, 2003). The few articles published on laboratories were mostly concerned with a single aspect of the IEQ, which is IAQ. Rumchev et al., (2003) investigated 15 laboratories at the Curtin University of Technology, Perth, Australia. Ugranli et al., (2015) investigated IAQ and two comfort related variables (air temperature and relative humidity) in chemistry and chemical engineering laboratories at Izmir Institute of Technology, Turkey.

This paper therefore reports the assessment conducted on two laboratories, with a view to finding how they perform environmentally in comparison to occupants' preferences and international comfort standards. Environmental parameters were physically measured while a sample of students completed paper based questionnaires on comfort parameters.

## **Methodology**

### ***Description of the research location***

Bayero University (BUK) is a conventional university, situated in Kano, Nigeria. Kano is located on latitude  $12^{\circ}\text{N}$  and longitude  $8.17^{\circ}\text{E}$ , 473 m above sea level and in the savannah vegetated region of West Africa. Maximum temperature reaches  $39^{\circ}\text{C}$  in April and May and goes down to  $12^{\circ}\text{C}$  in December and January and it is sunny 71% of the daylight hours (climatetemp.com, 2017). Relative humidity hovers between 10% and 80% and the annual precipitation is about 700 mm. As with other parts of Nigeria, the city is faced with the problem of perennial haze/dust blown in November to February from Sahara desert.

BUK has about 30,000 students admitted within 14 faculties, undergoing various programmes from three campuses spread across the city of Kano. From the last eight years the university's landscape has been transforming by adding new structures and retrofitting existing ones. The selected laboratories for the study were chosen from the Old campus and Teaching hospital. These are, Multipurpose Laboratory (ML), used for approximately 30 hours per week by Science faculty for their level 100 undergraduate students and Phantom Laboratory (PL), used for about 18 hours per week, by the clinical students of Dentistry faculty. The characteristics of the laboratories are shown in Table 1.

Table 1: Characteristics of the Laboratories

Attributes	Multi-purpose Laboratory (ML)	Phantom Laboratory (PL)
Capacity	120 seats	40 seats
Length x width x height	20 m x 15.50 m x 3.27 m	17.8 m x 7.3 m x 3.48 m
Occupancy density	2.58 m <sup>2</sup> /person	3.25 m <sup>2</sup> /person
Wall finishes	Light paint on cement plaster	Light paint on cement plaster
Ceiling finish	White Celotex acoustic boards	White Celotex acoustic boards
Area of glazing	41.86 m <sup>2</sup> (no blinds)	19.80 m <sup>2</sup> (has internal blinds)
Glazing factor	15.76%	15.24%
Number of window-walls	Three	Two
Window-walls orientations	South, East and North	West and East
Window-wall area ratio	South 23%, East 20% and North 15%	West 16% and East 16%
Type of furniture finish	Metal/wood tops and soft seats	Metal/wood tops and soft seats
Presence and type of shading	Shaded by fins	Internal blinds and one sided verandah

### Physical Measurement

Both the physical measurements and the surveys were conducted based on procedures consistent with ASHRAE standard 55-2013. A number of instruments were used to measure the indoor environmental parameters. The spot measuring instruments were simple and hand held. They include HOBO loggers for air and radiant temperatures, relative humidity, carbon dioxide (CO<sub>2</sub>) concentration, and illumination; Trotec BZ30 for air temperature, relative humidity and CO<sub>2</sub> concentration; Testo 435-2 meter for air velocity; PCE-DT 9880 for particulate matter (PM) and Extech HD600 meter measures sound pressure levels.

Temperature, relative humidity, air velocity, sound pressure levels and CO<sub>2</sub> concentration, using the hand held instruments by the researcher, were spot measured in five locations, each for five minutes and at 1.1m above the floor. Whereas illumination levels were spot measured in nine locations at the same height. Daylight was obtained when electric lights were off and window blinds opened. Photographs of the interiors of the laboratories and points of measurements are marked on the floor plans shown in Figures 1 and 2. Though air conditioners were not in operation, ceiling fans were on most of the time and windows opened. Measurements were conducted in two situations, during occupied and unoccupied conditions. External weather data were obtained using pendants on the buildings' exteriors.

Figure 1: Multipurpose Lab. (ML)

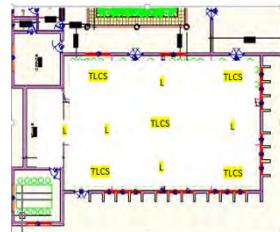

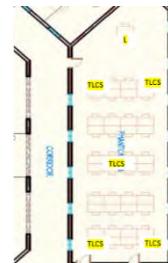

Figure 2: Phantom Lab. (PL)

NOTATIONS: T: Temperature; L: Lighting; C: Carbon dioxide concentration; S: Sound

### Subjective Measurement

In line with the capacities of the laboratories, a total of 160 paper based questionnaires were prepared, for the occupants to answer. It contains six sections covering; thermal, acoustic and visual comfort, indoor air quality and demographic information. In addition, sketches of the respective learning environments were included for the occupants to indicate their approximate sitting positions. A total of 105 questionnaires (86 and 19 for the ML and PL

respectively) were subsequently distributed, filled and collected back. The surveys were administered between 12 noon and 12:30 pm on 22<sup>nd</sup> August 2016 in the PL, while in the ML it took place on 29<sup>th</sup> August 2016 at 10:45 am. The questionnaires were answered by the students, teachers and support staff.

Typical questions on the parameters took the form of: how comfortable are you with thermal condition of this space now? How would you describe the temperature, natural and artificial lighting, noise and odour in this space? Responses required by these questions were made on a mixture of categorical (e.g. acceptable and unacceptable; comfortable and uncomfortable) and seven point Likert scales between two extremes; cold and hot; satisfactory and unsatisfactory; too much and too little; significant and not significant; pleasant and unpleasant, following the methods used in previous studies (Ai Maiyah et al., 2015; Montazami et. al., 2016).

Similarly a list of typical clothing ensembles worn by the respondents in the environment was provided for them to indicate the ones they had on. Thermal sensation vote was to be expressed on the ASHRAE standard 55 seven-point scale (e.g. cold, cool, slightly cool, neutral, slightly warm, warm and hot). This allows the evaluation of "actual mean vote" (AMV) and the dispersion regarding the "actual percentage of dissatisfied" (APD). These were compared with the Fanger's Predicted Mean Vote (PMV) and Predicted Percentage of Dissatisfied (PPD).

Table 2: Measured Internal Parameters

Laboratories		Air Temperature (°C)		Relative Humidity (%)		Illumination (lux)		CO <sub>2</sub> Concentration (ppm)		Background Noise dB(A)		Air Velocity (m/s)		Particulate Matter (per m <sup>3</sup> )	
		Unoccupied	Occupied	Unoccupied	Occupied	Day-light	Global	Unoccupied	Occupied	Unoccupied	Occupied	Fans off	Fans on	PM 2.5	PM 10
Multi purpose	Min	28.1	31.0	71.6	61.4	78	131	602	633	50.0	54.2	0.18	0.28	179	17
	Max	28.5	31.7	74.8	66.5	456	586	807	1028	50.4	62.3	0.21	0.34	222	48
	Mean	28.3	31.5	72.9	64.2	235	262	750	784	50.3	57.1	0.20	0.31	186	31
Phantom	Min	24.1	25.1	68.1	66.7	81	181	593	654	48.9	59.0	0.12	0.34	130	15
	Max	24.4	25.6	68.8	70.7	221	386	660	884	51.0	60.8	0.17	0.43	150	25
	Mean	24.3	25.3	68.4	68.8	188	286	627	727	50.0	59.7	0.15	0.40	139	17
Standards' Limits and ranges	24.5°C-28°C Summer 23.3°C-25.5°C winter (ASHRAE-55)		30-60% (ASHRAE-55)		500 lux for laboratory (EN-12464)		1200 ppm for any learning environment (ASHRAE 62-2004)		40-45dB(A) for laboratory (WHO 2006)						

Finally, demographic data of the participants was requested for the determination of their personal characteristics, which helped in developing appropriate summary statistics. In order to eliminate the impact of metabolic rate on the respondents, the questionnaires were administered in each space after 30 minutes into the laboratory sessions, adopted from previous study (Montazami et al., 2016). Similarly lighting, acoustic and air qualities parameters were evaluated on categorical and seven point Likert scales.

## **Results and Discussion**

International comfort standards' recommendations offered by ASHRAE Standard-55 2013 and EN 15251 and the grouping method followed by Almaiyah et al. (2014) were used for the evaluation of the laboratories' indoor environmental conditions. Thermal and visual comfort parameters were evaluated through both subjective and objective means. Likewise noise level was evaluated by measuring the background noise level and by asking the occupants about their aural perceptions. Indoor air quality was adjudged by measuring CO<sub>2</sub> concentration, PM<sub>2.5</sub> and PM<sub>10</sub>. It is worth noting here that, in this study however, only the singular values of PM<sub>2.5</sub> and PM<sub>10</sub> were used due to instrument limitation. The maximum, minimum and mean of the measured internal parameters as recorded during the survey are displayed in Table 2.

### **Measured Results**

Due to the differences in dates and times of measurements and the occupation situations, the air temperatures during the occupied time were generally higher, reaching 31.7 °C and 27.6 °C for ML and PL respectively. The reverse was the case with relative humidity, in ML it was higher when the space was unoccupied, reaching 74%, while the occupied figures stood at 66.5%. As with air temperature, the relative humidity in the PL was higher during the occupied time, reaching 70.7%. Air speed reached 0.34 m/s with fans on and windows opened in ML but was 0.45 m/s in PL. This variation could be as a result of the differences in the siting of the laboratories, as well as their design features and varied occupancy levels.

Light distribution in the laboratories was uneven, some locations in ML had as low as 78 lux natural lighting and 456 lux by the windows, with uniformity ratio (Emax/Emin) of 5.8:1. The daylight situation in PL was a little better, has uniformity ratio of 4.8:1. This could be due to the differences in the laboratories' compactness ratios. Differences exist in background noise levels in the laboratories, in ML had 62.3 dB(A) when occupied and PL 60.8 dB(A). Perhaps this could also be due to the location where PL was sited, being more isolated.

CO<sub>2</sub> concentration during the occupied time reached up to 1028 parts per million (ppm) in ML and was halved when unoccupied, while in PL it was only 884 ppm. These however did not exceed the ASHRAE 62's threshold value of 1200 ppm. PM<sub>2.5</sub> and PM<sub>10</sub> values respectively were 222 and 48 particles per m<sup>3</sup> in ML, but at some points they went as low as 179 and 17 particles per m<sup>3</sup>. However, these values were considerably lower in PL, which might be due to frequent use of chemicals in ML and less in PL.

### **Survey results**

The survey revealed that females accounted for 47% of the respondents, 94% were students and 89% were below the age of 25. From the clothing ensembles, clo values of 0.67 and 0.71 were calculated for ML and PL respectively (with a range of 0.5 to 0.85 clo). Metabolic rate for laboratory activity was fixed at 1.4 met (Tyler, 2013).

Generally the thermal perception in both laboratories was adjudged acceptable. From Figure 3, about two thirds of the respondents in ML reported that the space was comfortable and no one found PL uncomfortable. Despite this general acceptance, still some 8% and 21% of the respondents reported that the laboratories were "hot" or "too hot". In Figure 4, 41% and 0% reported they were "cold" or "too cold" in ML and PL respectively.

Figure 3: Thermal Acceptability

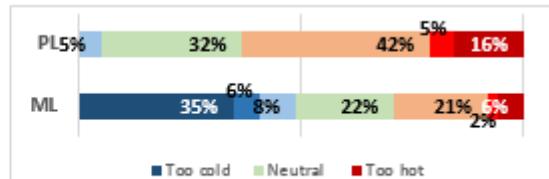

Figure 4: Thermal Sensation

On the quality of visual environment, 65% and 95% of the respondents in ML and PL respectively expressed their satisfaction with the global lighting levels as depicted in Figure 5. Similarly, only 21% and 22% reported that natural light was excessive and 23% and 17% said it was too little in ML and PL respectively. On the other hand, report on the level of glare perception as shown in Figure 6, was generally favourable, only 8% and 0% of the respondents perceived too much glare in the respective laboratories.

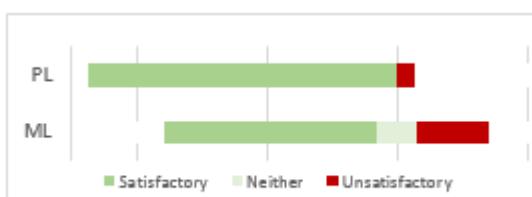

Figure 5: Global Visual Satisfaction

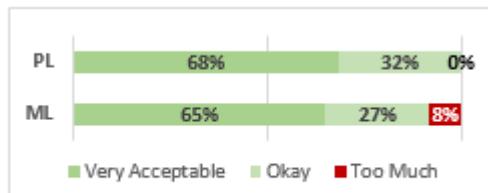

Figure 6: Glare Perception

Acoustically, the respondents showed very good satisfaction with the laboratories' background noise levels, only about 12% of those in ML showed their dissatisfaction, as depicted in Figure 7. It was concluded from the responses that the main sources of the acoustic discomfort in the ML were noise generated by their colleagues, this was reported by 43% of the respondents, while 25% of them said it was by external noise intrusion probably from traffic, as the lab is sited close to students' parking area.

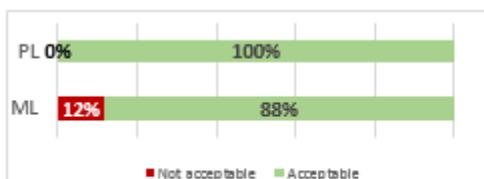

Figure 7: Background Noise Acceptability

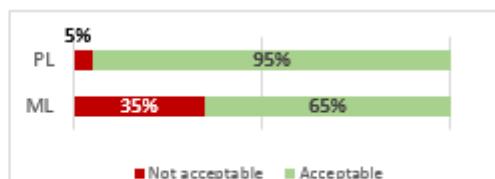

Figure 8: Air quality perception

Similarly the survey examined the respondents' perception about the quality of air in the laboratories. Figure 8 shows that there was general acceptability in the quality of air in ML, 65% attested to that, while 35% of them did not. Sources of the mild discomfort within the laboratory might be as a result of frequent use of chemicals, smoke rising from Bunsen burners, human effluents due to high occupancy level and absence of fume cupboards. However, there was an overwhelming acceptance of the air quality within PL, with as much as 95% of the respondents agreeing and only 5% showed their dissatisfaction.

## Comparison

Values of Fanger's PMV and PPD on the survey date, running mean, and operative and comfort temperatures for the laboratories were calculated. The values of the PMV stood at

+1.43 and +0.79 while PPD results were 47% and 18% respectively for ML and PL. These values indicate that the overall thermal sensation in both laboratories was warm, as laid out in the provisions of ISO 7730 (ISO, 2005). On the other hand, the AMV from the survey reported mixed perceptions, with -0.81 (cool) and +0.95 (warm) in ML and PL respectively. This therefore calls for further study. However, the calculated comfort ranges, according to EN 15251 (CEN, 2007) for buildings type II in ML, stood at 25.1°C to 31.1°C, while in PL it was 25.2°C to 31.2°C. This signifies that EN 15251 could perfectly be used in predicting thermal conditions in Kano, as reported by Mishra and Ramgopal (2015).

According to EN 12464 standard (CEN, 2011), global lighting levels in laboratories should be above 500 lux. The lighting situations in both laboratories were therefore insufficient, having averages of 262 and 286 lux. However, the survey results indicated otherwise. More than two thirds of the respondents were happy with the global lighting situations in both laboratories. Having higher lux and with greater percentage of respondents showing more satisfaction with the global lighting situations in PL, it revealed that PL was visually a preferred space. This could be attributed to PL's compactness, window height above the floor and the presence of high furniture in ML that restricts the passage of daylight.

Measurement revealed that the highest CO<sub>2</sub> concentration of 1028 ppm was found in ML, although it seemed high, it was however within the limit specified by ASHRAE 62, which is above 1200 ppm. Although the CO<sub>2</sub> concentrations in both laboratories were within the ASHRAE threshold, yet about one third of the respondents in ML reported their dissatisfaction and 5% in PL. This showed the subjectivity of comfort, which concurs with findings of Ugranli et al., (2015). The average background noise levels of 57.1 dB(A) and 50.0 dB(A) respectively found in ML and PL, though seemed low, but were found to be higher than the limit of 35 dB(A), as laid out by WHO (WHO, 1999). On the contrary, the respondents indicated their acceptance of the situations, only 12% of them were not satisfied with the aural conditions in ML, while 11% were undecided in PL.

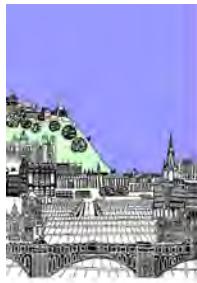

## Conclusion

The study, aimed at investigating IEQ in two laboratories in Bayero University, Kano, Nigeria, was conducted during the wet-warm season of August 2016. The scope included the comparison between experimental and surveyed data of the laboratories as well as against thresholds of relevant international comfort standards. Various physical parameters were measured which culminated into calculating some comfort indices. Concurrently, the occupants of the laboratories were subjected to a survey to determine their actual comfort perceptions. In line with the results obtained by some previous IEQ researches, this study, though part of a larger and longitudinal field work, also found discrepancies between measured and surveyed data, as well as with the comfort standards. Generally the results of the measured parameters were found to be higher than most of the standards thresholds with exception of CO<sub>2</sub> concentration. This divergence may not be unconnected with the situations of the dominant climatic conditions of the region at the time of the work. However, the survey data results showed acceptance of the indoor conditions of the laboratories by the respondents. Both the measured and the surveyed data of the PL were more consistent and acceptable to the respondents than those of the ML. This disparity may be explained by the compactness of PL and the siting of the two laboratories. PL is sited at the Teaching Hospital campus, though within the heart of the city, it is placed deep inside the campus and therefore buffered from the city traffic. ML, on the other hand, is sited at the Old campus and very close to the students housing parking area. It is therefore worth noting that good siting,

compactness, wide and operable windows as well as control of occupancy levels need to be taken into consideration when setting up a laboratory in the tropics.

## Measuring and presenting real time environmental indicators for optimised building performance

**John Allison, Joseph Clarke, Jeremy Cockroft, Anastasios Markopoulos, Aizaz Samuel**

Energy Systems Research Unit, Mechanical and Aerospace Engineering, University of Strathclyde, UK

**Abstract:** Building stock upgrade regarding both rebuilding and retrofitting has significant scope for emissions and energy reduction. Rebuilding may be favoured because of higher confidence in stricter current regulations than original. Retrofitting is more cost effective because of lower economic implications, faster turnaround times and less occupant disturbance. Retrofitting is possible at similar or higher level than legislation mandates but needs to be empirically proven. One method is to pervasively sense indoor conditions before and after retrofit. Comparisons can then made after compensating for weather conditions during monitoring periods. Independently developed calibrated dynamic simulation models can be used to benchmark expected performance improvements. Results may be relayed to interested parties in a format easily understandable by personnel not cognizant of building physics. This approach was deployed for buildings located in Greater Glasgow and managed by Glasgow City Council (GCC). Internet of Things technology was used for capturing data related to weather parameters, internal temperatures and humidity levels. Quantitative results and qualitative high-level observations were encapsulated within a software tool; training in use of which gave the Council means to independently and confidently assess quality of retrofit implemented by their contractors.

**Keywords:** Retrofit, Internet of Things, Pervasive Sensing, Modelling

### Introduction

The European building stock presents tremendous potential for reducing emissions and energy use. Another encouraging factor is that a major proportion was built before energy efficiency was fully introduced in building standards and consequentially presents a large room for improvement. Energy and emission benefits that can be realised by retrofit and rebuild – collectively called upgrading – for reduction of energy use also provide encouragement for economic growth in this sector. Resolution of the issue involves disciplines of building science, statistics, economics and social science and knowledge of trends in governmental guidelines and initiatives. Pilot projects have shown promise but technological and social barriers are such that successful upgrading efforts need to satisfy a large number of multivariate and often conflicting requirements. Consequentially quality of upgrading may be compromised thereby undermining the whole process.

It has been shown that upgraded buildings have lower embodied energy and can perform almost as well as new homes (Boardman et al., 2005). However, previous studies and findings from monitoring of upgraded houses have shown it is unusual that desired outcomes are obtained (Hong et al., 2006). Reasons for these shortfalls range from policy issues to technical problems and misunderstanding of social behaviour.

Most building stock improvement mechanisms are sponsored by government initiatives that promote efficiency upgrades and renewable technologies (Clarke et al., 2008). However, effective implementation is tricky because of large variability in age, composition, quality of build and use. Novel technologies such as distributed local renewable energy and fuel generation, smart grids and carbon capture methods are rapidly evolving. These may have a direct effect on energy performance of buildings but have not been well researched and established yet. There are gaps within existing upgrade practices with lack of skills and training being quoted often.

Although there have been some successes (URL 1) a large number of projects fall short of expectations. Negative outcomes have serious implications because the amount of investment and projected returns are large e.g. the estimated return for the US is \$1trillion over 10 years (Rockefeller Foundation and Deutsche Bank Group 2012). Similarly, Ernst & Young (2010) have estimated between \$25 and \$99 million in total economic activity in New South Wales. Figures for Europe can be expected to be comparable if not higher because it has a much older building stock than either of Australia or America.

Although some upgrading studies exist these have mostly relied on qualitative measures and arbitrary grading scales to determine feasibility of building upgrading (e.g. Caccavelli and Gugerli 2002). Some studies also report economic analysis (e.g. Kumbaroglu and Madlener 2012). Almost all studies use a particular type of building as a case study and some variation in the input data model is manually generated to be representative of a particular stock subset. A large number of optimisation scenarios are possible and different optimisation techniques used to determine a feasible set (e.g. Kaklauskas et al., 2005). Findings mostly focus on either energy or economics. Analysis of relevant domestic tools was conducted by Mills (2004) who evaluated 65 tools and found lack of content required for decision-making. Additionally he noted significant redundancy and fragmentation as well as inconsistencies.

One method for adequately assessing the energy implications of retrofit operations is to conduct pre and post retrofit conditions monitoring of a representative sample and extrapolate beneficial outcomes to the entire housing stock. Findings can then be encapsulated within a bespoke tool and training provided to interested parties. This is described in the remainder of this paper.

### **Data collection using pervasive sensing**

65,000 dwellings in Glasgow have a poor to moderate National Home Energy Rating (NHER) (SHSC, 2012). Installing or upgrading insulation is one of the most effective ways to improve the energy efficiency of these buildings and the Energy Saving Trust estimates that an uninsulated dwelling loses a third of all heat through the walls. As a result, insulation can significantly increase thermal comfort and reduce heating bills.

Consequently a low cost method for the assessment of upgrades applied in the urban context was developed. It comprised the monitoring of a representative sample of 65 dwellings and insulation upgrade approaches, with computer modelling studies used to undertake assessments and extrapolate beneficial outcomes to the entire housing stock. The project set out to test four hypotheses relating to demonstrating the usefulness of good quality building upgrading. It was hypothesised that:

- sensors can be deployed in dwellings to enable a low cost and rapid confirmation (or otherwise) of the efficacy of insulation upgrades;

- occupants will accept the imposition of short-term indoor monitoring in return for useful feedback or remedial action where appropriate;
- future upgrades will benefit from mandatory monitoring applied to a representative sample of the estate being targeted; and
- the quality assurance of upgrade programmes can be supported by the existence of openly available evidential case studies.

These hypotheses have been examined in relation to dwelling upgrades being undertaken within eight districts in the city of Glasgow. The buildings monitored had a range of characteristic types and age bands typical to the city. In brief, the properties consist of:

- ground and top floor flats of 4-in-block properties;
- ground, mid and top floor flats in tenement and high rise apartments blocks and two storey maisonettes; and
- semi-detached single and two storey dwellings.

Upgrade measures consisted of application or improvement of one or more of internal or external wall insulation, underfloor and/or loft insulation and double-glazing. The dwellings were mostly occupied by between one and three adults some of which were in full time occupation. A few dwellings had children. Figure 1 shows typical dwellings.

Figure 1 Typical uninsulated property (left) and externally insulated property (right)

Monitoring of these dwellings included a pre-upgrade and a post-upgrade period. It was made sure that monitoring was conducted within the heating season as far as possible. The upgrades involved real world complexities stemming from occupant behaviour, changing weather conditions, construction scheduling, privacy impacts etc. therefore it was necessary to adopt an approach that could normalise for such factors. The following steps were taken to ensure confidence in the measurements:

- initial deployment was at least one week prior to upgrade works commencing
- sensors were placed away from windows and doors and out of reach of children
- occupants were advised not to move the sensors
- occupants were advised not to disconnect power to the loggers
- sensors were removed after second post-upgrade meter reading

In the case of insulation upgrades undertaken in the summertime, it was necessary to arrange for the pre- and post-upgrade monitoring to take place during consecutive heating seasons. Where this was not possible post-upgrade monitoring still provided a valuable indication of the internal environmental conditions after insulation deployment and highlighted concerns where temperature and relative humidity measurements exceeded recommendations. Other factors affecting post-upgrade energy saving calculation include:

- occupants taking a holiday so that the property is unoccupied for several days; and
- periods of high outdoor temperature (normally during the Spring/Autumn) causing the heating system to switch off and internal temperatures to rise above normal controlled levels.

A weather station was installed at each site. The station transmits air temperature and humidity, and is located in a secure location sheltered from solar radiation. The real-time basis of the insulation upgrading programme meant that each upgrade began almost immediately after the occupant has agreed to take part, so before-and-after monitoring was not always practicable. Where possible, before-and-after and side-by-side comparisons of upgrades were undertaken.

Figure 2 A typical monitoring installation

The equipment required to monitor indoor conditions comprises two combined temperature and humidity sensors located within each dwelling, each with a built-in low power radio transmitter. Figure 2 shows a typical installation of sensors. A single radio receiver associated with each group of dwellings collects data from each sensor at 5-minute frequency. The receiver records the readings and these are then downloaded periodically. Sensors within properties have to be positioned in such a manner as to obtain a reasonable measure of temperature and humidity, but at the same time be unobtrusive to occupants and not susceptible to interference. To provide consistent measurements of room conditions, it was also necessary to ensure that each sensor is not moved significantly away from its location during the monitoring period, particularly if a property is insulated during that period. Small adjustments may be made to sensor readings to simulate a centre-of-room positioning. In each dwelling, one sensor was installed in a living or bedroom area, and a second sensor in a kitchen or bathroom depending on where high humidity levels are likely to be experienced. Figure 3 shows typical sensor/transmitter and receiver equipment.

Figure 3 Typical sensor (right) and receiver

The sensor is capable of wireless communication with the receiver. The receiver that has some local memory doubles up as logger. The receiver also has a router and server built into it. Details can be found in Clarke and Hand (2015). In addition to condition monitoring utility meters were also read for the pre- and post-upgrade period.

## Results

Figure 4 shows temperature recordings that are obtained from monitoring of two dwellings over a period of a few days. The most dominant variation that can be observed usually follows the daily fluctuations of outside temperature ( $T_{ext}$ ). There is a wide variation in temperatures possibly due to occupant behaviour despite these being similar properties. The property SH4, with occasional daily peaks in the kitchen most likely due to cooking activity, exhibits a distinctly higher temperature than the other does. Various occupant and heating system behaviours may be deduced by inspection of the graphs – some examples are highlighted on the figure.

Internal humidity levels are strongly related to internal temperature. A rise in temperature will lead to a fall in RH, without any moisture addition or removal. Considerable variation exists between properties, although most fall in the range 40-60% RH. Consistently high values of RH should be investigated, particularly after the property has been insulated, to ensure no internal condensation problems are occurring, particularly at cold bridges.

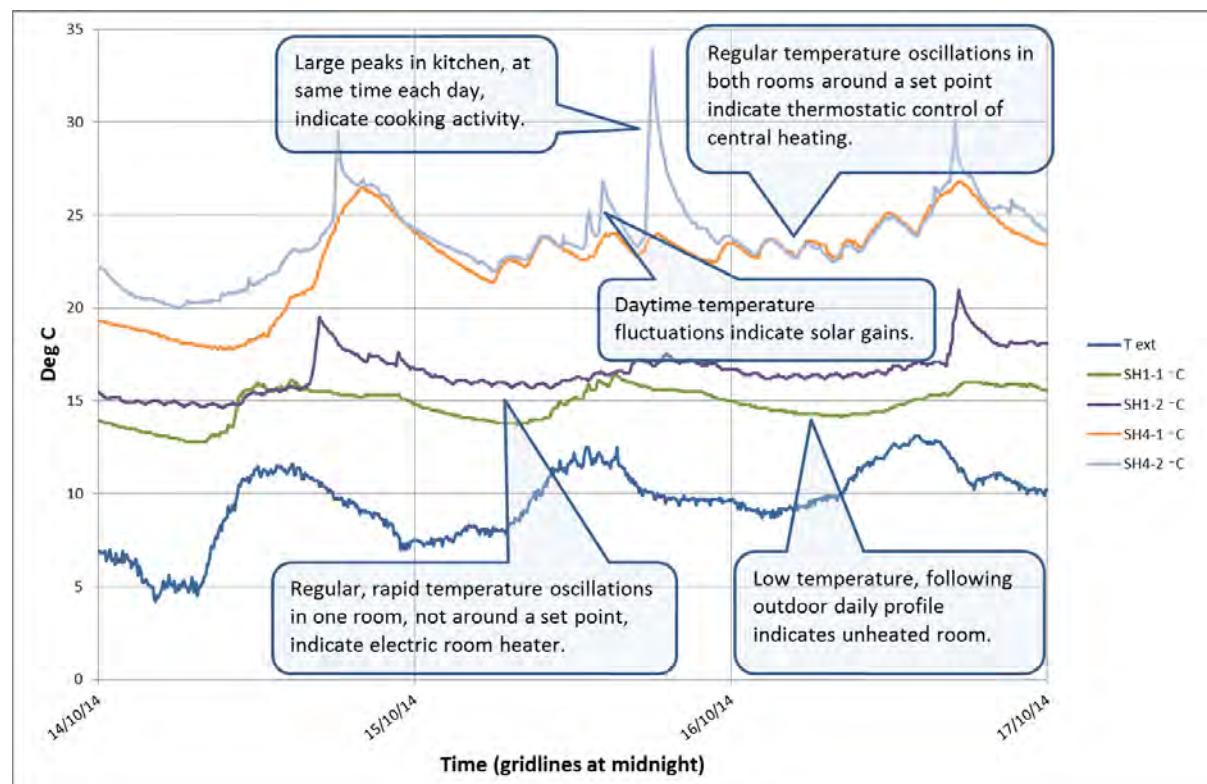

Figure 4 Typical temperature recording and observations for two properties SH1 and SH2 (for both indoor sensors 1 and 2)

The acceptable range of temperature is what the “average” occupant would report as being comfortable; in this case, the range is 19°C to 23°C (CIBSE, 2006). The same document also defines an acceptable RH range from 40% to 70% RH. Note is made of any notable fluctuations out with these limits, and their duration. Generally, short duration fluctuations do not cause problems. Longer duration fluctuations may need to be investigated.

One dwelling was found to exhibit variations in RH of up to 80%. It was known that the resident is disabled, and this might have a bearing on the data pertaining to this property. This property had been insulated, so an investigation might be called for here to ensure no internal condensation problems are occurring, particularly at thermal bridges. An example of a thermal bridge is shown in Figure 5 where insulation has been omitted around a gas meter and pipework.

Another property exhibited severe mould growth problems on the inside surface of the outer walls (Figure 6). Closer inspection revealed that mould had formed on the double glazed window seal, suggesting that condensation had been forming on the inner pane of the window. This suggests that the problem is condensation, not a building fault. The recorded data showed particularly high humidity levels regularly exceeding 80% RH. The dwelling will benefit from additional ventilation (opening windows perhaps) when cooking, bathing or drying clothes indoors. While the insulation applied to this property reduced the condensation problem on the walls, further inspection would be required to detect if any residual cold bridges had been created during the insulation process, as this could become a problematic source of hidden dampness.

Figure 5 Thermal bridge due to non-insulated section around a gas pipe and meter box and meter box

Figure 6 Occurrence of a severe mould growth problem on inside of windowsill

### **Environmental conditions analysis from monitored and modelled information**

Upgrades were assessed in terms of energy and indoor environment quality. The energy consumption measured during the monitored periods was used to estimate the annual energy saving because of applying the upgrades. This saving was compared with a benchmark saving estimate calculated using calibrated computer modelling after compensating for changes in external conditions during the whole process.

High humidity and temperature levels were diagnosed as shown in Table 1.

The diagnoses will be tempered by correlating the observations with maximum occupancy levels and average outside temperature and humidity conditions. For example, a high internal humidity level in winter when external humidity is high is of lesser concern than when external humidity is low. High internal humidity peaks are of less concern if occupancy is high. A priority rating system was proposed that, as a demonstration of a potential energy-related service, could be generated through automated data analysis via an intelligent agent.

Table 1 Environmental data.

	Temperature	Humidity	Energy use	Potential diagnosis
1	High for extended periods	Any	High	Poor temperature control / wasted energy.
2	Low for extended periods	Any	Low	Fuel poverty alert.
3	High peaks	High peaks	Any	Poor ventilation during cooking / bathing
4	Medium	High for extended periods	Any	Poor ventilation at all times / internal clothes drying.
5	Low	High	Any	As 3 with high internal condensation risk
6	Wide range	Low / medium	High	Excessive ventilation (maybe window opening).
7	Low / medium	Any	High	Check for thermal bridges.

### Front end graphical user interface

A Post Operations Evaluation Tool (POET) was developed to provide a method for the automatic confirmation of the quality of an insulation upgrade. This provides an evidence-based quality assurance test of the upgrade that supports project sign-off. The tool requires basic information on the property such as its archetype, construction, occupancy, floor area, upgrade type, and a suitable weather station location to be used in the analysis. It utilises meter readings and monitored indoor conditions data in order to assess the insulation upgrade. Feedback is provided based on analyses relating to energy performance and post-upgrade internal environmental conditions.

Based upon the property details a predicted energy performance benchmark is selected from a database of ideal performance benchmarks as determined from dynamic computer simulation. The pre- and post-upgrade energy consumption of the dwelling, determined from meter readings is normalised using the relevant outdoor temperature data from the selected weather station. This determines the savings achieved by the property's upgrade. The benchmark saving is compared to the actual saving achieved to determine how close the property came to achieving its theoretical value. This information used alongside the property energy survey data allows an assessor to determine if the upgrade has achieved its goal.

Textual feedback from an underlying environmental conditions assessment algorithm is also provided. This algorithm assesses the post-upgrade indoor temperature and humidity profiles as monitored in order to determine if these are within acceptable ranges. This allows the assessor to identify acceptable indoor environmental performance post-upgrade and isolate possible causal factors where this performance is deemed unacceptable. Details on the energy and environmental assessment algorithms are available from within the interface.

The assessment section of the tool launches the evaluation of the algorithms, and generates a compliance report. The report provides a summary of the dwelling's performance along with any recommendations for follow-up action.

In order to test the operation and application of the tool, it was deployed within the GCC's Housing Strategy Group and subjected to user trial using sample data as collected within the project and representing different possible upgrade outcomes (acceptable,

unacceptable and ambiguous). Training in the use of the tool allowed the assessors to easily assess quality of retrofits and generate compliance reports.

## Conclusions

It was shown that a pervasive monitoring approach is useful in appraising the quality of retrofit for domestic buildings. Results from pre- and post- retrofit monitoring of internal and external conditions and energy use were used to ascertain whether upgrades had been applied to an acceptable level or otherwise.

Patterns of temperature and humidity fluctuations and their correlation with external conditions and information about building use was used to determine additional features of the dwellings and their use. Such analyses can show problematic environmental control, fuel poverty, poor or excessive ventilation, risk of condensation and thermal bridging.

## Acknowledgement

Acknowledgement is made to the Engineering and Physical Sciences Research Council, UK for providing funding for this research within their pervasive sensing for collaborative facilities management project. The authors are also grateful to the Glasgow City Council for providing information from their refurbishment scheme to be made available for research purposes in order to deliver better quality assurance for the scheme.

## A New Parametric Framework: Developing Design Options in Real Time

Mohamed Aly Etman<sup>1\*</sup>, Naomi Keena<sup>2</sup> and Anna Dyson<sup>2</sup>

<sup>1</sup> Center for Architecture Science and Ecology (CASE), Rensselaer Polytechnic Institute, New York City/Troy, USA, \*Email: alyetm@rpi.edu.

**Abstract:** Current architectural design practice is limited in its consideration and understanding of life-cycle energy flows which comprise multiple phases, from material resource extraction, construction, building occupation within the built environment, and after demolition. Furthermore, bioclimatic environmental flows interact with the buildings, particularly at the building envelope, making it a rich interface for shaping energy flows towards buildings that are energy self-sufficient with clean on-site energy resources. The buildings we inhabit directly affect the greater built environment which is an inherent part of local ecosystems which compose part of larger ecologies at global scales, ultimately affecting the overall biosphere. As a result, the buildings we construct, directly and indirectly, affect our economies, the health, and well-being of our societies and our natural environments. This paper explores the development of a computational framework that provides architects and designers direct feedback on design performance at the schematic design stage. This allows designers to visualize, understand and evaluate their design choices in terms of their environmental implications and ecological efficacy. This framework for design analysis offers a more comprehensive ecological analysis than existing sustainability assessment tools, by considering the entire temporal building process. Working with Rhino/Grasshopper as a widely-used software platform allows for interactive feedback to architectural designers as they develop design options in real time. This paper will use a case study, assessing a solar decathlon house, demonstrating the qualitative and quantitative environmental impacts of the building design.

**Keywords:** multi-disciplinary, parametric modelling, building performance analysis, tool development.

### Introduction

Current architectural design practice is limited in its consideration and understanding of life-cycle energy flows, which comprise multiple phases, from material resource extraction, construction, to building occupation within the built environment (Keena, et al., 2016). Furthermore, bioclimatic environmental flows interact with the buildings, particularly at the building envelope, making it a rich interface (Schumacher, 2012) for shaping energy flows towards buildings that are energy self-sufficient with clean on-site energy resources. The process of constructing and operating buildings often leads to environmental outcomes that are not nourishing<sup>1</sup> to either physical or social ecosystems (Graham, 2009). Due to the siloed structure of the building industry and the endemic lack of environmental awareness among building professionals and the industry as whole, the process of delivering built environment systems has played a major role in the decline of Earth's ecological health (Hancock, 2011). Our built environments (Koren & Butler, 2006) are in fact built ecologies (Dyson, 2011) (Winn,

<sup>1</sup> According to the U.S. Energy Information Administration (EIA), the building sector consumes (47.6%) of all energy produced in the US, and 74.9% of all the electricity produced is used just to operate buildings. Therefore, the building sector is responsible for 44.6% of US CO<sub>2</sub> emissions in 2010.

et al., 2012) in that they are part of larger interdependent global ecosystems and they, directly and indirectly, have significant effects on our populations' health and well-being, our economies, and on global biodiversity (Raupach, et al., 2007) (Odum, 2007).

The innovation of built ecosystems that can sustain and be sustained by resilient, biodiverse, living systems is urgently required. This research aims to develop an approach towards protecting the life-supporting goods and services of ecosystems (Bakshi, 2002; Keena, et al., 2016) and providing the basis for sustained life opportunity on Earth by offering accessible information and feedback during the design decision-making process. This research is supporting the development of a novel visualization framework that characterizes both the characterization of thermodynamic as well as the ecological performance of the building systems (Aly Etman, et al., 2016), and the possibility to reshape the role of the building professional (architect) from one who directs the implementation of a structure, to one who designs and implements a system of relationships between ecosystems and human systems within the built environment. The eco-systemic integration across systems has become extremely difficult to achieve under the current paradigm, as the architecture, engineering, and construction (AEC) industry invested enormous resources towards the development of a building design and implementation process that separates consultants on the same design team, in order to clarify spheres of responsibility and to defend against liabilities.

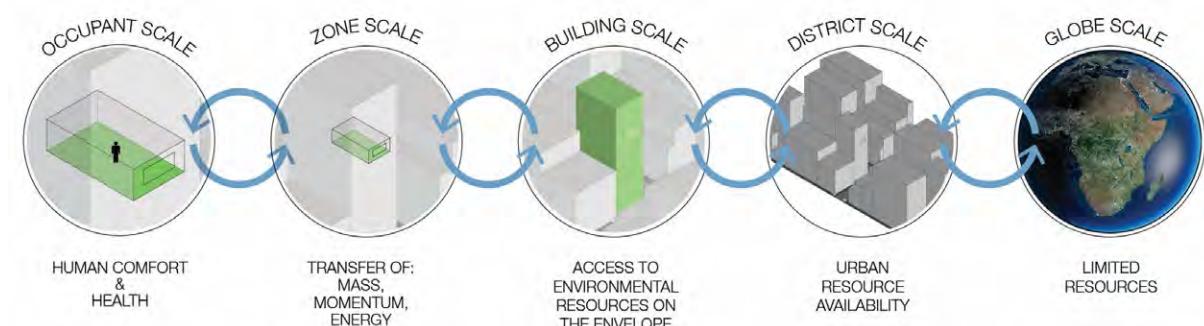

Figure 1 Our built environment is part of a larger global ecosystem affecting our global economies, our health and well-being, and our natural environment, i.e. Built Ecologies.

By contributing to explicate built environment systems, this research intends to help facilitate a transition from the mechanical paradigm (Kuhn, 1962) towards an ecological paradigm (Bateson, 1972) (Fernández-Galiano, 2000). This framework will provide architects facts and knowledge about the environmental influences on their design decisions and the interdependencies between the building next generation systems and nature, and will offer new approaches on how to achieve comfort with nature (Aly Etman, et al., 2016).

## Background

The building process is slow, expensive, and risky. Data is increasingly fast, cheap, easily accessible and seems to offer the hope of providing new levels of certainty on complex problems. A widespread paradigm shift has occurred in design thinking whereby performance requirements have far greater influence on the decision-making process, however, access to reliable and extensive data during critical phases in the decision making has been difficult to achieve. In architecture, generative computational frameworks can support systems design exploration and expand the solution space for a multitude of formal iterations while satisfying

and optimizing performance requirements (Winn, 2014). This paradigm also promises the designer the power to work through generative systems processes through parametric computation. This approach is identified as ‘Generative Performative Design’ whereby both form and performance requirements drive the generation process (Fasoulaki, 2008). The use of building performance simulation tools by design professionals has become a fundamental way to support design decisions for energy efficient buildings. Yet there are now so many environmental claims, simulation tools, and metrics that architects need a context within which to evaluate them in order to advance the conceptual design phase of high-performance buildings. Despite the plethora of environmental analysis tools, contemporary approaches to design are still often based on economic determinations of value, in which environmental contributions and renewable resources are almost entirely discounted or even considered free. In the context of these considerable challenges, a novel comprehensive and synthetic workflow environment is proposed that AEC professionals can use from the earliest and most impactful stages of design onwards to generate initial decisions that are environmentally responsive.

Recent studies have discussed the potential benefits of better integrating environmental analysis and building simulation into the design process (Weytjens, et al., 2012). Weytjens has demonstrated that the interface and input method should be intuitive; thus proprietary modeling rules must be avoided. In addition, energy analysis tools should harmonize with architects’ typical working methods to add value to the architectural design process. Architects used to be restricted by what they could calculate. With new computational tools, architectural practices can model, understand and simulate the flows. Currently, the development of such tools is booming. However, since the built environment with its complex matrix and fluxes is a giant information-rich interface, the resulting outcomes have become overwhelming. These databases present numerous challenges for visualization, interaction, and participation for the designer and the public. For example, a significant amount of effort and time is often spent organizing the data before extracting any analysis to infer new knowledge from them. This research proposes a framework to allow architects to handle, visualize and interact with the spatiality and complexity of current and new buildings.

### **Previous Efforts**

In order to investigate the impact of design decisions properly, we should examine the temporal energy flows at the pre-building, building, and post-building phases. The existing tools and software available were developed with one aspect of the problem in mind, so they do not fully support the integrated design process. However, the resulted calculations are still challenging and tedious, and best practices for analysis are not well defined or propagated. Current tools, such as Energy Plus, Radiance, Sefaira and so on, can help predict and project the impact of our proposed (design) building, but they only focus on one phase: either the material lifecycle or the operational energy. This disconnection is forcing the investigator to use multiple tools, which increases the effort needed and invites errors. Eco-centric views and techniques are crucial for appreciating the contribution of ecosystems to all human activities and meeting the challenges of sustainable development.

## Proposed Solution: Integration Of Design And Analysis In A Parametric Environment

This paper is built on research that uses disciplinary-specific methodologies for data collection and analysis but employs a mixed method feedback loop for collaborative design and integrated system evaluation.

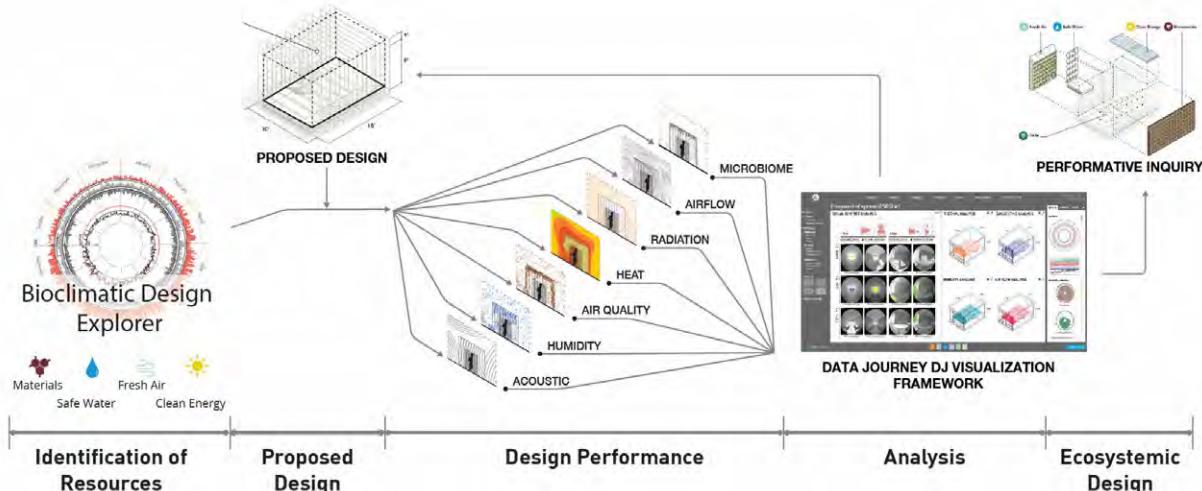

Figure 2 Proposed design and evaluation framework. Feedback loops between all three scales highlight the importance of inter-scalar design strategies.

Parametric modeling tools have recently introduced a new modeling and design approach to the architectural community. Parametric modeling, by nature, is based on data; connections and changes between different levels of evidence (data) are instantaneous. This method provides multiple benefits for integrating design and analysis. The ability to visualize environmental analysis data within the design platform allows designers to make clear connections between data analysis and design. Within the parametric platform of Grasshopper3D, the visual programming language and environment for Rhinoceros3D, building details, which are generated from the base geometry, remain as layers of the base data. When optimization of the base geometry occurs, which is appropriate for environmental analysis modeling, the parametrically-linked details automatically update. A single model is used for both the design model and the analysis model, facilitating a smoother, more integrative and efficient workflow. The proposed framework, shown in Figure 2, is intended to leverage the popularity and ease of use of existing plugins that allow interfacing validated software, i.e. Ladybug and Honeybee, by extending their capabilities so they can analyze the projected impacts of the proposed design on the environment.

### Case Study

To test this framework, a case study, based on the guidelines of the solar decathlon houses (U.S. Department of Energy, 2002), was proposed as a foundation for designing a net-positive, solar powered residence and adapted that model to fulfill the research objectives better. This house was designed to be placed in Paris, France and followed the design limitations of a solar decathlon house. A house that wins the solar decathlon could easily be (and has been in the past) a black box of solar panels, but this research calls for a higher standard of performance relative to human health and comfort, ecological health, and systems intelligence.

### **Step1: Identification of resources**

The first step, the identification of the available resources, within the proposed framework required the development of a visualization strategy which builds upon existing radial graphical layouts to contribute customized techniques for exploring patterns in multivariate weather datasets. Shown in Figure 3, the 'Climate Clock' design tool accompanied by a series of smaller 'Fob Clock' visualizations, present a multi-faceted interactive visual representation of multiple aspects of climate synthetically. The 'Fob Clocks' are designed and implemented to allow the user to explore and investigate the various potential bioclimatic design approaches based on specific weather data imported as Typical Meteorological Year (TMY) datasets. The Climate Clock represents the annual weather data both cyclically and linearly, via a zoom function which allows the user to explore a specific range of the cyclically represented data in a linear fashion. The Fob Clocks, a group of radial area charts, and a Psychrometric chart supplement the visualization with bioclimatic analyses that direct the user to identify the existing resources.

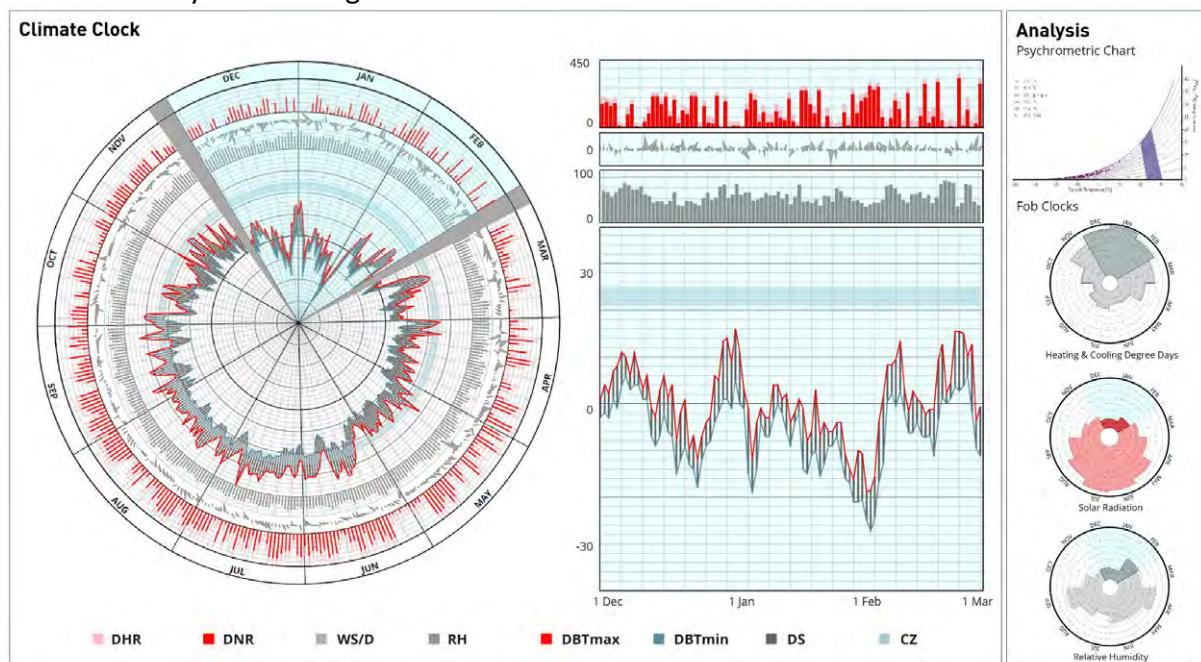

Figure 3 The Climate Clock tool.

### **Step 2: Developing a design:**

In order to investigate the proposed framework, a schematic design of a solar decathlon house for an artist in residence has been selected, shown in Figure 4, which created some additional design criteria. For example, it brings the house into an interesting category somewhere between residential and commercial. There is a greater need for calibrated lighting conditions, additional plug loads, and a re-invention of the typical occupancy schedule.

It utilizes layered active and passive systems to create a data collecting, energetically net-positive house that is thermodynamically and visually comfortable while fostering productive, creative, healthy occupants. The design objective was established to achieve a net-positive, solar powered residence. The design ecosystem was designed to harvest and metabolizes solar energy, to thermo-regulate its internal temperature in healthy and efficient ways, to utilize biomechanical lungs to produce fresh air from within, to manage energy flows

between the environment and occupants intelligently, and to contribute to the health of the ecology at large.

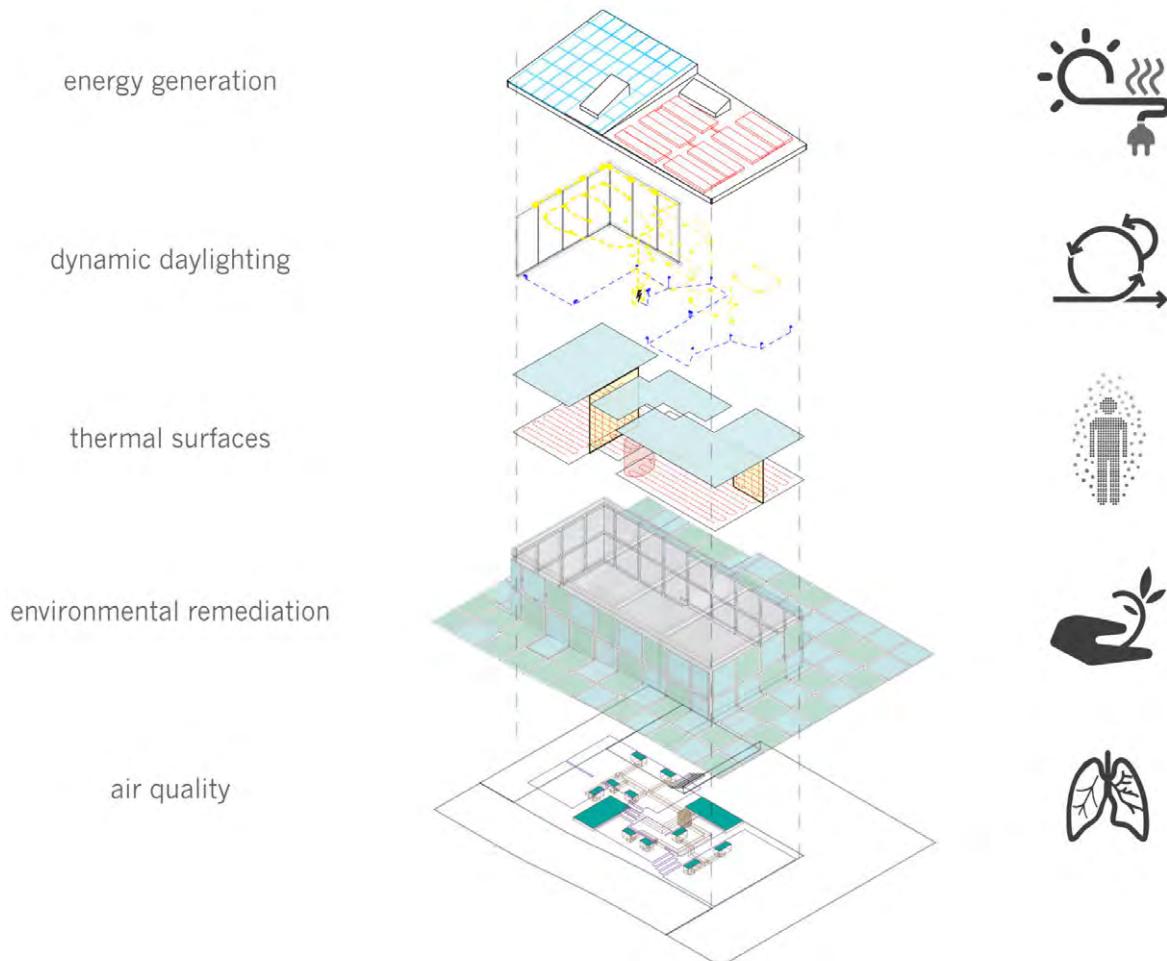

Figure 4: Diagram of the proposed design and the selected mechanical systems.

### **Step 3: Design performance:**

The next steps are to investigate the resources (climatic), selected systems performance, and their interdependency. By analyzing a matrix of system behaviors, the framework will help the user to understand which systems are most effective for the selected climate. In this case, we studied how various behaviors affect the relationships between climate inputs, building demand, resources, and performance criteria. Moreover, then proceeded to select and develop nested systems that meet our energetic performance criteria as well as human serviceability, comfort, and control criteria. The performance of the selected systems is simulated using Energyplus v.8.4 through grasshopper plugins (i.e. Ladybug, Honeybee) for the proposed design. The simulation outputs in (Figure 5) show the parameters of investigation alongside the criteria of analysis.

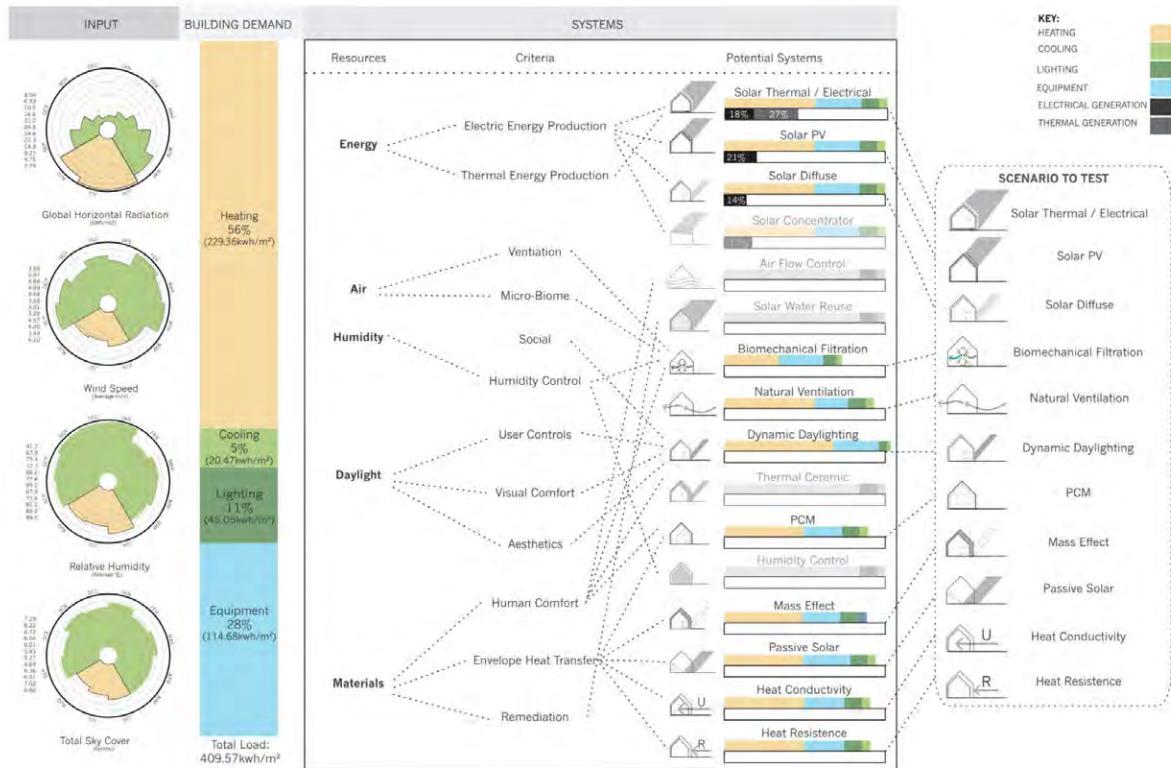

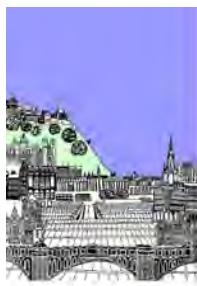

Figure 5: The analysis of systems integration of the different cases in ( $\text{kWh}/\text{m}^2$ )

## Conclusion and Discussion

Current building research and development frameworks view the architect as the one who directs the implementation of a structure. However, with increasing access to data and modeling attributes, the architect within the proposed research framework has the agency and opportunity to foster a system of relationships between ecosystems and human systems within the built environment under critical broadened performance criteria. The aim of the research is to develop a parametric framework that can be flexibly scaled for testing multiple building typologies, current and next generation systems. The framework will empower the designer to design climatically responsive buildings that can not only achieve thermal comfort for occupants, but that can also make significant reductions in energy consumption in heating and cooling, and the spread of air pollution. Such a tool would help architects develop built ecologies that will allow for buildings to function as ecosystems working with their microclimates. The parametric tools should enable designers to overcome the previous workflow limitations. Implementing building performance simulation tools in the designer's environment should encourage an environmentally-conscious design workflow. Such tools will create an awareness of the environmental impact of our buildings and design processes on our environment. In this framework, architects and designers can compare different weather conditions for several contexts, various design options, material types, and numerous building systems. Different designs can be compared and analyzed parametrically to show the entire built environment process, which at the early phases of design (while there is not the budget nor time to conduct extensive investigations) holds great potential.

## Experimental evaluation of the impact of window improvement in Social Housing and in real weather conditions REVen Laboratory in Madrid

Beatriz Arranz<sup>1</sup>, Ignacio Oteiza<sup>1</sup>

<sup>1</sup>Instituto de Ciencias de la Construcción Eduardo Torroja (CSIC), Madrid, Spain  
beatriz.arranz@ietcc.csic.es

**Abstract:** This work is developed within the framework of the REVen Project “Energy retrofitting of social housing, using innovative window products with technical approval (DIT, ETA)”, whose overall objective is to generate window solutions for social housing retrofitting, considering technical and socioeconomic aspects. This is being done through different specific objectives developed mainly through simulations and experimental research. Experimental research has two main tasks: 1. Laboratory research: The REVen Laboratory will compare a low performance window with a higher quality window, which incorporate solar control devices in Madrid in real weather conditions, in Southern orientation. Heating and cooling loads, as well as other aspects of indoor environmental quality will be monitored; 2. Social Housing: In a dwelling in Madrid, consumption measurements have been taken for two years, windows have been replaced and measurements after the improvement are being performed. This paper addresses firstly, REVen Lab construction and monitoring and then a Social Housing monitoring before and after the improvement of the windows and results available will be those from winter 2017. Heating savings of 25% are measured.

### Introduction

For existing buildings, the Energy Performance of Buildings Directive (European Commission, 2010) considers that the greater efficiency of the investment with respect to the improvements achieved is reached in major renovations of buildings, or the parts with the highest incidence on building energy consumption. In this sense, windows can be considered as elements of great incidence on consumption and therefore with great potential for associated energy saving. In Spain, (IDAE, 2011) between 25% and 30% of our heating needs are due to the heat losses that arise through windows.

In 2010, (Asociación de Ciencias Ambientales, 2012) 10% of homes in Spain did not have sufficient means to maintain a suitable temperature during the cold months, and/or spent a high percentage of their income to cover basic needs (heating, refrigeration, kitchen, lighting, hot water). In addition to being in a situation of thermal discomfort, there are serious health consequences that derive from living in a house with an inadequate temperature. Therefore, there is a percentage of users for whom action on the envelope of their dwelling is going to imply an improvement in their living conditions without necessarily seeing it reflected in their consumption, since they do not consume because they are in a situation of “Energy Poverty”.

The European Commission has already included the concept of energy poverty in its energy and consumer protection policies. Directives of the internal electricity and gas market oblige Member States to develop plans to address this issue (EC, 2009). Achieving optimum environmental quality will, therefore, be another objective set by the European Commission, as necessary as achieving an efficient use of energy.

Interior environmental quality refers to the state of health and comfort conditions of the different elements that condition our life. The main aspects to be considered in order to assure the internal environmental quality must satisfy the conditions of hydrothermal comfort, acoustic comfort, luminous comfort, physicochemical and microbiological contaminants in the air, and the electromagnetic environment (Bluyssen P.M.,2009) Out of all these aspects, the window intervenes in four of them: hydrothermal comfort, daylighting comfort, acoustic comfort, and air quality.

In addition to the complexity of its energy efficiency, it is necessary to treat windows as an essential element in relation to users and the indoor environmental quality. Modifying the essential elements of the window to improve its energy efficiency can be detrimental to some of its benefits. Determining the optimal window solution for each specific situation will involve an overall approach, analysing the compatibility between energy efficiency and IEQ.

REVen Projects aims to perform an overall analysis, this paper addresses the experimental research carried out so far: REVen Lab construction, monitoring and data analysis from the Social dwelling. Results available will be those from winter 2017.

## Methodology

The Project proposes a documentary/theoretical methodology that will be developed in parallel to an experimental one, in which measurement in real climatic conditions will be performed. In this experimental part there are two tasks: In REVen Laboratory a low performance window will be compared with a higher quality window, in real climatic conditions, in a south orientation. Heating, cooling, light and other electrical consumption will be measured and other aspects of indoor environmental quality will be monitored; in a social dwelling, consumption measurements have been taken during two years, the windows have been replaced; annual heating savings have been quantified, electrical consumption, CO<sub>2</sub>, relative humidity and air temperature are being monitored.

Figure 1. Experimental methodology: REVen Lab and Social Dwelling.

### **REVen Lab**

In glazing systems selection it is important to achieve a compromise solution, which will not be optimum in summer or winter conditions, but optimum during the annual cycle. Giving a

balanced response to all the energy flows that occur through this element and the requirements of interior comfort associated with it.

In order to characterize energy flows and internal environmental conditions, the REVen Laboratory (outdoor laboratory in real weather conditions) has been built, where different window solutions can be monitored, allowing to discretize variables, and to estimate its impact on both energy demand and environmental quality.

REVen Lab is built through a new industrialized construction system. It is a volume with two separate, quasi-adiabatic spaces facing south where the energy flow through the windows and the consumption associated with the different solutions will be monitored.

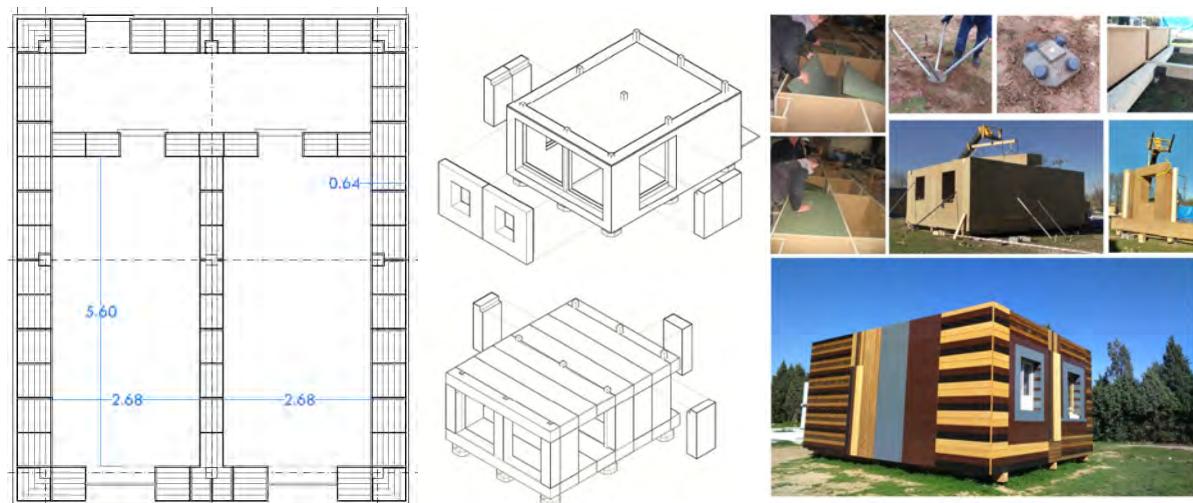

Figure 2. REVen Lab's Layout and Construction.

It has been built with wood, given the characteristics of the project; we want it to have the least possible environmental impact in addition to advancing knowledge of industrialized building construction with this material. It consists of an envelope of 60 cm of regenerated cotton insulation confined by wood panels, and laminated wood structure.

Dimensions of each room are 2.68m wide by 5.60m long; there is a service room at the north to enter to each space. The Lab can be disassembled and placed at another location. South, East and West façade modules can be removed to carry out future research on those areas.

#### ***Definitions of samples to be tested***

The reference window is a traditional window, aluminium (with thermal bridge), simple clear 4mm glazing and white awning, a common solution.

The optimised window incorporates an innovative wood frame, it has a greater surface of glass than a traditional wood framed window, the blade being even with the frame, the glazing incorporates argon, white louvres and integrates an innovative heat exchanger designed specifically for windows PremiVent.

The samples to be compared are 1.5m in height by 1.25m wide.

Table 1. Samples

	FRAME	GLASS	SOLAR DEVISE	AIR RENOVATION
Reference window:	Aluminium	4mm glazing	White awning	Open-Close window(traditional)
Optimised window:	Wood LighTEK 68	Planitherm XN F2 4(16 argon)4.	White louvres	PremiVent

Figure 4. Samples to be tested. On the left side Reference Window, on the right side Optimised Window.

### **Monitoring**

In order to evaluate the efficiency and operation of the selected system, monitoring of the experimental cells will be carried out.

Figure 5 Monitoring Layout

The evaluation of the efficiency of the systems comparing the HVAC consumption of the two rooms with the different window elements started in March 2017. In addition, other parameters related to user comfort, such as lighting levels, CO<sub>2</sub> levels, relative humidity, temperature and surface temperature of the windows are also being measured.

In each adiabatic space the following variables are being measured: 6 measurements of surface temperature by means of thermocouples, 1 relative humidity measure in the centre of the module, 1 air quality measure (CO<sub>2</sub>) in the centre of the module, 1 interior

temperature measure in the centre of the module and 3 daylighting measures. Independent measures of electrical consumption of: the heat pumps, lighting, solar protections, the heat exchanger and the window opening-closing motor.

### Social housing

REVen Project relies on previous research work REFAVIV Project (2013-2017), which focuses on opaque envelopes. They are complementary projects, as REVen is focused on windows. In REFAVIV Project, Social Houses were analysed, electrical and heating consumptions were monitored during two years. REVen Project continues working in one of those social houses.

Both Projects are conceived as “citizen science” where scientists, professionals and citizens collaborate. The selection of the houses is based on the housing stock characterization (Alonso et al., 2015), and due to the III National Plan of housing (1961-76), there is a great Social Housing building stock from this period which needs to be retrofitted, generally envelopes are poorly insulated.

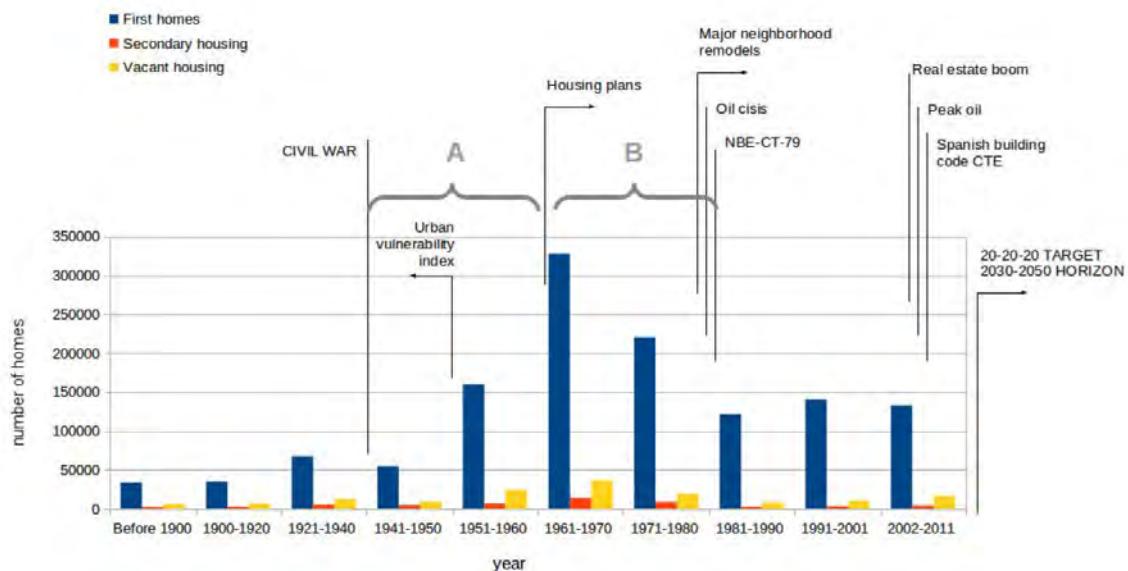

Figure 6: Number of dwellings built since 1900.

In figure 6, green indicates the number of main dwellings, and pink the number of secondary and empty dwellings according to the 2011 census of population and housing (INE, 2011). The dwelling in which this project is taking measurements is located in a multi-family block of five floors. Construction date is 1960 (the project data is from 1957) and the constructed area of the house is 71m<sup>2</sup>. It has a bedroom and living room oriented to SW and two bedrooms, kitchen and bathroom oriented to NE. The houses in this type of block are passages, which allow cross ventilation. The facade has a surface of 20.6 m<sup>2</sup> to NE (with 23% of window area) and 17.5 m<sup>2</sup> to SW (with 25% of window area).

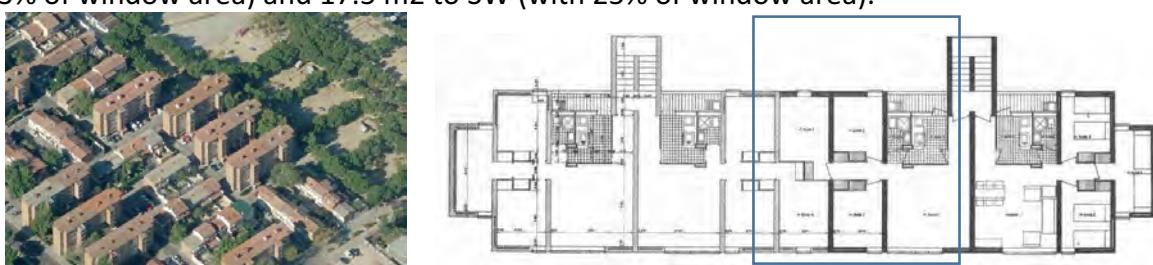

Figure 7. On the left, an image of Social Housing neighbourhood in Manoteras, Madrid. On the right, Social Housing Plan.

### **Definition of samples to be tested**

The composition of the windows follows a scheme quite common in Spanish homes: the original wooden frames have been replaced at some time by aluminium frames with thermal bridge and simple clear glass, later a second window has been added.

Table 2. Samples

	FRAME	GLASS	SOLAR DEVISE
Before (Single o double)	Aluminium	4mm glazing	Traditional louvres
Now	Wood IntelTEK 69	Climalit plus Planitherm XN F2 4(16 argon)4.	Traditional louvres

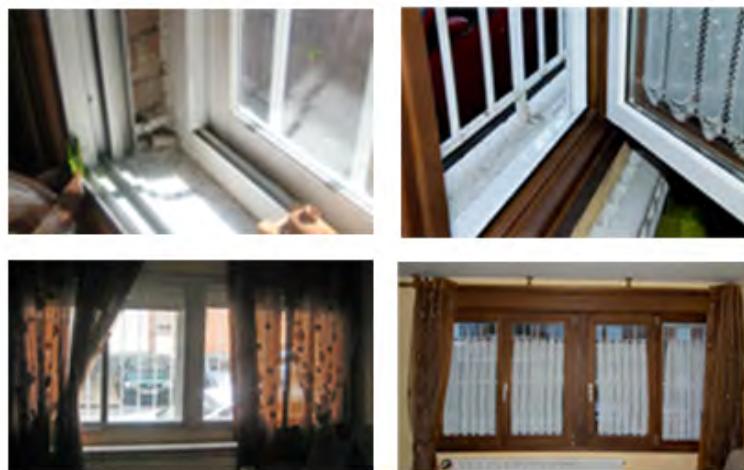

Figure 8. Social Housing windows before and after the renovation.

### **Monitoring**

Non-intrusive IEQ monitoring: air temperature, relative humidity, CO<sub>2</sub>, electrical consumption, heating consumption (Flowmeter).

Figure 9. Monitoring devises.

The heating installation is an individual gas boiler model Themaclassic C 25 Saunier Duval, whose performance according to manufacturer data is 91.5%. It is an atmospheric mixture boiler for heating and instant ACS. The thermostat is in the living room at a height of 1.6m. Setpoint temperatures according to user are: from 8:00am to 2:00pm 17 °C, from 2:00pm to 11:00pm 20°C, from 11:00pm to 8:00am 18 °C. There is no air conditioning or mechanical ventilation system.

### **Results**

Heating consumption during the winter 2015-2016 and the winter 2016-2017 are compared in figure 10, 25% of savings are observed. Exterior temperatures of both winters are shown in figure 11, winter (2015-2016) can be considered milder than winter (2016-2017), nevertheless in December and January the consumption has been similar for those months. In February, average temperatures are similar but minimal temperatures are higher in 2017, which is reflected in a consumption reduction.

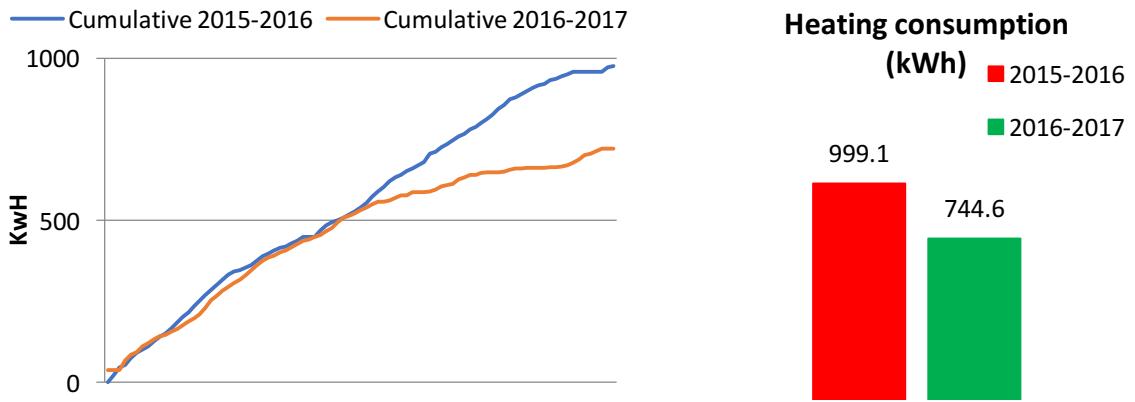

Figure 10. Heating consumption of the winter 2015-2016 and the winter 2016-2017.

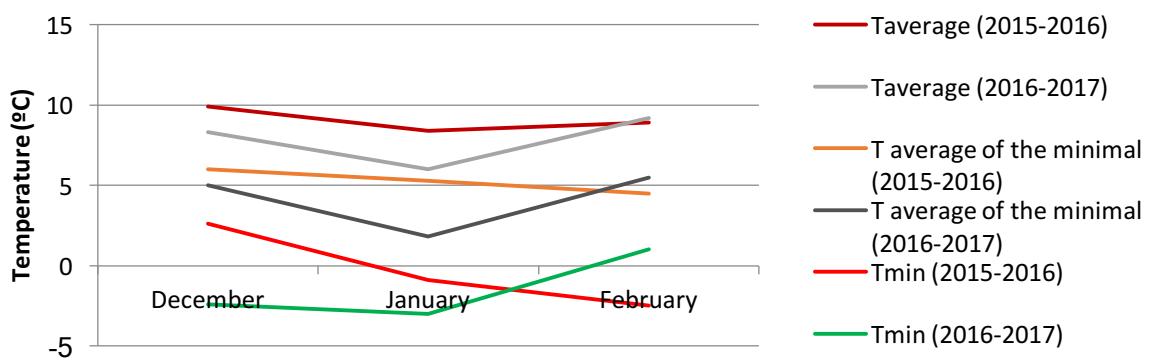

Figure 11. Exterior temperatures (minimal, average and average of the minimal).

CO<sub>2</sub> and HR records show generally higher values since windows have been improved. In Figure 12 the average per day can be observed.

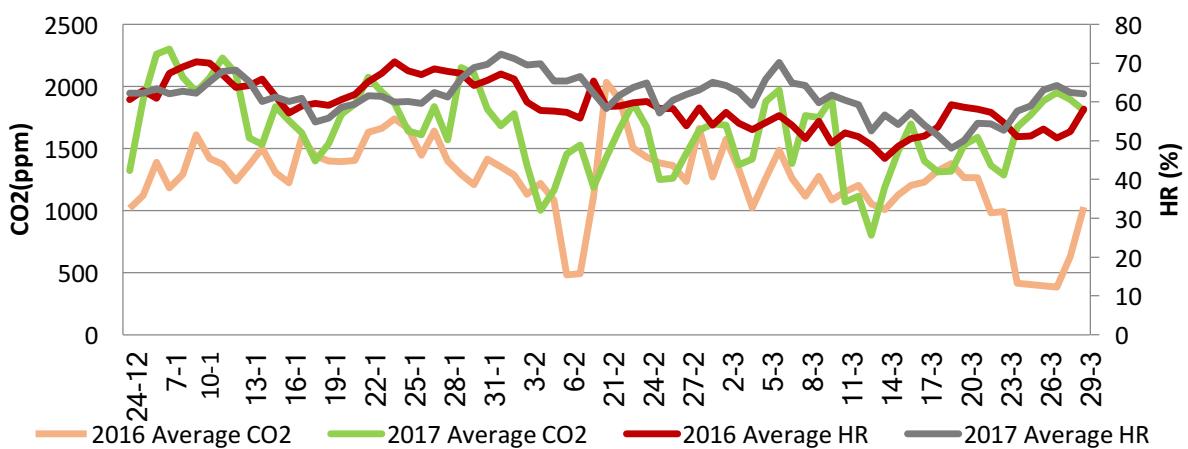

Figure 12. CO<sub>2</sub> and HR average per day.

## Conclusions

Heating savings have been 25% since windows have been improved, which is higher than expected. First hypothesis, considering CO<sub>2</sub> and HR records as well as users reports indicate air infiltrations through windows may have a greater influence than initially thought. Further work is going to be developed in this direction. Before changing the windows a

blower door test was performed, another one will be performed in the same conditions next month. Winter 2017-2018 data will also be recorded and analysed.

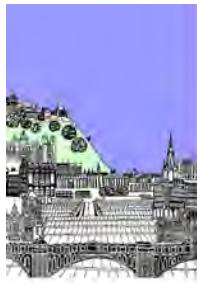

Simulations performed with Design Builder predicted lower heating savings; further work will approach the adjustment of the simulation with real data of the infiltrations and real weather data.

## Acknowledgement

This research was funded by REVen Project is funded by the state of Spain and the European Community (federal funds), namely: Economy, Competitiveness and Industry Ministry. The authors would like to thank our industrial sponsors who took part in the construction of REVen Lab: TAUJEL has assembled the panels of the envelope with FINSA wood boards, GEOPANNEL recycled cotton insulation and HECO screws; TAUJEL has carried out and assembled the panels on PILOEDRE industrialized foundation, HASLACHER structure, DUPOND barrier, STORAENSO ventilated facade and DANOSA waterproofing. The optimised window is a CARPINTEK wooden frame with SAINT-GOBAIN glass, ZEHNDER heat recover, SOMFY motor and SCHENKER-STOREN solar protection. Other companies that also sponsor: VAILLANT, SIMATEC and GERLINGER-KLEBEBAND. We would also like to thank the family who agree to take part in Social House Dwelling work. And again CARPINTEK and SAINT-GOBAIN glass who have supplied and installed the windows in the dwelling.

**Abstract:** Buildings are increasingly complex; saturated with systems that need coherent controls if design goals are to be achieved. Depending on the typology, users need different levels of control. More research is needed to better understand the cause of ‘unintended’ uses of controls in real buildings. A usability tool (UT) is presented demonstrating new insights into the relationship between design and user interaction with all the available controls in five case study buildings. Experiences from applying the tool in the UK domestic context are compared with a non-domestic application in Mexico City. Several early findings result from this study. Firstly the architects’ involvement in the selection of control interfaces as well as their location in a building is crucial. Also user guidance has to challenge the users’ preconceptions about internal environment controls, incorporating information about the use of specific interfaces and the rationale for using them, showing how they tie in with other elements of internal environment control. Cultural context always needs to be considered and the UT adjusted accordingly when applying the tool in different case studies. The assisted UT has the potential to become a vital learning point for building users. The unassisted UT provides guidelines.

**Keywords:** BPE, home use, user experience, building control, usability

### Introduction

Building Performance Evaluation (BPE) studies have repeatedly found that availability and good use of internal environment controls by the user is key to better building performance and improved user satisfaction (Raja et al., 2001; Bordass et al., 2007; Palmer et al., 2016a). Numerous field studies of low energy homes and offices in a major UK government funded BPE programme have demonstrated a general discrepancy between the modelled and measured energy use observed in buildings and as high as a ten-fold variation in energy use per m<sup>2</sup> per annum; the poor reliability of modelling highlighted the role of user control over internal environment: '*buildings with poor control of space and water heating and/or lighting often had high emissions*' (Palmer et al., 2016b). There is a clear link between underperformance and controls which was further stressed in the summary report of this programme: '*Controls are a problem. There is a tendency to make controls for mechanical and electrical services too complicated. This alienates occupants and can mean the building defaults to high energy use.*' (Innovate UK, 2016b, p.4). Top-down efforts to disseminate design intentions related to the use of environmental controls in a domestic context (Munton et al., 2014) have meant their generic approach is not directly applicable. Home handover tours and user guides are intended to deliver context specific information and skills in relation to systems control and maintenance yet these fail in many cases (Stevenson

et al., 2013; Baborska-Narozny et al., 2016). Using collective learning via social media to improve occupant skills in relation to using controls has become another valid strategy for households within comparable fabric and systems contexts (Baborska-Narozny et al., 2017).

Early ethnographic studies highlight the discrepancy between expert and user understanding of technologies and their control in a domestic context. They reveal surprisingly poor correlation between increased technical correctness and a behaviour that is actually better for saving energy: '*the folk theory that is endorsed by the experts may not work as well in practical day-to-day application. A theory that is useful for designing thermostats is not guaranteed to be a good theory for using them*' (Kempton, 1986, p. 81). Thus, merely passing design intention down the information chain to the user is not always enough to secure 'good use' of controls for a healthy indoor environment with minimal energy input. Recent discourse on building-user interaction in the domestic sector analyses housing case studies through lens of theory of practice (Gram-Hanssen, 2011) or domestication (Hargreaves, 2017). This points towards a need for an in-depth understanding of the context specific user perspective on controls which is only possible through 'real world' research methods e.g. walk-through, surveys or interviews. A recent study in the office environment provides a link between behaviour, satisfaction and a good understanding of how to operate an energy efficient building (Day & Gunderson, 2015), highlighting the need to explore and develop effective educational strategies for building occupants. Our paper addresses this gap directly and proposes an evolved usability methodology (UT) aiming to ascertain user understanding, skills and satisfaction with the controls provided, in order to use and maintain the systems installed. Each stage of methodology development is presented in the following section. The application of the different versions of the tool is introduced next. The discussion on early findings, points towards the architects' role in enhancing better user interaction with controls, the UT role for occupant learning, guidance on learning needs for property managers and a source of feedback for the design and procurement team.

## The Usability Survey

Three evolutionary versions of the UT have been developed to date.

### Version 1

An evaluative tool focusing on environmental controls in a domestic context was first developed in 2011 by Stevenson et al. (2013). It comprised of an expert qualitative evaluation of domestic controls for all the in-built systems and appliances based on a walk though. A matrix dedicated to each control for systems such as heating, allowed rating of usability against a colour coded scale from poor to excellent (Fig.1). The usability criteria considered were: *clarity of purpose, intuitive switching, labelling and annotation, ease of use, indication of system response and degree of fine control*. Each matrix was accompanied by a photo of a control and a comment box. Additionally summary comments covering the overall control of each system were encouraged from occupants. The basic application of the tool by an expert was possible, even in isolation from other BPE methods and tools, by completing a matrix template in situ with relevant data. Depending on the complexity level of the property evaluated this could take a few hours on-site. A report resulting from the walk-through data gives a clear visual overview of the usability of controls. Ideally, however, the on-site visit should be preceded with a design audit to identify any gaps between design

intentions and the as built situation to enhance feedback given to the design and procurement teams.

### **Version 2**

In the next version developed in 2014, the expert based approach was replaced by an interview-based multiple choice user questionnaire with comment boxes to elicit quantitative and qualitative information directly from the occupant. Here it was obligatory to have a prior understanding of all the controls included in a bespoke survey sheet before entering an occupied property for a quick 20 minute survey. The assisted survey did not include any photos this time of the controls, only their technical names. Questions related to user guidance available and maintenance requirements were added. The respondents were also asked to rate their perceived skills in using the technical devices. User interfaces were grouped under the systems they controlled. The new questionnaire covered all environmental home controls – or ‘touchpoints’ of interaction between user and environmental technologies. Each control was evaluated against same criteria as in version 1 with additional criteria for the ‘location’ and ‘understanding of the need for interaction’. The survey questions gave three answer options: ‘Yes’, ‘No’, or ‘I don’t know’. The occupant answered the questions first and the researcher only intervened to clarify the questions if needed taking notes of what was unclear. Any questions related to the functioning of the systems and controls were answered after the questionnaire had been completed. This way the researcher did not influence the survey results.

### **Version 3**

The latest version of the survey developed in 2016 was adapted for completion without assistance for larger samples of occupants. Pictures of controls were added in for clarity and to aid understanding by the occupants.

Table 1. Three UT versions key characteristics.

Usability tool version	1	2	3
...methodology	Walk-through expert evaluation	Assisted occupant survey	Unassisted occupant survey
... criteria considered	clarity of purpose intuitive switching ease of use labelling feedback fine-tuning	clarity of purpose understanding the operation ease of use labelling feedback fine-tuning location understanding of the need for interaction	
...prerequisites of application	Access to a property	Access to a property + understanding of all systems and controls installed	
...on site data collection time	A few hours	Ca. 20min/survey + 20 min. q&a + prep.	A few hours + preparation
...reporting	Immediate visual - colour coded matrices + key comments	Basic - descriptive statistics + key comments Advanced - varied options possible	

### **Case-studies**

Versions 1 and 2 were applied in several residential buildings in the UK (Table 2). Version 1 was applied in two demonstration low energy new built dwellings (case A) as a part two Technology Strategy Board BPE research projects (Stevenson et al., 2013). Similarly Version 2 was applied in conjunction with other BPE methods as a part of an EU funded in-depth evaluation of two residential developments: a low energy new built co-housing development (case B) and a private developer led deep retrofit built to comply with regulations (case C). In both developments the occupants moved in at least 8 months before being surveyed. Version 3 was applied as a stand-alone tool in a university campus in Mexico City, Mexico (case D). The building had been occupied for three years. The research project was funded by The University of Sheffield Global Learning Opportunities in Social Science (GLOSS Associate Scheme) (Baker et al., 2016).

The different levels of energy use targets in the case-study buildings resulted in varying levels of mechanical and electrical systems complexity. For example, cases A and B are equipped with mechanical ventilation with heat recovery and case C has continuous mechanical extract ventilation installed. The Mexican university building by contrast (case D) is naturally ventilated.

Table 2. UT method applications.

Usability tool version	1	2	3
Pilot application			
...date	2011	2014	2016
...number of respondents	2	2x20	102
...location	UK	UK	Mexico
...case-study typology	2x domestic (cases A1, A2)	2x domestic (cases B, C)	Non-domestic (university building) (case D)
...energy standard	EcoHomes Excellent (case A1) CfSH5 (case A2)	Low energy CfSH4 (case B) Reg. compliant (case C)	Reg. compliant
M&E complexity level	Medium (case A1) High (case A2)	High (case B) Medium (case C)	Medium

### **Findings and discussion**

Analysis of qualitative user comments and quantitative surveys results from the three versions of the UT reveals an array of in-use issues with controls that contribute to using them other than intended at the design stage or not using them at all. An additional key source of researchers understanding the context of occupant issues with controls occurred while they assisted the respondents and engaged in an occupant initiated walkthrough to answer questions raised by the survey. Isolated detailed reports and analysis of each UT application were published earlier (Stevenson et al., 2013; Baborska-Narozny et al., 2016a,b, Baker et al., 2016). The purpose of the discussion below is to highlight the key findings arising from consideration of all the UT versions and also to reflect on the impact of the different tools used on the findings as a result.

The causes of the occupancy stage issues with controls can be split into two main groups:

- *Usability* problems due to poor design of specific controls, their inconvenient or unintuitive location.
- Problems with occupant *understanding* due to questions left unaddressed by design, handover and aftercare related to their needs, expectations and skills to control their internal environment.

### *Usability*

The first group of issues is mainly linked with the design and procurement stages flaws. Installing two exactly identical switches next to each other for different functions (one for controlling lights and the other for MVHR boost or a bathroom towel rail (cases B and C) shows poor design team understanding of the usability of such a solution. Similarly, specifying electric radiator panels equipped with a battery powered control panel that dies before the heating season starts and stays non-responsive even after a new battery is provided until a tiny button is pressed with a pin (which only the most inquisitive occupants discovered) resulted in 75% of occupants stating that the control is not easy to operate (case C). Architects have an important role to play in the specification of ‘user friendly’ controls as well as their careful location in a spatial context.

### *Understanding*

However as the UT results show, usability itself may not be enough if occupants are not also familiarised with a system they control. One difficulty with familiarising modern technology is its ‘black box’ operation coexisting with unclear payoffs (Nax et al., 2015). The mechanical extract ventilation (MEV) in Case C was designed to work continuously on low flow rates so as to be unnoticed. The extract fans located on a wall in an open plan kitchen were purposely disguised with a cover to aesthetically match the sleek kitchen design. The isolating switches for the fans were deliberately located by the designer high up in a closed cupboard to discourage any user interaction, whereas the boost button was in an exposed location near the fan for ease of use. However, most occupants found a way to switch the fans off permanently, fairly early on after moving into their homes. In stark contrast to the design intention, the UT survey revealed that 75% of occupants were not aware of the functionality of the visible boost switch on wall – the attempts by occupants to use it did not bring any results as the fans were switched off elsewhere, with no indication of being switched off. A short explanation by the researcher was enough to clarify the MEV operation and boost button link. In a different survey (BUS) two month later, the same sample occupants covered by the UT survey (and subsequent researcher assistance) knew that they had the MEV, while 30% of the population of the development stated they didn’t have it installed, revealing major gap in understanding. In many similar cases the UT assisted survey provided an excellent learning opportunity – the occupants were confronted with their own lack of awareness of certain controls, and were interested to find out what they were misunderstanding. The tool offered a neutral learning medium with no judgement of the occupant.

The learning/understanding aspect of the UT version 2 (assisted survey) also touches on the first group of usability issues with the controls in buildings. The two different methods revealed that the expert driven in-situ evaluation version 1 is more appropriate to pick up the issues linked with usability and location. The occupant misunderstandings in the second group are unlikely to be reliably foreseen by an expert, hence the importance of

asking occupants if and how they interact with controls in daily situations. For example, the thermostatic radiator valve (TRV) was expert evaluated as poor in terms of clarity of purpose and intuitive switching (case A) whereas all the surveyed occupants knew what the control did and whether they should interact with it (case B). On the other hand, a consumer unit received an expert rating of excellent (case A) when 40% of respondents didn't know what the same unit did and whether they should interact with it (case B). A technically inquisitive resident commented that while responding to the UT survey he found that the consumer unit was incorrectly labelled, leading to major health and safety risk. His finding resulted in the residents checking labelling across the development and tracing another faulty label in all 20 dwellings. In daily life, home use controls only occasionally become the focus of occupants' attention - the assisted UT survey provides a rare opportunity for ensuring learning about controls happens. Ironically, expert judgement may be a proxy only for the most technically skilled and inquisitive occupants who actively seek answers in relation to controls, regardless of the information provided at the handover stage or in a user guidance. The large difference in rating of controls by the average and the more inquisitive occupants is particularly visible for the technically advanced interfaces that are new to users, such as an MVHR control panel or boiler control.

The incorporation of the new 'touchpoints' into relevant control practices is linked with an occupant's motivation to learn and adapt, as shown by the correlation between previous contact with controls and the level of their understanding. The controls most familiar to them from their previous accommodation were those best understood. When new systems and controls are introduced, design teams need to facilitate the process by disseminating the design intention, ideally in dialogue with potential occupants, using their tacit knowledge derived from their previous accommodation. For example where a future occupant is unlikely to have any previous experience with continuous MEV and MVHR it is not enough to say in home user guidance '*To maintain the minimum ventilation, the main power to the fan unit should be kept permanently on*' (case C). Further explanation is needed to give a rationale for using the fan here, even though it isn't necessarily needed in a typical leaky home, otherwise the advice will be ignored 'to save energy' or for other reasons adopted by an occupant. There is a vicious circle with lack of occupant interest in home user guidance (half of Case C occupants were unaware of having a home user guide) reinforcing the poorly perceived applicability of such guidance when needed. All the survey results also pointed towards a need for repeated learning opportunities in relation to controls that are rarely used, i.e. emergency controls. This came as a surprise to the researchers - the emergency controls scored very highly in an expert evaluation (case A) but worryingly, 75% of occupants in case B or C could not rate their usability because they had never seen them and didn't even know where to find them. As a result, the occupants took the initiative and prepared a bespoke guide shared with all the households where each emergency control i.e. gas and water stop cocks or fire alarm, etc. was covered (case B). In Case D most occupants were also unaware of how to use the fire emergency equipment if needed. Detailed actionable recommendations of training needs were consequently delivered to relevant university stakeholders following UT survey analysis.

#### *UK vs. Mexican application*

The survey was effective in both the UK and Mexican contexts even though in the later environment research focused on usability of controls in buildings was a novelty. The questions were considered in terms of the specific cultural context and adapted accordingly in order to be well understood, i.e. as the concept of feedback is not well known in Mexico,

the question '*does it show a response to your actions?*' was substituted with '*does this control tell you whether it is actually working or not?*'. In the Mexican university building the controls related to access and security proved to be particularly unusable and misunderstood. This was not as evident in the UK domestic context, where the security controls are generally less complicated.

## Conclusions

Several key findings result from this study of various evolutions of a UT tool in various contexts. Firstly the architects' involvement in the initial selection of control interfaces as well as their location in a building is crucial. User guidance has to challenge the occupants preconceptions about their internal environment controls, incorporating information about the use of specific interfaces and the rationale for using them, showing how the interfaces tie in with other elements of internal environment control. Cultural context always needs to be considered and the UT adjusted accordingly when applying the tool in different case studies. The assisted UT has the potential to become a vital learning point for building users. All UT surveys reveal gaps in occupant training and provide guidance for improvement. The Mexican application of the tool highlights the hierarchy of occupants concerns in relation to their interaction with building controls that go beyond the usability and cover areas such as security.

The UT version 1 was efficient in providing an expert driven overview of the usability of controls as installed in a specific context. The method can be applied without involving the users at any stage of occupancy or even before the handover. In a domestic context this aspect is advantageous, given difficulty with access to inhabited dwellings for research purposes. The major drawback of this method, however, is that it relies on expert evaluation and its results cannot always be regarded as a proxy for occupants' actual perceptions. An expert projects their own experience and expectations towards the evaluated controls. In some cases of evident design and usability flaws these may be quickly picked up and ideally corrected before the user comes in. This builds a case for introducing the UT 1 as a tool for the design and procurement team visiting a site during the commissioning stage. However in less clear cut cases, expert evaluation may be different from that of future occupants, and here the UT versions 2 and 3 maybe more helpful, with pre-planning by the expert, followed by input directly from the occupants. Any tacit gap between the expert expectations and user reality can then be identified and resolved.

Helping occupants to actually achieve satisfactory energy performance in their buildings is beyond the scope of the UT survey. Future research into understanding the link between the use of controls and subsequent energy performance could help to improve energy efficiency per se and should be considered for future iterations of the survey.

**Abstract:** The objective of this article is to show the results obtained so far, in the evaluation of the performance, under the ergonomic approach, of the buildings of the Brazilian modernist architecture, in São Paulo. These are: Conjunto Nacional Building (1963), designed by David Libeskind; Itália Building (1964), designed by Franz Heep and Copan Building (1964), designed by Oscar Niemeyer. The purpose of the research is to understand the interrelationships of ergonomics with other areas of environmental comfort (lighting and thermal). Moreover, it intends to assist in understanding the overall performance of buildings, both in physical space and in environmental aspects. In this way, it evaluates not only the adaptations made for greater functionality that occurred during the useful life of the buildings, but also the users' expectations about WORK activity. The method used in the research is inductive experimental with field research of physical and environmental variables. The results are analyzed in a comparative way between the experimental data of the buildings in their current settings and design, combined with ergonomic performance criteria. Until now, the research indicates that some buildings have been modified from the original floor plan which have compromised their proper performance, hampering the comfort conditions and aggravating the dependence on active strategies of environmental conditioning.

**Keywords:** Brazil Modern Architecture, Ergonomic Comfort, Evaluation, Performance , Project.

### Introduction

The buildings, icons of Brazilian modernist architecture, chosen for this research were: Conjunto Nacional (1963), designed by David Libeskind - Figure 1; The Italia building (1964), designed by Franz Heep - Figure 2 - and the Copan building (1964), designed by Oscar Niemeyer - Figure 3. These are examples of the application of design strategies with regard to shape, building orientation, façade shading, openings for natural ventilation and natural lighting. Also, the use of the structure and other constructive components such as thermal mass for the control of internal temperatures, among other environmental characteristics and purposes.

Brazilian architecture of this period, therefore, is also known as bioclimatic architecture (CORBELLA and YANNAS, 2003), due to its climatic insertion characteristics. This aims to control solar radiation, natural light, natural ventilation and temperature fluctuations with the use of the inherent thermal mass, which is mainly the concrete structure. Together, the three buildings selected as case studies of this research bring

together architectural solutions that summarize both the essence and the diversities of the acme of the Brazilian modernist architecture of the commercial building.

The intention of including examples of commercial architecture as case studies comes from the fact that these are the architectural functions that correspond to the largest number of buildings in the city, which have distinct requirements of environmental comfort and also different design solutions. In addition, they are considered constructions that added value and brought identity to the brazilian commercial buildings and residences.

Concerning the environmental scope, for ergonomic performance evaluation, aspects of thermal performance and luminosity were included, since they interact with each other, at the same time they should be evaluated according to the functionality of the space. Even today it is little known about the qualitative and quantitative performance of these buildings and their particular solutions, designed to handle with the users demands regarding the environmental comfort.

Using on-site measurements and interviews with the building users, it is possible to formulate an insight about the current performance of these buildings according the current comfort requirements. Complementing this analysis, with the ergonomic evaluation, it can be learn about the performance of the building when it was designed, in the original floor plan with no possible changes and, above all, in the original situation of the built surroundings.

Based on case studies in the city of São Paulo, this research focuses on learning about the ergonomic performance, quantification and qualification of the commercial and residential buildings of brazilian modernist bioclimatic architecture, between 1930 and 1960. In addition, it seeks to understand the interrelations of ergonomics with other areas of environmental comfort (lighting and thermal) and to help in understanding the overall performance of buildings. Therefore, analysing the adaptations made for greater functionality, in the physical space and in environmental aspects in order to relate with the expectations of the users regarding the WORK. From these data, will be formulated architectural recommendations for the environmental suitability of contemporary projects.

## Ergonomics

The insertion of environmental comfort, the focus on ergonomics, the design and evaluation of architectural projects and existing buildings, the questioning and the redefinition of an "environmental comfort", which, despite its specificities, Influenced by values of convenience, Adequacy, expressiveness, convenience and pleasure (VIRILIO, 1993). This perception encompasses not only all its variables and interferences, but also several behavioural factors, which were marked in four large structuring groups: social, cultural, psychological, environmental and physical (SHMID, 2005).

One thing that can be criticized about this approach is it's deepening and level of details in terms of the physical factors instead of others. This occurs once the project is usually restricted by aspects such as anthropometry and accessibility. The core of the project, thought, is define Ergonomics role, not only as one of the areas of environmental comfort, but also in its real part: design, structuring and evaluation of projects

Ergonomics come up in the after war period - 1972 - with the basic goal of improve the factories working conditions at a time when large production and limitless physical efforts were common. For a long time it were connected exclusively to dimensional, anthropometric and, most recently, accessibility matters. Despite it, understanding work as any man's action in its environment brought the real state of ERGONOMICS.

Based on the assumption that Ergonomics in Architecture has man as object in space, it can be defined as the study of the actions and the mutual influences between human being and space through reciprocal interfaces. In this way, the contribution of ergonomics in architecture is to propose relations and conditions of action and mobility, to define proportions and to establish dimensions in specific conditions for natural and constructed environments. It is based on environmental comfort, which presupposes the individual perception of qualities, influenced by values of convenience, suitability, expressiveness, comfort and pleasure.

Based on these assumptions, ergonomics, using its four structuring factors, supports design actions that aim for comfort, and these are: the measurable and the non-measurable. They are object of study of Ergonomics applied to Architecture and Urbanism.

In general, environmental comfort is not yet adequately addressed in most Brazilian building projects. When assessing the urban context, the quality of spaces and the insertion of these in the city, the situation are similar. In spite of this, the icons of Brazilian

modernism analyzed are known for aspects related to environmental comfort. Thus, such studies can provide great insight into the design techniques of comfort and ergonomics.

### **Modernist Architecture**

The Copan building (1964), in the downtown district, is currently composed of a two-volume building complex, with a horizontal base for commercial use and a vertical tower with 32 floors for residential use. It was designed as a stretch of the city in order to constitute a great urban equipment, since it concentrates a big diversity of equipments configuring a "vertical city". The original design had humanistic characteristics with a well integrated architectural set that consisted in a horizontal volume with commercial and services uses and two blocks - a rectilinear, intended to be a hotel, and another curve, intended to be residential. The design of the building aimed to articulate the building with the city so that the sidewalk floor invaded the building as an extension of the city.

The variety of types of habitations along the curved block comprehends typologies from smaller areas, the kitchenettes, to the larger ones, the apartments with 3 bedrooms. In the original project there were 5 blocks A, B, C, D and E. The block A was planned to be for kitchenettes with a long internal corridor, the block B, C and D were apartments with three bedrooms, with differences between the areas. Blocks E and F, were the larger, with apartments between 3 and 4 bedrooms.

The approved design had tremendous differences from the original design. Some more significant changes were: the rectilinear block, initially thought to be a hotel, was changed to be a Bradesco bank. Also, the apartments in block A were divided into two more blocks one with two bedrooms and the other with kitchenettes.

In aspects of design and environmental comfort Copan was the first building to be approved by the prefecture with internal sanitary and forced ventilation. This due to the demand for small apartments created by the urban expansion and housing deficit. For solar protection, the main façade of the building was designed with horizontal "brisés soleil" (a common type o shader element in the brazilian modernist architecture) with 1.45m wide and spaced 1 meter apart. These brises had not only the function of shading but also, they play a fundamental role in the formal characterization of the building. In addition, on the back façade was used the hollow brick wall, cobogó, that shades and ventilates the environments.

Another architectural complex of the period, in the city of São Paulo, was Conjunto Nacional (1963), comprising the residential and commercial function in a single high tower, over a horizontal base of commercial and public use, with a garden terrace between the base and the tower (IACOCCA, 1998). The Conjunto Nacional architecture have the hollow brick wall elements, cobogó, a narrow floor plan, a combination of opaque parts and glazed parts on the main façades, solar protection for the blocking of solar radiation (brisés soleil) and the control of natural light . In addition, facing Avenida Paulista, the Conjunto Nacional is oriented north and south, which favours the natural lighting of the building.

The project was thought to be an extension of the street, therefore, there are access through the streets that border the building and the sidewalk floor get in the commercial bloc. The Conjunto Nacional was designed for cellular offices and is occupied in this way until today. It inaugurates the occupation of Avenida Paulista and it was the first one with such dimensions. It is distinguished by its type of occupation and design in which the limits of the block are the limits of the building itself. The original design has passed by major changes. Initially, it was planned, a horizontal commercial bloc and a vertical bloc divided

into two functions, a hotel and a commercial complex. Also, movie theater, a theater and a garden terrace were also designed.

The Italian Circolo Building, better known as the Italy Building, 1956, was for a long time the largest building in the city of São Paulo, with 165 meters high. It is mostly occupied by offices, but also has, on the first three floors, the Italian Circolo Association which has a library, a games room and a theater. With 44 floors plus a basement and 19 elevators, its 52,000 square meters has a capacity for 10,000 people and a floating population of 25,000 people.

The implantation of the building, on the corner of Av. Ipiranga and Av. São Luiz, facing the Republic Square, was decisive for the building project to be approved by the prefecture as a landmark of the city. Following the same logic of Conjunto Nacional building, the Italia building is based on a basement bloc and a vertical volume. To cover the gables of the adjacent buildings, the architect designed two narrow blocs with eight floors - this was the height allowed for buildings at the plot land boundary at that time - coated with glass blocks with framed windows.

The Italia building was considered a pioneer of the brazilian large buildings both in the constructive technical way and in the architectural way. One of the innovative solutions for that time was the vertical circulation made through 19 lifts, 5 for exclusive use of the Italian Circolo and 14 for common use. To rationalize the supply system, at each interruption of a group of elevators the two subsequent floors receive their engine houses and water tanks.

The flexibility of the building's office floors is ensured, mainly, by two factors first the hydraulic and electrical installations that run around the perimeter of the building, guaranteeing freedom in the location of the toilets and in the offices layout. Second, the structural system adopted - the building has 12 pillars and four structural walls besides the column of elevators that has structural function. The small number of pillars occurs due to the distribution of the cargo weight by more than one hundred pillars located in the perimeter of the ellipse. These also have the function of bracing, allowing a building with the size of the Italian Circolo has an immense freedom and an open floor plan.

## Search and data

A bibliographical research was made to obtain significant work in the area and academic research for concrete results on ergonomic evaluation. Therefore, the concepts and proposals were analyzed, to deepen the theme and confirm its complexity. Two works were more used for the research: *Habitar El Presente*, by Josep Maria Montaner and Cláudia Andrade's *History of the Work Environment in Office Buildings*. In addition, the master's thesis "The Importance of the study of functions and activities in the design and dimensioning of housing", by André Luiz Souza Barbosa, which presented an evaluation method with a table that proved to be adequate for the work in this research. The table facilitates an ergonomic inventory to evaluate the interior of the buildings based on the description of the activities performed by each user. This description is classified by the nature of the activity, location, and the user's classification.

Also, technical data and design data were searched in books and collections in order to obtain information (technical detailing and design drawings) on the current situation of the studied buildings, as well as its original floor plans. It was possible to find technical drawings from various periods of the buildings, so specific bibliography was used for each one. Public collections of architectural drawings and a library of projects were also consulted at FAUUSP. The plants that were deteriorated by time were transferred in 2D and

3D softwares. This methodology is important for the understanding of functions and use activities in commercial buildings and services. They also act as an instrument of understanding project design as they simulate the possible demands and paths of users in a certain environment.

### **Field research and ergonomic performance analysis**

Three buildings were selected to carry out this research. For each one, a sufficient number of users were calculated to carry out valid measurements and questionnaires. For the Copan six apartments were elected; for the Conjunto Nacional three distinct offices and for the Italia Building two offices on different floors. In addition, questionnaires (ergonomics, thermal and light comfort) were applied to the residents and comfort measurements - Figure 4 and 5 - were taken of the surroundings and the most used spaces by the interviewees. In addition, it was conducted surveys for ergonomic assessment, which resulted in a series of data and tables from where it was possible to generate charts and diagrams. Computational simulations were also made in the ambience - Figure 6 - in order to understand the environmental conditions.

In the evaluation of the interior of the buildings the ergonomic analysis basically covers 03 phases. The first focuses on the task analysis - uses and functions of ambiences - of obstacles and task study. In the second phase the anthropometric analysis of the task is performed - Ergokit application and Julius Pañero's anthropometric database - assessment of the suitability of the environments and dimensioning for the activities. Finally, the third phase is the inventory of the furniture used and the comparison with modifications made from the original design as well as recommendations for ergonomic comfort.

The field research was made in the three buildings selected between 03/18/2015 and 04/14/2015. Researches were also carried out in the external area of buildings with the objective of obtaining comfort data, user opinion and ergonomics of the surroundings. With the data obtained in the measurements and questionnaires it was possible to start initial analytical procedures for the performance evaluation with ergonomic approach of the buildings.

From the floor plans, it was verified that all the three buildings were intensively modified over the years. The offices changed both the ideological concept and the layout. This may be associated with comfort issues, cost and doctrine issues, or even both. Moreover it was possible, from the design bases, to verify qualities and possible design problems that can interfere with the user's daily routine.

In the Circolo Italiano building the 13º and 33º floors were measured, mainly, where formal changes and layout were observed. Both evaluated floors changed their design to an office of closed rooms, hierarchical, without spaces of integration of free plans, without partitions and with more integrated layout. Both offices evaluated at this stage had furniture arranged on a regular way, however, with differences in the type and style of the furniture. On 33th floor the furniture was more similar to workstations with folding screens, furniture attached and few variations. While on the 13th floor the furniture was self-supporting with separation between the folding screens and the furniture.

Another important finding from the measurements was the pavement performance, since, in the cases studied, there was both mechanical ventilation and air conditioning. In the case of air-conditioned pavement, the thermal performance of the pavement showed a worse condition of comfort compared to the one with natural ventilation.

In the Conjunto Nacional Building were measured three rooms - one on the 5th floor and two on the 23rd. The rooms have also been changed from the original plants, but the change is less drastic compared to the previous case. The number of tables and occupants has been increased so that the rooms, previously intended to be a part of an office now has an entire staff. In addition, the rooms on the 23rd floor presented problems in the layout of the office since there is light reflection in the work area obfuscating the user and disrupting the work. This interferes with the use of shutters and air conditioning system.

In the Copan building the plant changes were the most radical. The measurements were made mostly in Kitchenettes which allowed the evaluation of the minimum space of a house, as well as of conflicts resulting from the disposition of the furniture. Furthermore, problems with ventilation and lighting have been repeatedly identified since, depending on the exposed façade, the apartment receives a lot or very little natural light.

In the coming months there will be more visits to offices and apartments with the FAUUSP LABAUT team. During these visits, questionnaires and interviews will be applied in order to better understand the activities carried out in the offices. There will also be ergonomic measurements of the locations so that it is possible to evaluate the workspace. With the data obtained by ergonomics measurements we intend to create a diagram of influences of the activities performed and the space required for them.

## Conclusion

The results obtained so far indicate that some buildings have experienced changes in relation to the original plan that have compromised their adequate performance. The analysis indicates that many of these modifications, in search of greater "functionality" besides impairing the adequacy of the environmental variables, made also the dependence of active strategies of thermal conditioning and lighting worsened the overall performance of the buildings. Other buildings, which maintained the original design without major alterations, are able to maintain today a higher environmental quality. Another point to be analysed in relation to the performance of buildings is the interaction between the user's behaviour in the ambience and the ergonomic suitability for offices and homes that are a need to meet the best performance goals.

## How user practice and habits impact the energy consumption in nearly zero energy youth housing in Denmark

Anne Kirkegaard Bejder<sup>1</sup>, Mary-Ann Knudstrup<sup>1</sup> and Camilla Brunsgaard<sup>1</sup>

<sup>1</sup> Aalborg University, Department of Architecture, Design and Media Technology, Aalborg, Denmark. Correspondence email: akbe@create.aau.dk

**Abstract:** Several projects constructed during the last years demonstrate that it is possible to design buildings which can be defined as “zero-energy buildings”. However, research show that it can be difficult to meet the expected low energy consumption. Studies suggest that one of the reasons for this is that occupants’ behaviour and lifestyle strongly influence the final energy consumption. This paper presents a preliminary study of a larger research project that studies the relation between energy use and user practice and habits as well as the users’ expectations to and experiences of living in a newly built nearly zero-energy youth housing complex in Denmark. The objective of this study is to examine to what extend user practice and habits influence the energy consumption and on that basis to identify representative user characteristics within this specific user group. Methodologically this is done through a case study where data on measured energy consumption for space heating is juxtaposed with the results of a questionnaire survey. The study indicates that variations in heat consumption across the apartments are not primarily related to apartment type, orientation or floor, but rather related to the inhabitants’ use of their apartment.

**Keywords:** sustainable architecture, inhabitants’ daily practice, youth housing

### Introduction

Although it is still not common practice, several projects built during the last years demonstrate that it is possible to design buildings which can be defined as “zero energy buildings”. However, research shows that low-energy buildings do not always live up to the expectations, among others due to discrepancies between the expected (calculated) energy need and the actual (measured) energy use after commissioning (Larsen & Brunsgaard 2010). Studies suggest that one of the reasons for this is that occupant behaviour strongly influences the energy consumption of buildings (Gram-Hanssen, 2010, 2013 & 2014, Steemers & Yun, 2009). Therefore, as accounted for by Gram-Hanssen (2013), there has been an emerging interest in documenting the importance of user behaviour on buildings’ energy consumption, also within more technical oriented research. In a study performed by Steemers and Yun (2009) it is clarified that the second most important parameters that determines energy use relates to occupant behavior, especially related to the choices made about heating and cooling systems and the control of these. Steemers & Yun conclude: “The central role of occupant and behavioural aspects is evident and is essential for understanding, evaluating or predicting building energy use” (Steemers & Yun, 2009, p. 635). Furthermore, studies suggest that there is a trend towards that people adapt their comfort to the type of housing they live in, i.e. in old houses one typically put on a sweater and slippers in wintertime, whereas one who lives in new low energy houses wears a T-shirt all

year long (Gram-Hanssen, 2015). Hence, the expected energy savings in low energy houses risk to be absorbed in increased comfort. However, is this trend general for all user groups?

Current paper presents a preliminary study of a larger research project that studies the relation between energy use and user practice and habits as well as the users' expectations to and experiences of living in a newly built nearly zero energy youth housing complex in Denmark. The building is a 99 apartment youth housing complex classified as a nearly zero energy building (nearly ZEB) and several passive and active strategies have been applied in order to minimize the energy demand, including among others: high-insulated and air-tight building envelope, natural ventilation as passive cooling, mechanical ventilation with heat recovery, and heat recovery of the domestic hot water (DHW). The 99 apartments are relatively uniform as regards type and size. The inhabitants are young people who are all enrolled in education. Hence, the group is relatively homogeneous and shares many conditions. On this basis, it is presumed reasonable that the study can lead to an identification of typical user characteristics. Therefore, the objective of this study is to examine to what extend user practice and habits influence the energy consumption and on that basis to identify representative user characteristics within this specific user group.

### ***Background information***

The youth housing complex was built in 2011-12 and was the winner of an invited turnkey contract competition put out to tender by the Danish housing association Ringgården. According to the energy labelling report the building complies with the current Danish 2020 requirements (the demand for energy supply for heating, ventilation, cooling and DHW per m<sup>2</sup> of heated floor area must not exceed 20 kWh/m<sup>2</sup> per year (Bygningsreglementet.dk, 2017: 7.2.4.2) and has a calculated surplus production of energy of 7.3 kWh/m<sup>2</sup>. The majority of the apartments have two-rooms and a net area ranging from 29.6 m<sup>2</sup> – 33.6 m<sup>2</sup>. There are only 5 one-room studios with a net area of 28.6 m<sup>2</sup>. The building has 12 stories (excl basement and garret), floor-to-ceiling height is 2600 mm, and the building is supplied by district heating. The building is one out of four high-rise youth housings placed close together at Aarhus (DK) waterfront. South-east (SE) of the building is a 12-storey high-rise, towards west (W) is a 9-storey building and towards north-west (NW) a 6-storey building.

### **Methodology and data**

The inquiry is based on a holistic single-case study (Yin, 2003) using a mixed methods approach (Bryman, 2012) to reach a nuanced understanding of the case. The data applied are drawings of the building, descriptions of the building, meter readings of energy consumption and a questionnaire survey sent to the tenants. The questionnaire has been composed in the software program SurveyMonkey (2017) and was sent to the tenants by email containing an invitation to participate in the survey and a brief introduction to the topic and themes in the questionnaire. The addresses were provided by Ringgården, the tenants could answer the questionnaire online and respondents were promised anonymity. Two reminders were sent to the tenants who had not answered in order to collect more answers before the deadline. The participation in the questionnaire was voluntary but among the responses two winners of 2 x tickets for the cinema was found by draw.

### **Data**

The measured data is based on meter readings of the 99 apartments' energy consumption. The meter readings are provided by the housing association Ringgården whom has

constructed and runs the building. The housing association logs systematically the energy consumption of each apartment for space heating, cold water, domestic hot water (DHW) and electricity every day, all year round. The data used in this paper is the sum of daily meter readings of the 99 apartments' energy consumption for space heating, measured over two years; 2014 and 2015. The validity of the study is thus assuming correctness in the data received from the housing association. The energy consumption for space heating is not adjusted for degree days since the primary objective of this study is to get an overview of the level and variation of energy consumption for space heating for the 99 apartments and not to compare the two years. Year 2014 and 2015 are, however, relatively comparable since both years were mild. According to the Danish Technological Institute (TI) the number of degree days in 2014 and 2015 was 2100 and 2278 respectively. Compared to TI's "average year" with 2906 degree days this means that the energy consumption for space heating in 2015 could be expected to be 21% lower compared to an average year but 8% higher than 2014 (Teknologisk.dk, 2017). Likewise, as the study focuses on the apartments and the impact of the inhabitants' behavior and habits on the energy consumption, the energy consumption related to the overall building operation, including common facilities and areas, is not included.

The questionnaire survey has been distributed to 95 of the 99 inhabitants, four had just moved in and for that reason ruled out. 49 responses were received but two of them where insufficiently filled out. 47 inhabitants completed the survey; hence the response rate is 49.5%. The questionnaire aims to gather knowledge of how the inhabitants use their apartment, for which reason they are asked about how much time they spend there, if they prefer different temperatures in different rooms, and their practices in regard to adjusting the indoor environment, etc. The study is based on the assumption that the 47 responses of the questionnaire survey are representative for the user group. If not otherwise specified n=47. The survey results are stated in round numbers. Instead of comparing the 47 responses with specific data on energy consumption of the respondents' apartment, it is chosen to compare the responses with the larger data set of measurements on all 99 apartments. One reason for this is that not all 47 respondents have lived in the building for the entire period when the measurements have been collected (at the beginning of 2014 to the end of 2015), since the inhabitants must enrolled in education. Of the 47 respondents nearly 80% lived in the apartment for all or part of the period in which measurements are collected. The main motive is, however, that the aim is to clarify *tendencies of this specific user group* rather than to describe the particularities of individual users.

## **Results and discussion**

In order to reach a deeper understanding of what characterizes this specific user group, it is first and foremost interesting to clarify why they have chosen to live in this nearly zero-energy youth housing. The respondents were asked about what the reason(-s) for choosing to apply for an apartment in this particular building were. The respondent could give more than one answer; hence, the sum is not 100%. The options were: The location of the building near Aarhus city centre; The location of the building near the water; Because it is a new building; Because the building as a nearly ZEB; Close to place of study; Close to family; The architecture; The size and/or layout of the apartment; The common facilities; Because I knew one who lived here; It was the apartment I was offered; and Other (please note).

The reasons that had most influence on their choice is the location of the building near the city centre (83%) and by the water (49%), as well as the inhabitants place of study

(55%), but also the fact that it is a new building (70%) and simply because it was the apartment they were offered (49%). Only 8 out of 47 respondents (17%) it was a causal factor that the building is categorized as a (nearly) zero-energy building (ZEB). When asked if they knew that the building is a nearly ZEB, 4/5 of the respondents reply that they were aware of it, but only 24 respondents (51%) answer that this means that they have particular expectations to the building. Generally the supplementary comments that elaborate expectations related to the low energy standard of the building are the expectations of lower consumption and costs. 31 respondents (66%) also reply that they feel they have the opportunity to influence their heat and electric bill through a resource-conscious behavior, whereas 5 respondents (11%) do not feel they have an impact on the bill and 11 respondents (23%) reply "don't know". The latter might indicate that they are either not conscious about their behavior; about how their behavior could influence it; or perhaps it just does not interest them. When asked about to what extent they generally are concerned about saving energy, 10 respondents (21%) answer "to a great extent" and 24 (51%) answers "to some extent", whereas 8 (17%) reply "neither/nor" and 5 (11%) "to a little extent" or "not at all".

All in all, the results here indicate that a clear characteristic of this user group is their appreciation of being close to the city centre and that the location for the majority in general means a lot. By comparison, the low-energy standard of the building only seems significant to a part of the group. Generally, the results seem to identify two sub groups in the otherwise homogeneous group; one group to whom the low-energy standard of the building is significant which also means that the group have specific expectations to it; and one group to whom the energy standard seems relatively unimportant, whether this is due to lack of knowledge or lack of interest. The first group seems to be covering the majority; this is also supported by the fact that more than 2/3 consider themselves to be generally concerned about saving energy.

Looking at the energy consumption for space heating of the 99 apartments in 2014 and 2015 (figure 1), we see that the heat consumption is virtually the same the two years and so is the variation across the apartments. When data for 2016 are released the validity of this tendency can be further examined.

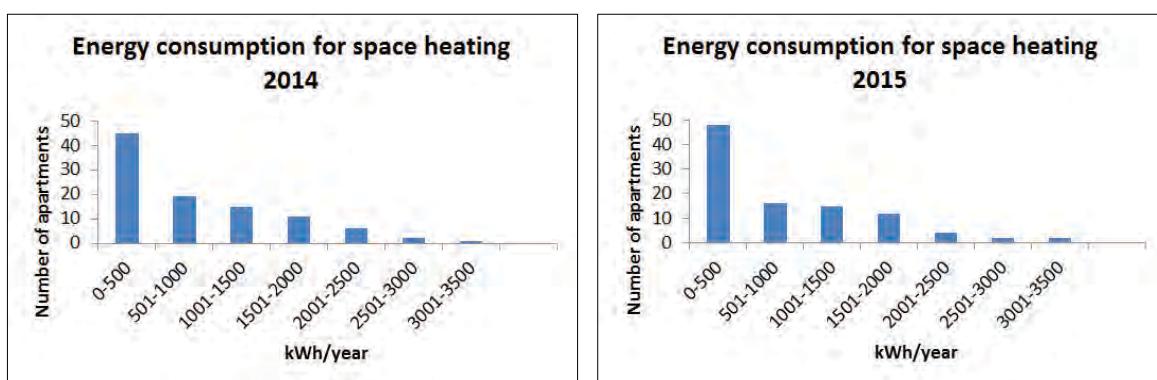

Figure 1. Heat consumption of the 99 apartments, classified in intervals of 500. Not adjusted for degree days.

In 2014 45% and in 2015 48% of the apartments had yearly energy consumption for space heating between 0-500 kWh. 45% and 43%, respectively, had yearly energy consumption between 501-2000 kWh and well over 9% and 8% of the apartments had a consumption between 2001-3500 kWh which is minimum 4 times higher than almost half of the

apartments. If we look deeper into the numbers we see that in 2014 4 apartments actually did not use any energy for space heating at all and in 2015 this number had increased to 20 apartments. Hence, the measurements show that the energy consumption for space heating in this building is generally very low; even with 20% using 0 kWh in 2015, but compared with and in contrast to this, a smaller amount of apartments have quite high heat consumptions; a few even more than 3000 kWh. The generally low heating demand is expected since the building fulfill the energy demands for the Danish building class 2020 and may be explained by the compact building form, the high-insulated and air-tight building envelope, and the fact that both years were mild (as described earlier). However, can the building physics also explain the higher heating consumption of the 8-9% of the apartments?

The data show that two of the apartments with the highest heat consumption is placed on the 1<sup>st</sup> floor (level 0) at which the higher consumption may be explained by a higher heat loss towards the basement. However, the neighboring apartment has a heat demand of approx. 780 kWh in 2014 and 0 kWh in 2015. Likewise, two other apartments with a heat demand above 3000 kWh are placed on the 3<sup>rd</sup> and 10<sup>th</sup> floor. The four apartments which have the highest heat consumptions are oriented towards NW, E, E and SE. The tall neighboring buildings towards NW, W and SW will of course shade from the sun, but the apartments with the highest heat consumption are not placed in particularly shaded places of the building. Likewise, if we look at the apartments with a heat consumption of 0 kWh, there do not seem to be a pattern in type of apartment, orientation, or area of external envelope. The majority of these are placed on the 5<sup>th</sup> floor and above, however, apartments with generally low heat consumption up to 500 kWh occur fairly evenly distributed in the floors. Summing up, there are only four apartments that have heat consumption above 2400 kWh in both years and these are located in the bottom, the middle and the top of the building and towards different corners of the world. It is not possible to draw an absolute conclusion on this basis; nevertheless, the data indicate that neither orientation nor the floor can explain the high variation in heat consumption.

In most cases it is not the same apartments that have high heat consumptions in 2014 as in 2015. In some cases the heat consumption is reduced to the half or even to a fourth from 2014 to 2015 and similarly, increased to the double and even quadruple from 2014 to 2015. This support the findings above and could indicate that either there has been a change of tenant, a change in the number of users in the apartment, or a significant change in the use of the apartment over the two years, e.g. caused by a parental leave or similar. All in all this leads to the assumption that the high heat consumptions and variations in these are not (primarily) related to building physics or orientation but may possibly be related to the user composition or user behavior.

The questionnaire survey can first of all offer an insight into what characterizes this particular user group. The responses show that in 90% of the apartments there are two residents, in 8% only one resident, and in 2% (one out of the 47 submitted responses) there are three residents. Out of the 47 responses two reply that they have a child living in the apartment (corresponding to 4%). The responses show that far the majority of the residents are between 22 and 27 years old (approx. 83%), the youngest resident is 21 and the oldest 34 years old. Hence, the user group is quite homogeneous when it comes to user composition as well as age. Since 9 out of 10 apartments have two residents nor does the number of inhabitants seem to be able to explain the variation in the heat consumption. It cannot, however, be excluded that the number of inhabitants in the apartment can be a contributing explanation of the 9% with highest heat consumptions, as the number of

persons in the household is relatively more important for the heat demand in low energy buildings (Jensen et al. 2011).

In order to get a better understanding of where the inhabitants put their consumption in general – at home or out in the city – it could be interesting to look deeper into how much time they spend in their apartments. The questionnaire survey tells us that on an average weekday, 19 out of 47 respondents (40%) spend 15-19 hours a day in their apartment, 24 respondents (51%) spend 10-14 hours there and 3 (approx. 6%) are home for 9 hours or less. On an average weekend day, 24 respondents (51%) spend 15-19 hours and 10 (21%) spend 20-24 hours in the apartment. Hence, it seems quite characteristic to this user group that the majority spend relatively much time in their apartment. The responses furthermore show that little more than two third have periods of minimum one week where no one lives in the apartment. From the supplementary comments it appears that several of the inhabitants are away from home in more than a few weeks during the year, some up to 5 and 6 weeks. Generally, they leave their apartment in connection with holidays, i.e. over Christmas and New Year's, for winter break (usually in February), Easter and summer break (usually within the period July – August). The heating season in Denmark is typically from October to April, both included, and the fact that some inhabitants leave their home for weeks in this period and others do not, might be part of the explanation for the variation in heat consumptions of the apartments.

Another explanation for the variation might be found in the habitants' practice and habits in regard to ensuring thermal comfort. The thermostat valve stands at 3 by default, which in most cases provides a room temperature at 21 degrees Celsius. The responses show that 30 out of 44 respondents (68%) typically set the thermostat valve lower than 3 in the bedroom, 5 out of 44 (11%) set it on 3 and 2 out of 44 (5%) higher than 3. 7 respondents out of 44 (16%) answer "don't know". For the living room 20 out of 45 respondents (44%) typically set the thermostat lower than 3, 15 out of 45 (33%) on 3 and 5 out of 45 (11%) higher than 3. 5 of the respondents (11%) answer "don't know". In the supplementary comments several respondents moreover note that in fact heating is never on in their apartment. The latter correspond well with the measurements, according to which 20 apartments had no heat consumption at all in 2015. The respondents who never have heat on in their apartment might be among the respondents who answered "don't know", since the questionnaire did not include the option "heat is never on" to this question. The variation in the setting of the thermostat is supported by the responses which state that 27 out of 47 respondents (57%) wish to have different temperatures in the different rooms. When asked how they act to ensure the temperature difference (the respondents could choose more than one options for which reason the sum is not 100%), 26 out of 38 respondents (68%) reply that they close the door between the rooms, 20 out of 38 (53%) open the window to air out before bedtime, 18 respondents out of 38 (47%) adjust the temperature by the thermostat valve and 12 out of 38 (32%) sleep with an open window. Add to this that 31 out of 47 (66%) respond that they turn off the heating if they open a window for more than 5 minutes, whereas 14 out of 47 (30%) do not turn off the heating. When asked about what they do if they find that it is too warm in the apartment (the respondents could choose more than one option for which reason the sum is not 100%), 40 out of 47 respondents (85%) respond that they open a window, 32 (68%) answer that they turn down the heat and only 3 respondents (6%) boost the mechanical ventilation. From the supplementary comments it also appears (again) that several do not have heat turned on at all. A respondent furthermore mentions that he/she wears less clothes when it is too warm.

A similar passive strategy is applied in cases when it gets too cold. 42 out of 47 respondents (90%) reply that they put on a sweater or socks if they find it too cold, whereas 30 out of 47 (64%) note that they turn up the heat.

All in all the responses above indicate that the majority of the inhabitants are quite conscious about how they control the thermal environment in the apartment without wasting energy. The majority turns off the heat when venting and many also seem to choose passive means like e.g. closing the door between rooms to ensure different temperatures, wearing more or less clothes to adjust for shorter periods outside thermal comfort, and opening a window to naturally cool down the room. However, there are also inhabitants whose thermostats are set higher than most and a full 30% of the respondents whom do not turn off the heat when opening windows for a longer period. This type of practice, especially if they are combined, might be part of the reason that some of the apartments have heat consumptions much higher than others. Whether this practice has its ground in lack of knowledge, lack of interest or something else entirely is beyond the scope of this paper to determine. However, it indicates that there is potential for further improvements and future studies may clarify how and by which means energy-conscious practices are best communicated to this particular user group.

## Conclusion

The objective of this study has been twofold; to examine to what extend user practice and habits influence the energy consumption for space heating in a newly built zero-energy youth housing complex in Denmark; and to identify representative user characteristics within this specific user group. On the basis of an analysis where measured data on heat consumptions is juxtaposed with drawings of the building and results from a questionnaire, it is found that the variation in heat consumption across the apartments are not primarily related to apartment type, orientation or floor, but rather related to the inhabitants use of their apartment as well as user practices in regard to thermal comfort.

It is not possible to draw absolute conclusions on the profile of the user group, on the basis of the data presented here. However, the study indicates some general characteristics of this particular user group and some general tendencies in their practices related to ensuring comfort as well as some indications of how this seem to impact the energy consumption. A general characteristic of the group is their appreciation of the right location. This is of far more importance than the energy standard of the building, when they choose where to live. The majority spends relatively much time in their apartment, and consider themselves to be generally concerned about saving energy.

The study identifies two sub groups in the otherwise homogeneous group, and these show two different tendencies. The majority of the user group appears to have general interest in energy-saving aspects and energy-conscious practices as regards ensuring thermal comfort which do not result in high space heating consumptions. This sub group, therefore, do not seem to follow the trend that the expected energy savings in low energy houses are absorbed in increased comfort. To the other sub group, on the other hand, energy-related aspects seem relatively unimportant. The study shows that this smaller group seems to have practices in regard to ensuring thermal comfort which may result in unexpected high heat consumption. Hence, this sub group might be an example of the trend of increased comfort expectations in low energy buildings. Whether this approach and practice is caused by lack of knowledge or lack of interest, is, however, unclear. Although the majority of the group has very low heat consumption, the study concludes that there is

potential for further improvements in order to guide the smaller sub group to more energy-saving practices.

**Abstract:** Mechanical cooling and ventilating of buildings is responsible for a significant proportion of their energy consumption. In any benchmarking strategy or operational performance assessment for energy efficiency, it is important to consider calculations or correction factors to account for the impacts of external conditions on the cooling load. Many emerging economies have stocks of commercial buildings of which some operate in fully air-conditioned modes and others in mixed-mode, using air conditioning for a significant proportion of the year. In warm climates, these buildings may interact with the external climate in different ways. In detailed analyses of energy consumption in 32 office buildings across Brazil, buildings are categorised according to HVAC system type and energy consumption is calculated end-use. For each building, the statistical relationship between climate and energy consumption is measured, using cooling degree hours. Buildings which are fully air conditioned show large variations in energy consumption, indicating that although they are conditioned to standard temperatures, they face operational challenges. The buildings with mixed-mode operation are shown to have a more even correlation with external conditions even at high temperatures. This result has implications for steady-state building energy models, benchmark development and climate correction calculations for monitoring and verification.

**Keywords:** Benchmarking, Cooling energy consumption, Climate correction, Energy audit

### Introduction

Improving energy efficiency in buildings requires performance benchmarking. Benchmarks can be used to rate and evaluate energy performance, to identify improvement potential or to track performance through time. A benchmark performance level can be based on top-down methodologies including statistical evaluations of building stocks or bottom-up models developed through building physics (Burman et al. 2013; Hong et al. 2013; Borgstein et al. 2016). Current work in performance benchmarking aims to reconcile the difference between these types of models to produce building performance evaluations where physical characteristics can be used to interpret statistical performance data.

For the purposes of energy performance evaluations, the factors affecting energy consumption in buildings can generally be separated into:

- External factors – principally climate but also local factors such as shading;
- Building efficiency – including both the envelope and the building systems;

- Operational efficiency – most buildings are not optimally operated; and
- Service provision – indoor environmental conditions and usage intensity.

### ***Cooling and HVAC energy in warm climates***

In tropical and sub-tropical climates, especially in emerging economies, commercial buildings generally have no space heating systems but space conditioning often remains the largest energy consumer. As external temperatures will often be within comfortable ranges, a building can aim to provide adequate thermal conditions for its occupants through a fully conditioned (AC) approach, a Naturally Ventilated (NV) approach or a Mixed-Mode (MM) approach. These will require distinct design strategies in order to produce efficient, comfortable buildings (CIBSE 2017).

Many bottom-up models for energy performance evaluation will assume constant internal temperatures during operating hours; this is unlikely to be the case in NV or MM buildings. ASHRAE Standard 55-2013 (ANSI/ASHRAE 2013) includes an adaptive comfort model which can be applied to buildings in which the thermal conditions are regulated by the users primarily through the opening and closing of windows. There are models available to evaluate the performance of NV buildings. For example, Rackes et al have carried out extensive modelling to evaluate the impact of building characteristics on energy consumption of NV buildings, specifically identifying the discomfort hours likely in low-rise buildings, principally schools (Rackes et al. 2016). However, there is a challenge in applying the same tools to mixed-mode buildings, which may use both operable windows and air conditioning during the same day, or sometimes simultaneously.

## **Methodology**

### ***Building data***

Simple building information, such as energy bills, typology and floor area, are often used to carry out simple benchmarking exercises or performance evaluations in homogenous building typologies (Borgstein & Lamberts 2014). However, this simplified information does not provide enough detail to be able to carry out effective performance analyses comparing mixed-mode and fully conditioned buildings.

For this evaluation, detailed building information have been collected on 32 commercial buildings in Brazil. These were primarily office buildings, distributed in 14 cities across the country. Each building was subjected to a full energy audit, following ASHRAE Procedures, levels one or two (ASHRAE 2011). The principal building systems and envelope were catalogued and evaluated, a full end-use breakdown was estimated using CIBSE's TM22 methodology (CIBSE 2006) and energy saving measures were listed. Each of the buildings exhibits unique characteristics related to its occupation, systems and operations. Data collection is difficult and requires repeated site visits. Several different definitions of area are used and often these are not clearly defined. Occupancy rates vary significantly throughout the year and record-keeping is not always accurate. Often building managers supplied incomplete or erroneous information, requiring detailed investigation and checking.

### ***Levels of service provision***

The buildings evaluated have different levels of operational and systems efficiency. Several buildings do not meet full requirements for occupant satisfaction, either through underperforming air conditioning systems or low lighting levels. There were also major

differences in building floor area ratios; some had air conditioning installed in less than 50% of the area, others were only partially occupied whilst others were fully occupied and conditioned. Finally, use intensity varied: one building was dominated by a cultural centre, another by a major data centre, others had varying densities of occupation ( $\text{m}^2$  per person). These factors all have major impacts on the total energy consumption.

### **Climate data**

Energy consumption in buildings can be impacted by factors like air temperature, humidity, wind speed, direct solar radiation and cloud cover. These will have different impacts, depending on the type of building, but a meta-model developed by Rackes et al shows that for the commercial buildings studied in warm climates (principally low-rise buildings), the number of cooling degree hours is the single characteristic with the greatest impact on energy consumption of simulated buildings, (Rackes et al. 2016).

The Brazilian Institute of Metrology (INMET) has provided historical climate data for several hundred cities in Brazil, which has been used to produce weather years that are provided online for building performance simulation (LABEEE, n.d.). In addition, some recent data is made freely available by INMET, including air temperature and relative humidity. As dry-bulb air temperature is the dominant climate impact on building energy consumption, cooling degree hours (CDHs) are calculated and used to map climate intensity and evaluate performance. Based on the authors' experience in modelling balance temperatures for buildings in warm climates, 22°C is selected as the base temperature for calculating CDH according to Equation 1.

$$CDH = \sum_{hours} (T - T_{base})^+$$

Equation 1.

T = mean hourly temperature;  $T_{base}$  = base temperature, 22°C

CDHs can be easily calculated for both the weather years used for simulation in Brazil, and the real recent weather conditions in selected cities. In order to use them for performance evaluations, they are calculated and tabulated on a monthly basis.

In general, the term climate normalisation or climate correction is used for comparing energy consumption by buildings in different climatic regions (spatial adjustment), while weather normalisation is used to compare building performance over time in the same region (time adjustment). As described in Table 1 and illustrated in Figure 1, there is a significant difference between the historical weather data provided for some major cities in Brazil, and the actual recent climatic conditions. Although some months are colder than historical data would indicate, the greatest differences appear to be in peak temperatures during hot months. This is likely to be due to a combination of climate change and urban heat islands, leading to more intense climatic events such as heat-waves in the summer. This would seem to clearly indicate the importance of using weather normalisation for building performance evaluation, especially when monthly data are considered. The three-year average CDH is close to the INMET level for Brasília and Belo Horizonte (within 10%), but is 43% and 67% above the INMET level for Rio de Janeiro and São Paulo respectively.

Table 1 – Monthly means of cooling degree hours in selected Brazilian cities

Mean monthly CDH	Rio de Janeiro	São Paulo	Belo Horizonte	Brasília
2014-2016 (3 years)	2427	980	1355	1097
INMET	1694	588	1228	1152

## Climate-related energy consumption

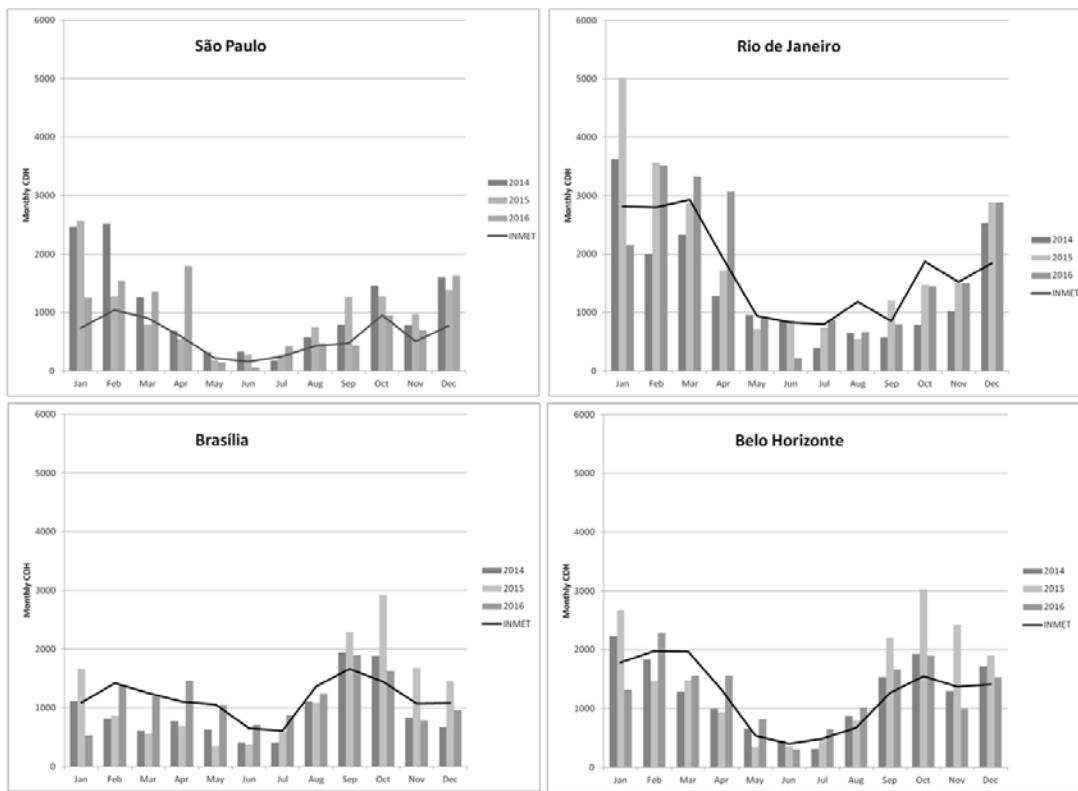

Figure 1. Comparisons of cooling degree hours calculated from historical weather data (INMET) and measured temperature for recent years

In order to carry out evaluations of energy performance related to weather in different building types, it was necessary to clean the data. Firstly, monthly energy consumption was calculated and normalised by the useful floor area. The major end-uses which are not classed as normal building services for offices (usually data centres) were subtracted from total energy consumption, using the mean annual percentage of the energy consumed by these systems. A correction factor was applied for the number of working days per month, to account for some months containing more weekends and national public holidays. Finally, buildings which could not be classified as principally office spaces were removed from the dataset.

The building HVAC systems were described and their primary cooling technology tabulated. In larger buildings, centralised HVAC systems are used to condition a whole building and are generally chilled water systems, although some may be variable refrigerant flow (VRF). Generally, in buildings with centralised systems over 80% of the area is conditioned (stairwells and corridors are usually not conditioned) and these buildings almost always have central control and operation. Distributed HVAC systems nearly always use direct expansion (DX) units, primarily split air conditioners. They may be fully conditioned or may only have air conditioning installed in a small proportion of the building, but the air conditioning is operated locally and does not have a central control system. Separately, the buildings were evaluated according to their window operation. By noting whether the majority of windows were operable, the number of windows open during the visits and the use of windows cited in interviews with building managers, buildings were classified as having fixed or operable windows.

With few exceptions, smaller buildings had operable windows and distributed HVAC systems and were considered Mixed-Mode (MM), while larger buildings had fixed windows

and centralised HVAC systems and were considered Fully Conditioned (AC). One smaller building had a DX system but did not have operable windows, so was classified AC, while one large building classed as MM – it did not have a central air conditioning system because it was built before such systems were available.

## Results

The energy consumption for the 32 buildings in the dataset was broken down five end-use groups: HVAC, lighting, plug loads, data centres and other. The division of the energy consumption according to these categories is shown in Figure 2 for the MM buildings in the dataset (14 buildings) and in Figure 3 for the AC buildings (18 buildings). This data is not normalised for occupancy density or for climate, but it is clear that AC buildings generally have a larger consumption for HVAC, while data centres can cause significant distortions of the results.

The energy disaggregation provided for the buildings during the energy audits is based on estimated or calculated data, generally using a few spot measurements to calibrate estimates. As such, the end-use data was not deemed accurate enough to separate cooling energy consumption for an isolated analysis. Instead, the removal of major distortions from data centres and non-standard energy uses left a more uniform basis for comparison, based on standard building services (cooling, ventilation, heating, plug loads, lighting, elevators and UPS systems). Although no correction was made for occupant density, the vacancy rates were considered in the calculation (consumption was normalised by occupied area), and operational hours were found to be similar in all the buildings.

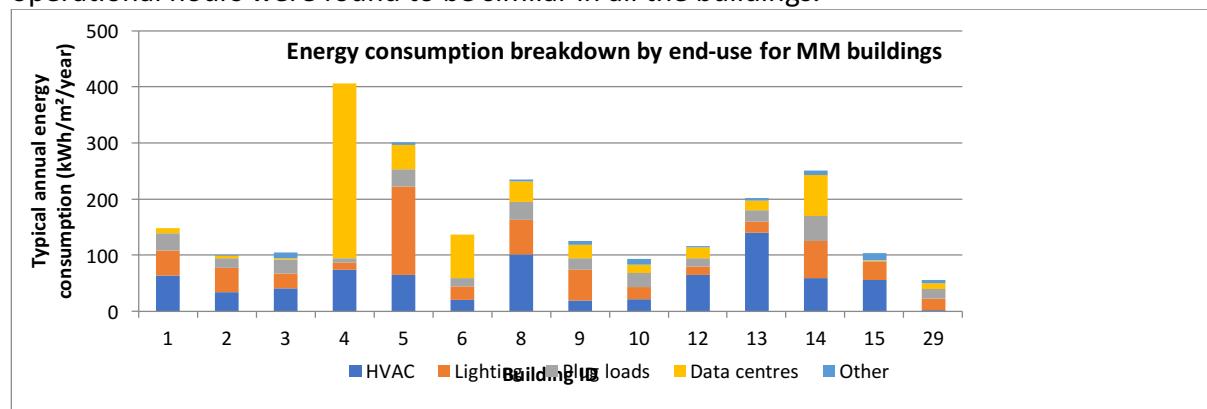

Figure 2. Energy consumption in five major end-use categories, calculated for mixed-mode buildings

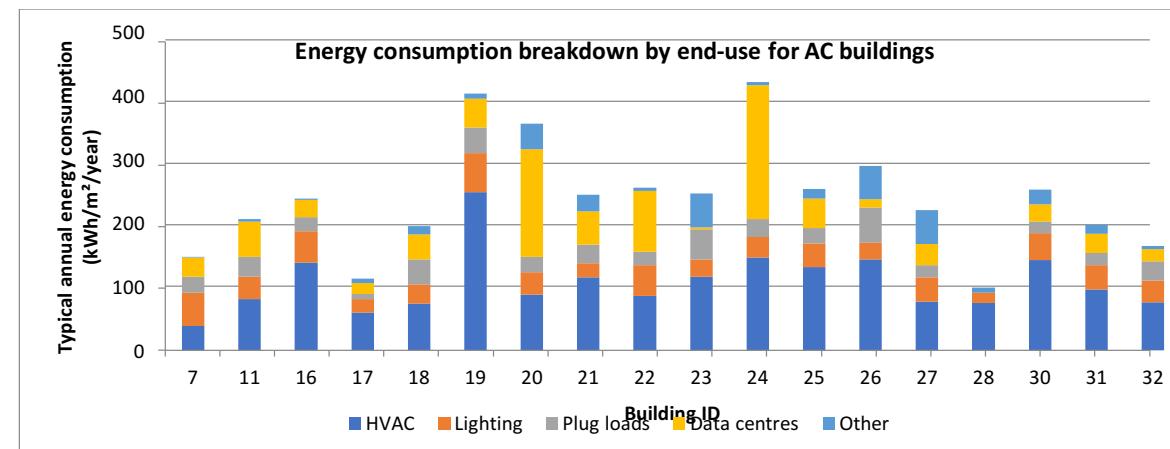

Figure 3. Energy consumption in five major end-use categories, calculated for fully conditioned buildings

The corrected monthly energy consumption for each building was then paired with the monthly degree days calculated for the month in which the energy consumption took place. Buildings 4 and 23 were excluded and there were between 12 and 24 energy bills available for each building, producing a total of 617 data points (292 in MM buildings and 325 in AC buildings).

Figure 4 shows the energy consumption of mixed-mode and air-conditioned buildings, plotted against the energy consumption of the relevant month. A linear, least-squares regression between degree days and energy consumption gave a positive correlation for each building individually, with one exception (this AC building was undergoing retro-commissioning at the time when the data were collected). However, there is clearly a large variation between buildings and the statistical relationships were generally weak. Overall, the AC buildings demonstrate higher energy consumption and greater variability, as well as a slightly higher energy consumption increase in higher temperatures. A further evaluation was carried out on the MM buildings, removing the buildings which had in which the conditioned area was below 50% of the total useful area, as these buildings would be expected to show different relationships with temperature. The scatter-plot in Figure 5 shows the results in the ten remaining buildings, with a linear least-squares regression. Although the  $R^2$  value is still only 35%, this plot shows a clearer statistical relationship between energy and temperature.

The higher energy consumption of AC buildings is to be expected, as fully conditioned buildings are generally expected to provide a higher level of service: constant year-round temperatures, air filtration, barriers to noise pollution and low air speeds, for example. Several of the buildings in this study were considered AAA-level corporate offices, which may also have higher equipment densities due to the use of UPSs and tasks which are more computer-intensive. Several of the AC buildings had undergone sustainability certifications at the time of construction, which requires the inclusion of high-efficiency equipment to meet international certification parameters (Brazilian legislation does not currently include any energy efficiency requirements for commercial buildings). Although these buildings showed less variation than other buildings in the AC dataset, they still demonstrate higher energy consumption than MM buildings. In general, the high variation and low predictability of performance amongst the AC buildings is likely to be related to their use of larger, more complex equipment for building conditioning. Although this equipment can be designed and operated in a highly efficient fashion, the data from the energy audits showed that HVAC equipment was never operating under optimal conditions and, in some cases, was responsible for sharply increased energy consumption because of incorrect operational parameters. The lack of professional commissioning, poor maintenance, the low level of expertise of building managers and a lack of strategic oversight or energy management are responsible for this variation.

In MM buildings, there was also a significant variation in energy performance, with some buildings showing characteristics that were far from typical. However, there was a greater degree of standardisation of equipment and operation: air conditioning was provided through split or window units and building occupants could operate windows as and when required. Four of these buildings were only partially conditioned, and once these were removed from the dataset, there was a high degree of correlation between energy consumption and climate.

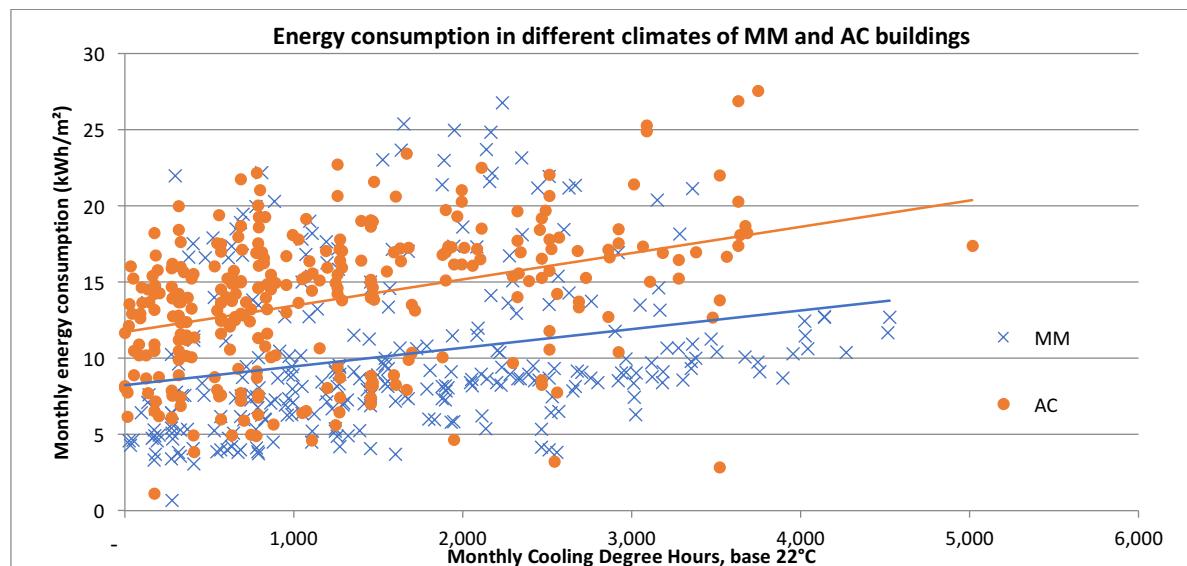

Figure 4. Energy consumption versus CDH in mixed-mode and fully conditioned buildings (30 buildings, data centre energy consumption excluded)

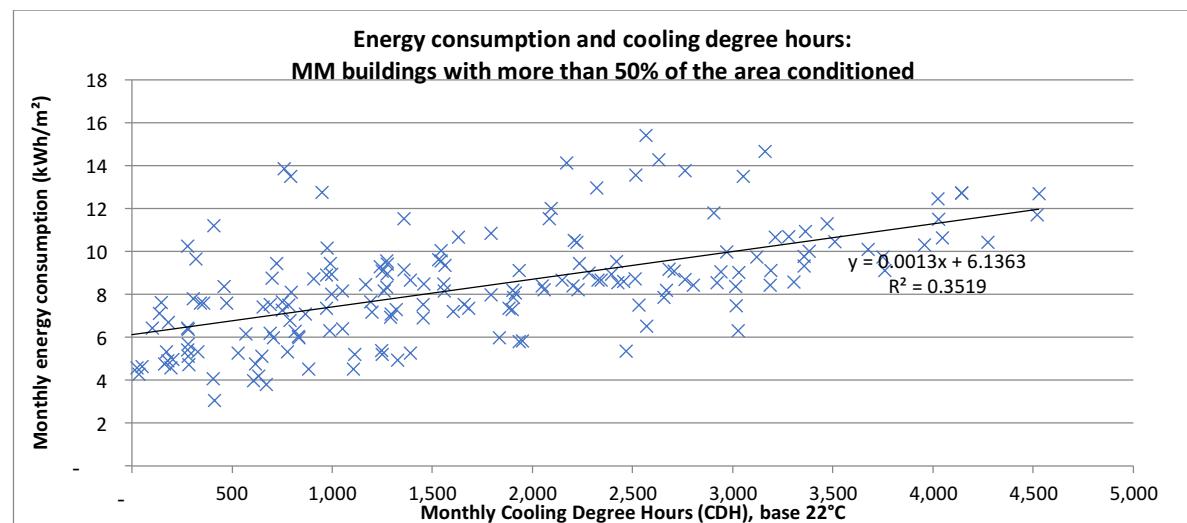

Figure 5 - Energy consumption versus temperature for mixed-mode (MM) buildings in which the majority of the area is conditioned (8 buildings, data centre energy consumption excluded)

## Discussion

Although some AC buildings show performance levels equivalent to MM buildings, most have higher energy consumption. Excluding data centres, the mean annual energy consumption of MM buildings was 124 kWh/m<sup>2</sup>/year and only three of the 18 AC buildings had energy consumption below this level; the mean for MM buildings was 188 kWh/m<sup>2</sup>/year. As AC buildings tend to have more complex systems, with efficient chillers or VRF units, they might be expected to demonstrate better levels of efficiency at higher temperatures, where their systems would be fully utilised. Following this logic, MM buildings would have higher energy consumption at high temperatures due to their low efficiency, while external temperatures would be too high to allow windows to be opened. However, this is not demonstrated in the results, which instead show that the energy consumption of AC buildings increases with temperature at a faster rate than that of MM buildings. Reasons are likely to involve poor operational practice, lack of design optimisation, higher internal loads and some levels of discomfort at high temperatures in MM buildings.

The adaptive comfort model from ASHRAE 55-2013 would indicate that MM buildings can operate in a wider range of temperatures; the results of this paper seem to indicate that the impacts on energy consumption of the wider comfort range are measurable and significant. Clearly, there are several other factors with significant impact on energy consumption that were not considered here. Amongst external factors, levels of wind speed, solar radiation, humidity and external shading were not considered. The simple normalisation carried out made no attempt to correct for levels of occupant density, systems efficiency and operational efficiency; these three factors are likely to account for a significant proportion of the remaining variation in building energy consumption.

These results indicate several areas for further research. Additional weather variables (beyond CDH) should be tested to find out which, if any, will be required for benchmarking climate-related energy consumption. With a weather correction factor applied, further development of analytical tools to separate the energy consumption due to operational inefficiency and systems efficiency should be carried out, to show the performance improvement potential for an individual building.

## Acknowledgements

This work was led by the Brazilian Sustainable Construction Council (CBCS) and was carried out under UNDP Project BRA/09/G31, coordinated by the Ministry of the Environment, implemented by the UNDP and financed by GEF.

## List of abbreviations

CDH – Cooling Degree Hours, considering dry-bulb temperatures with base 22°C unless otherwise specified  
MM – Mixed-mode building, which can operate using air conditioning and/or operable windows  
AC – Air conditioned building, does not typically operate opening windows in the majority of the usable area  
NV – Naturally ventilated building, which has little or no air conditioning.  
INMET – Brazilian Institute for Metrology, which publishes weather data from across the country.  
DX – Direct expansion air conditioning system (typically includes split and window systems)  
UPS – Uninterruptible Power Supply

**Abstract:** A lot of effort has been devoted recently to investigating if a new breed of 'active design', where occupants are no longer develop their activities at a single fixed-location, can actually help increasing physical activity. This trend in workspace design is known as Activity-Based Working. Despite all the best efforts made this far when trying to understand positive and negative aspects of different workspace layouts on occupants' physical activity, a knowledge gap remains when it comes to detailed investigations focusing on ABW settings. This is particularly true in Australia where the uptake of ABW has plumped in recent years. This paper presents results from a case study, aimed quantifying workers' physical activity before and after relocation from a contemporary open plan office to an ABW setting. This paper also discusses occupants' perceived productivity and overall satisfaction before and after relocation. A total of 89 volunteers participated on the occupancy survey and 20 during the physical activity monitoring. Wearable devices were used to monitor step count and physical activity for two weeks during the pre-evaluation (contemporary open plan office) and post-evaluation survey (ABW). After moving to an ABW layout occupants were slightly more active than before, walking 0.2km more on average daily. A significant reduction of 6% in sedentary time was also observed with an increase of 20% on active time. Post-occupancy results also indicated a significant increase on perceived productivity and consistent improvements on occupants' satisfaction on all IEQ variables. These preliminary results suggest that active workspace design may have a positive impact on workers' physical activity, perceived productivity and satisfaction and should therefore be more investigated.

**Keywords:** Indoor Environmental Quality (IEQ), Post-Occupancy Evaluation (POE), workspace design, green buildings.

### Introduction

Sustained sitting has colloquially been termed 'the new smoking' and with millions of people spending most of their time at work, there is plenty of evidence indicating the workplace as central to public health. A large-scale study focusing on contemporary workspace in the UK has found that office workers demonstrated high levels of sitting during the working week (approximate 10.6 hours per day) (Smith et al 2015). Recent Australian research has linked excessive sitting to an increased risk of chronic disease-related morbidity and mortality (Thorp et al 2011). Awareness about the benefits of moving more and sitting less during the day can be exemplified by the 10,000 steps/day campaigns and trend in use growing popularity of sit-stand desks.

Activity Based Working (ABW) includes changes on organizations' culture and space configuration and it is based on two key points: (i) non-individual territoriality, and (ii) a

variety of spaces purposively designed to accommodate different tasks. The implementation of these points varies largely from organization to organization and there is agreement that tailoring is needed for successful implementation. The ABW configuration of office space fits into the active design trend framework it may enable incidental physical activity opportunities and workers' movement may occur more frequently (Active Design Guidelines, 2010).

Despite all the best efforts made this far when trying to understand positive and negative aspects of different workspace layouts on occupants' physical activity, a knowledge gap remains when it comes to detailed investigations focusing on ABW settings. This is particularly true in Australia where the uptake of ABW has plumped in recent years. Preliminary results from a pre-post evaluation study found a 14% reduction in daily sitting time, partially compensated for by increases in standing (10%) and stepping time (2%) in occupants from a large company after moving into an ABW fit-out (Foley et al 2016). Significant differences were also found by Engelen et al (2017) before and after relocation to an active space with regards to the time workers spent seated (72%-66) and standing (15%-19) but walking remained unchanged.

With at least 10 million workers spending most of their time in their workplace (Heart Foundation, 2012), and the penetration of ABW in the property market getting higher, the opportunity cost of lack of studies to understand this new way of working is simply too high to be ignored. This paper presents results from a case study, aimed quantifying workers' physical activity before and after relocation from a contemporary open plan office to an ABW setting. This paper also discusses occupants' perceived productivity and overall satisfaction from Post-Occupancy Evaluation (POE) surveys conducted before and after relocation.

## Methodology

A total of 89 office workers from the same organization were relocated from a combi office into an Activity-Based Working setting. All workers were invited to participate on the pre and post POE surveys and a subset of 20 volunteered to contribute to the physical activity monitoring. The post survey was conducted six months after relocation to the new premise.

The old fit-out featured two open-plan offices with a combi typology. Occupants worked from the same workstation and used shared facilities, including meeting rooms of various sizes. The new ABW fit-out adopts active design principles and introduced spaces for breaks and more zones allocated for supporting collaboration and concentration. Physical environments are flexible and workers' mobility is enabled by technology. The new office also features a multi-purpose space designed to support a variety of activities, including mindfulness sessions, events, collaboration and breaks. All workstations are sit/stand and workers are required to work from different locations every day. Clean desk policy, lockers, end of trip facilities and portable keyboards were also implemented. There was a strong engagement process before and after relocation. All buildings surveyed have air-conditioning system and fit-outs are relatively new or had some sort of refurbishment done less than 5 years before the study was conducted. Personal control systems are non-existing. Table 1 shows demographic data for surveyed buildings.

The study presented here used the Building Occupants Survey System Australia (BOSSA) Time-Lapse questionnaire for the purposes of pre and post surveys. BOSSA is an IEQ assessment system for office buildings. Details about the project and methodology can be found on Candido et al (2016). The BOSSA Time-Lapse questionnaire includes background

questions addressing participants' gender, age, type of work, time spent in buildings, workspace arrangement and modules focusing on spatial comfort, individual space, indoor air quality, thermal comfort, noise distraction and privacy, visual comfort, personal control, building image and overall occupant satisfaction. Workers rate their satisfaction on a seven-point scale (1 = the lowest rating; 4 = neutral and 7 = the highest rating). In addition to the survey, floor plans and building metrics information (including base building and fit-out information) are also collected. Combined, this information is a unique feature of the BOSSA POE tool and it has been helping researchers to contextualize occupant survey responses. For the purposes of this paper, a total of 97 BOSSA Time-Lapse questionnaires were analyzed - 41 responses came from pre-evaluation surveys and a subsequent 56 sample from post-evaluation.

Table 1. Demographic data for surveyed buildings, including pre and post relocation.

	Combi (n = 41)	ABW (n = 56)
Tenant Net Lettable Area	940	1234
Gender		
<i>Female</i>	26.8%	23.2%
<i>Male</i>	73.2%	76.8%
Age		
<i>30 years old or under</i>	17%	29%
<i>31 to 50 years old</i>	68%	54%
<i>Over 50 years old</i>	15%	18%
Type of work		
<i>Administrative</i>	17%	13%
<i>Technical</i>	27%	21%
<i>Professional</i>	44%	52%
<i>Managerial</i>	12%	11%
<i>Other</i>	0%	4%

Wrist-worn devices were used to monitor step count and physical activity for two weeks during the pre-evaluation and post-evaluation surveys. Weekends, public holidays and the shutdown period over Christmas were excluded. Only the data from the participants who provided data in both pre and post occupancy periods were used – some people left the organization before the post-occupancy stage.

## Results

Results from Figure 1 indicate that building occupants reported higher satisfaction on Indoor Environmental Quality conditions of the new workspace. Mean score results from the BOSSA Time-Lapse survey on thermal comfort (summer and winter), acoustics (interruptions, sound privacy and overall noise), Indoor Air Quality, lighting/access to daylight and the degree of freedom to adapt their work area were significantly higher on ABW configuration. These results were consistent to findings from comparative analysis conducted on the entire BOSSA database (Candido et al, 2016, 2017) and differ from previous findings from De Been and Beijer (2014).

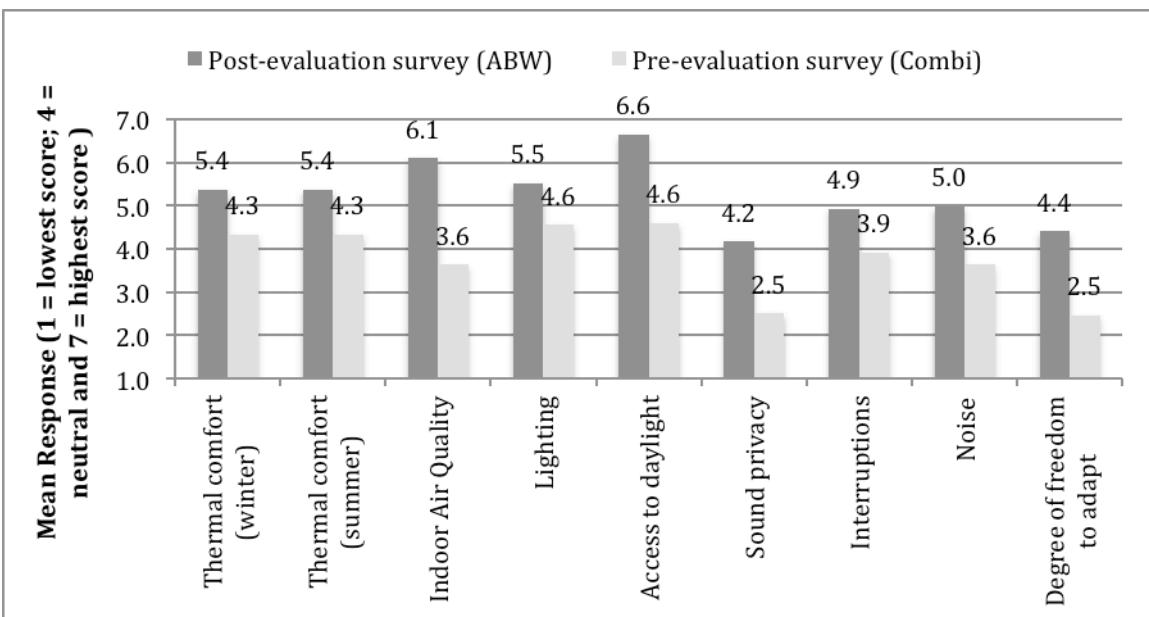

Figure 1. Break down of BOSSA Time-Lapse survey results on thermal comfort, Indoor Quality, visual comfort and acoustics.

Interestingly, when it comes to acoustics, sound privacy and distraction/unwanted interruptions – a critical issue of open-plan offices, workers reported higher satisfaction in the new ABW office. This may due to the implementation of spaces for concentration, private conversations and phone calls in ABW layouts, which did not exist on the combi layout. The overall openness of the floor plan of the new office and the layout that facilitates access to daylight and views may justify occupants' perception of lighting and daylight. Another possibility is the flexibility to work from workstations by the building façade, which is a feature of the new office configuration. The ability to move around the workspace may in turn give workers more choice. This may justify the significantly higher satisfaction results on the degree of freedom to adapt their work area question noted post-relocation.
